On the left side all four branches generally *arise* from the first portion of the vessel, but on the right side the superior intercostal usually arises from the second portion of the vessel. On both sides of the body the first three branches arise close together at the inner margin of the *Scalenus anticus*; in the majority of cases a free interval of from half an inch to an inch exists between the commencement of the artery and the origin of the nearest branch. The vertebral artery arises from the upper and posterior part of the subclavian artery, the internal mammary from the upper and posterior part of the subclavian artery, the internal mammary from the lower part of the artery; the thyroid axis from in front and the superior intercostal from behind.

The **vertebral artery**, the first branch of the subclavian, is distributed entirely to the head and neck, chiefly supplying the posterior portion of the brain. It has been described on pages 621 to 625.

The **thyroid axis** (*truncus thyrocervicalis*) (Figs. 438 and 459) is a short thick trunk which *arises* from the fore part of the first portion of the subclavian artery, close to the inner border of the *Scalenus anticus* muscle, and divides, almost immediately after its origin, into three branches—the **inferior thyroid**, **suprascapular**, and **transverse cervical**.

The **inferior thyroid artery** (*a. thyreidea inferior*) (Fig. 438) passes upward, in front of the vertebral artery and *Longus colli* muscle; then turns inward behind the sheath of the common carotid artery and internal jugular vein, and also behind

the sympathetic cord, the middle cervical ganglion resting upon the vessel, and, reaching the lower border of the lateral lobe of the thyroid gland, it divides into two branches, which supply the postero-inferior parts of the gland, and anastomose with the superior thyroid and with the corresponding artery of the opposite side. The recurrent laryngeal nerve passes upward, generally behind, but occasionally in front of, the artery. Its branches are:

Inferior laryngeal.
Tracheal.

Œsophageal.
Ascending cervical.

Muscular.

The **inferior laryngeal branch** (*a. laryngea inferior*) ascends upon the trachea to the back part of the larynx, in company with the recurrent laryngeal nerve, and supplies the muscles and mucous membrane of this part, anastomosing with the inferior laryngeal branch from the opposite side and with the laryngeal branch from the superior thyroid artery.

The **tracheal branches** (*rami tracheales*) are distributed upon the trachea, anastomosing below with the bronchial arteries.

The **œsophageal branches** (*rami œsophagei*) are distributed to the œsophagus, and anastomose with the œsophageal branches of the aorta.

The **ascending cervical** (*a. cervicalis ascendens*) is a small branch which arises from the inferior thyroid just where that vessel is passing behind the common carotid artery, and runs up on the anterior tubercles of the transverse processes of the cervical vertebræ in the interval between the Scalenus anticus and Rectus capitis anticus major muscles. It gives branches to the muscles of the neck, which anastomose with branches of the vertebral, and sends one or two branches into the vertebral canal through the intervertebral foramina to be distributed to the spinal cord and its membranes, and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral. It anastomoses with the ascending pharyngeal and occipital arteries.

The **muscular branches** supply the Depressors of the hyoid bone, the Longus colli, the Scalenus anticus, and the Inferior constrictor of the pharynx. One of the muscular branches passes between the transverse processes of the fourth and fifth cervical vertebræ and reaches the deep muscles of the neck. It is called the **ramus profundus**.

Applied Anatomy.—Before extirpating a goitrous lobe of the thyroid the superior and inferior thyroid arteries of the diseased side are to be ligated. An incision is made along the anterior border of the Sternomastoid down to the clavicle. After the deep fascia has been divided, the Sternomastoid and carotid vessels are drawn outward and the *carotid tubercle* (*Chassaignac's tubercle*) sought for. The vessel will be found just below this tubercle, between the carotid sheath on the outer side of the trachea and œsophagus on the inner side. In passing the ligature great care must be exercised to avoid including the recurrent laryngeal nerve, which is occasionally found crossing *in front* of the vessel.

The **suprascapular artery** (*a. transversa scapulae*) (Figs. 438 and 458) passes at first downward and outward across the Scalenus anticus and phrenic nerve, being covered by the Sternomastoid; it then crosses the subclavian artery and the cords of the brachial plexus, and runs outward, behind and parallel with the clavicle and Subclavius muscle, and beneath the posterior belly of the Omohyoid, to the superior border of the scapula, where it passes over the transverse ligament of the scapula, which separates it from the suprascapular nerve, and reaches the supraspinous fossa. In this situation it lies close to the bone, and ramifies between it and the Supraspinatus muscle, to which it supplies branches. It then passes downward behind the neck of the scapula, to reach the infraspinous fossa, where it anastomoses with the dorsalis scapulae branch of the subscapular artery

and branches of the posterior scapular arteries. Besides distributing branches to the Sternomastoid, Subclavius, and neighboring muscles, it gives off a **supra-sternal branch**, which crosses over the sternal end of the clavicle to the skin of the upper part of the chest; and a **supra-acromial branch** (*ramus acromialis*), which, piercing the Trapezius muscle, supplies the skin over the acromion, anastomosing with a branch of the acromiothoracic artery. A small **subscapular branch** is given off as the artery passes over the transverse ligament of the scapula; it descends into the subscapular fossa, ramifies beneath the Subscapular muscle, and anastomoses with the posterior and subscapular arteries. The suprascapular artery also sends branches to the acromioclavicular and shoulder-joints, and a nutrient artery to the clavicle.

FIG. 458.—The scapular and circumflex arteries.

The **transverse cervical artery** (*a. transversa colli*) (Fig. 438), larger than the suprascapular, passes transversely outward, across the upper part of the subclavian triangle, to the anterior margin of the Trapezius muscle, beneath which it divides into two branches, the **superficial cervical** and the **posterior scapular**. In its passage across the neck it crosses in front of the phrenic nerve, Scaleri muscles, and the brachial plexus, between the divisions of which it sometimes passes, and is covered by the Platysma, Sternomastoid, Omohyoid, and Trapezius muscles.

The **superficial cervical** (*ramus ascendens*) ascends beneath the anterior margin of the Trapezius, distributing branches to it and to the neighboring muscles and lymph nodes in the neck, and anastomosing with the superficial branch of the *arteria princeps cervicis*.

The **posterior scapular** (*ramus descendens*) (Fig. 458) passes beneath the Levator anguli scapulae muscle to the superior angle of the scapula, and then descends along the posterior border of that bone as far as the inferior angle. In its course it is covered by the Rhomboid muscles, supplying them and the Latissimus dorsi and Trapezius, and anastomosing with the suprascapular and subscapular arteries. and with the posterior branches of some of the intercostal arteries.

Peculiarities.—The superficial cervical frequently arises as a separate branch from the thyroid axis; and the posterior scapular, from the third, more rarely from the second, part of the subclavian.

The **internal mammary artery** (*a. mamma interna*) (Fig. 459) arises from the under surface of the first portion of the subclavian artery, opposite the thyroid

FIG. 459.—The internal mammary artery and its branches.

axis. It descends behind the cartilages of the upper six ribs at a distance of about half an inch from the margin of the sternum; and at the level of the sixth intercostal space divides into the **musculophrenic** and **superior epigastric arteries**.

Relations.—At its origin it is covered by the internal jugular and subclavian veins, and as it enters the thorax is crossed from without inward by the phrenic nerve, and then passes forward close to the outer side of the innominate vein. In the upper part of the thorax it lies behind the costal cartilages and Internal intercostal muscles, and is crossed by the terminations of the upper six intercostal nerves. Behind it lies upon the pleura, as far as the third costal cartilage; below this level upon the Triangularis sterni muscle. It is accompanied by two venae comites; these unite into a single vein, which passes to the inner side of the artery and ends in the corresponding innominate vein.

Branches.—The branches of the internal mammary are:

Comes nervi phrenici.
Mediastinal.
Pericardiac.
Sternal.

Anterior intercostal.
Perforating.
Musculophrenic.
Superior epigastric.

The **comes nervi phrenici** (*a. pericardiacophrenica*) is a long slender branch which accompanies the phrenic nerve, between the pleura and pericardium, to the Diaphragm to which it is distributed; it anastomoses with the other phrenic branches from the internal mammary and with phrenic branches of the abdominal aorta.

The **mediastinal branches** (*aa. mediastinales anteriores*) are small vessels which are distributed to the areolar tissue and lymph nodes in the anterior mediastinum and to the remains of the thymus gland.

The **pericardiac branches** supply the upper part of the anterior surface of the pericardium, the lower part receiving branches from the musculophrenic artery.

The **sternal branches** (*rami sternales*) are distributed to the Triangularis sterni and to the posterior surface of the sternum.

The mediastinal, pericardiac, and sternal branches, together with some twigs from the comes nervi phrenici, anastomose with branches from the intercostal and bronchial arteries, and form a minute plexus beneath the pleura, which has been named by Turner the **subpleural mediastinal plexus**.

The **anterior intercostal arteries** (*rami intercostales*) supply the five or six upper intercostal spaces. The branch corresponding to each space soon divides into two, or the two branches may come off separately from the parent trunk. The small vessels pass outward in the intercostal spaces, one, the larger, lying near the lower margin of the rib above, and the other, the smaller, near the upper margin of the rib below, and anastomose with the intercostal arteries from the aorta. They are at first situated between the pleura and the Internal intercostal muscles, and then between the Internal and External intercostal muscles. They supply the Intercostal muscles, and, by branches which perforate the External intercostal muscle, reach the Pectoral muscles and the mammary gland.

The **perforating arteries** (*rami perforantes*) correspond to the five or six upper intercostal spaces. They arise from the internal mammary, pass forward through the intercostal spaces, and, curving outward, supply the Pectoralis major and the integument. Those which correspond to the second, third, and fourth spaces are distributed to the mammary gland. In females, during lactation, these branches are of large size.

The **musculophrenic artery** (*a. musculophrenica*) is directed obliquely downward and outward, behind the cartilages of the false ribs, perforating the Diaphragm at the eighth or ninth rib, and terminating, considerably reduced in size, opposite the last intercostal space. It gives off anterior intercostal arteries to each of the intercostal spaces across which it passes; these diminish in size as the spaces decrease in length, and are distributed in a manner precisely similar to the anterior intercostals from the internal mammary. The musculophrenic also

gives branches to the lower part of the pericardium, and others which run backward to the Diaphragm and downward to the Abdominal muscles.

The **superior epigastric** (*a. epigastrica superior*) continues in the original direction of the internal mammary; it descends through the cellular interval between the costal and sternal attachments of the Diaphragm, and enters the sheath of the Rectus abdominis muscle, at first lying behind the muscle, and then perforating it and supplying it, and anastomosing with the deep epigastric artery from the external iliac. Some branches perforate the sheath of the Rectus and supply the muscles of the abdomen and the integument, and a small branch, which passes inward upon the side of the ensiform appendix, anastomoses in front of that cartilage with the superior epigastric artery of the opposite side. It also gives some twigs to the Diaphragm, while from the artery of the right side small branches extend into the falciform ligament of the liver and anastomose with the hepatic artery.

Applied Anatomy.—The course of the internal mammary artery may be defined by drawing a line across the six upper intercostal spaces half an inch from and parallel with the sternum. The position of the vessel must be remembered, as it is liable to be wounded in stabs of the thoracic wall. It is most easily reached by a transverse incision in the second intercostal space.

The **superior intercostal** (*truncus costocervicalis*) (Figs. 447 and 465) arises from the upper and back part of the subclavian artery, behind the Scalenus anticus muscle on the right side and to the inner side of that muscle on the left side. Passing backward, it gives off the **deep cervical branch**, and then descends behind the pleura in front of the necks of the first two ribs, and anastomoses with the first aortic intercostal. As it crosses the neck of the first rib it lies to the inner side of the anterior division of the first thoracic nerve and to the outer side of the first thoracic ganglion of the sympathetic.

In the first intercostal space it gives off a branch which is distributed in a manner similar to the distribution of the aortic intercostals. The branch for the second intercostal space usually joins with one from the highest aortic intercostal. Each intercostal gives off a branch to the posterior spinal muscles, and a small branch which passes through the corresponding intervertebral foramen to the spinal cord and its membranes.

The **deep cervical branch** (*a. cervicalis profunda*) arises, in most cases, from the superior intercostal, and is analogous to the posterior branch of an aortic intercostal artery; occasionally it arises as a separate branch from the subclavian artery. Passing backward, above the eighth cervical nerve and between the transverse process of the seventh cervical vertebra and the first rib, it runs up the back part of the neck, between the Complexus and Semispinalis colli muscles, as high as the axis vertebra, supplying these and adjacent muscles, and anastomosing with the deep branch of the arteria princeps cervicis of the occipital, and with branches which pass outward from the vertebral. It gives off a special branch which enters the vertebral canal through the intervertebral foramen between the seventh cervical and first thoracic vertebræ.

THE AXILLA.

The **axilla** is a pyramidal space, situated between the upper and lateral part of the thorax and the inner side of the arm.

Boundaries.—Its *apex*, which is directed upward toward the root of the neck, corresponds to the interval between the first rib, the upper edge of the scapula, and the clavicle, through which the axillary vessels, the brachial plexus of nerves, and the long thoracic nerve pass. This interval is the **cervicoaxillary passage**.

The *base*, directed downward, is formed by the integument and a thick layer of fascia, the **axillary fascia** (*fascia axillaris*) (Fig. 348), extending between the lower border of the Pectoralis major in front and the lower border of the Latissimus dorsi behind (page 407). The axilla is broad internally at the thorax, but narrow and pointed externally at the arm. The *anterior* wall is formed by the Pectoralis major and minor muscles, the former covering the whole of the anterior wall of the axilla, the latter covering only its central part, the costocoracoid membrane, the clavicle, and the Subclavius muscle. The *posterior boundary*, which extends somewhat lower than the anterior, is formed by the Subscapularis above, the Teres major and Latissimus dorsi below. On the *inner side* are the first four ribs with their corresponding Intercostal muscles, and part of the Serratus magnus. On the *outer side*, where the anterior and posterior boundaries converge, the space is narrow, and bounded by the humerus, the Coracobrachialis and Biceps muscles.

Contents.—It contains the axillary vessels, and the brachial plexus of nerves, with their branches, some branches of the intercostal nerves, and a large number of lymph nodes, all connected by a quantity of fat and loose areolar tissue.

Position of the Contents.—The axillary artery and vein, with the brachial plexus of nerves, extend obliquely along the outer boundary of the axilla, from its apex to its base, and are placed much nearer the anterior than the posterior wall, the vein lying to the inner or thoracic side of the artery and partially concealing it. At the fore part of the axilla, in contact with the Pectoral muscles, and along the anterior margin are the thoracic branches of the axillary artery, and along the lower margin of the Pectoralis minor the long thoracic artery extends to the side of the thorax. At the back part, in contact with the lower margin of the Subscapularis muscle, are the subscapular vessels and nerves; winding around the outer border of this muscle is the dorsalis scapulae artery and veins; and, close to the neck of the humerus, the posterior circumflex vessels and the circumflex nerve are seen curving backward to the shoulder.

Along the inner or thoracic side no vessel of any importance exists, the upper part of the space being crossed merely by a few small branches from the superior thoracic artery. There are some important nerves, however, in this situation—viz., the long thoracic or external respiratory nerve, descending on the surface of the Serratus magnus, to which it is distributed; and perforating the upper and anterior part of this wall, the intercostohumeral nerve or nerves, passing across the axilla to the inner side of the arm.

The cavity of the axilla is filled by a quantity of loose areolar tissue and a large number of small arteries and veins, all of which are, however, of inconsiderable size, and numerous lymph nodes, the position and arrangement of which are described on a subsequent page.

Applied Anatomy.—The axilla is a space of considerable surgical importance. It transmits the large vessels and nerves to the upper extremity, and these may be the seat of injury or disease; it contains numerous lymph nodes which may require removal when diseased; in it is a quantity of loose connective and adipose tissue which may be readily infiltrated with blood or pus. The axilla may be the seat of rapidly growing tumors. Moreover, it is covered at its base by thin skin, largely supplied with sebaceous and sweat glands, which is frequently the seat of small cutaneous *abscesses* and *boils*, and of eruptions due to irritation.

In *suppuration* in the axilla the arrangement of the fasciae plays a very important part in the direction which the pus takes. As described on p. 457, the costocoracoid membrane, after covering in the space between the clavicle and the upper border of the Pectoralis minor, splits to enclose this muscle, and, reblending at its lower border, becomes incorporated with the axillary fascia at the anterior fold of the axilla. Suppuration may take place either superficial to or beneath this layer of fascia; that is, either between the Pectorals or beneath the Pectoralis minor; in the former case the pus would point either at the anterior border of the axillary fold or in the groove between the Deltoid and the Pectoralis major; in the latter, the pus would have a tendency to surround the vessels and nerves and ascend into the neck, that being the direction in which there is least resistance. Its progress toward the skin is prevented by the axillary

fascia; its progress backward, by the Serratus magnus; forward, by the costocoracoid fascia; inward, by the wall of the thorax; and outward, by the upper limb. The pus in these cases, after extending into the neck, has been known to spread through the superior opening of the thorax into the mediastinum.

In opening an *axillary abscess* the knife should be entered in the floor of the axilla, midway between the anterior and posterior margins and near the thoracic side of the space. It is well to use a director and dressing forceps after an incision has been made through the skin and fascia in the manner directed by the late Mr. Hilton.

The relations of the vessels and nerves in the several parts of the axilla are important, for it is the universal plan to remove the nodes from the axilla in operating for *cancer of the breast*.

FIG. 460.—The axillary artery and its branches.

The Axillary Artery (A. Axillaris) (Fig. 460).

The **axillary artery**, the continuation of the subclavian, commences at the outer border of the first rib, and terminates at the lower border of the tendon of the *Teres major* muscle, where it takes the name of brachial. Its direction varies with the position of the limb; when the arm lies by the side of the thorax, the vessel forms a gentle curve, the convexity being upward and outward; when the arm is directed at right angles with the trunk, the vessel is nearly straight; and when the arm is elevated still higher, the arteries describe a curve the concavity of which is directed upward. At its commencement the artery is very deeply situated, but near its termination it is superficial, being covered only by the skin and fascia. The description of the relations of this vessel is facilitated by its division into three portions, the first portion being above, the second portion behind, and the third below the *Pectoralis minor*.

Relations.—The first portion of the axillary artery is in relation, *in front*, with the clavicular portion of the Pectoralis major, the costocoracoid membrane, the external anterior thoracic nerve,

and the acromiothoracic and cephalic veins; *behind*, with the first intercostal space, the corresponding Intercostal muscle, the first and second digitations of the Serratus magnus, and the posterior thoracic nerve; on its *outer side*, with the brachial plexus, from which it is separated by a little cellular interval; on its *inner* or thoracic side, with the axillary vein, which overlaps the artery. It is enclosed, together with the axillary vein and the brachial plexus, in a fibrous sheath—the **axillary sheath**—continuous above with the cervical fascia.

RELATIONS OF THE FIRST PORTION OF THE AXILLARY ARTERY.

In front.

Pectoralis major.
Costocoracoid membrane.
External anterior thoracic nerve.
Acromiothoracic and cephalic veins.

Outer side.
Brachial plexus.

Inner side.
Axillary vein.

Behind.

First Intercostal space and Intercostal muscle.
First and Second digitations of Serratus magnus.
Posterior thoracic and internal anterior thoracic nerves.

The **second portion** is covered, *in front*, by the Pectoralis major and minor muscles; *behind* it is the posterior cord of the brachial plexus and some areolar tissue which intervenes between it and the Subscapularis; on the *inner side* is the axillary vein, separated from the artery by the inner cord of the brachial plexus and the internal anterior thoracic nerve; on the *outer side* is the outer cord of the brachial plexus. The brachial plexus of nerves thus surrounds the artery on three sides, and separates it from direct contact with the vein and adjacent muscles.

RELATIONS OF THE SECOND PORTION OF THE AXILLARY ARTERY.

In front.

Pectoralis major and minor.

Outer side.
Outer cord of brachial plexus.

Inner side.
Axillary vein.
Inner cord of brachial plexus.
Internal anterior thoracic nerve.

Behind.

Subscapularis.
Posterior cord of brachial plexus.

The **third portion** of the axillary artery extends from the lower border of the Pectoralis minor to the lower border of the tendon of the Teres major. It is in relation, *in front*, with the lower part of the Pectoralis major above, being covered only by the integument and fascia below; *behind*, with the lower part of the Subscapularis and the tendons of the Latissimus dorsi and Teres major; on its *outer side*, with the Coracobrachialis; on its *inner* or thoracic side, with the axillary vein. The nerves of the brachial plexus bear the following relation to the artery in this part of its course; on the *outer side* is the median nerve and the musculocutaneous for a short distance; on the *inner side*, the ulnar nerve (between the vein and artery) and the lesser internal cutaneous nerve (to the inner side of the vein); *in front* are the inner head of the median and the internal cutaneous nerve, and *behind*, the musculospiral and circumflex, the latter extending only as far as the lower border of the Subscapularis muscle.

RELATIONS OF THE THIRD PORTION OF THE AXILLARY ARTERY.

In front.

Integument and fascia.
Pectoralis major.
Inner head of median nerve.
Internal cutaneous nerve.

Outer side.

Coracobrachialis.
Median nerve.
Musculocutaneous nerve.

*Inner side.*

Ulnar nerve.
Axillary vein.
Lesser internal cutaneous nerve.

Behind.

Subscapularis.
Tendons of Latissimus dorsi and Teres major.
Musculospiral and circumflex nerves.

Peculiarities.—The axillary artery, in about one case out of every ten, gives off a large branch, which forms either one of the arteries of the forearm or a large muscular trunk. In the first set of cases this artery is most frequently the radial (1 in 33), sometimes the ulnar (1 in 72) and, very rarely, the interosseous (1 in 506). In the second set of cases the trunk has been found to give origin to the subscapular, circumflex, and profunda arteries of the arm. Sometimes only one of the circumflex, or one of the profunda arteries, arises from the trunk. In these cases the brachial plexus surrounded the trunk of the branches and not the main vessel.

Surface Marking.—The course of the axillary artery may be marked out by raising the arm to a right angle with the body and drawing a line from the middle of the clavicle to the point where the tendon of the Pectoralis major crosses the prominence caused by the Coracobrachialis as it emerges from under cover of the anterior fold of the axilla. The third portion of the artery can be felt pulsating beneath the skin and fascia, at the junction of the anterior with the middle third of the space between the anterior and posterior folds of the axilla, close to the inner border of the Coracobrachialis muscle.

Applied Anatomy.—*Compression* of the vessel may be required in the removal of tumors or in amputation of the upper part of the arm; and the only situation in which this can be effectually made is in the lower part of its course; by pressing on it in this situation from within outward against the humerus the circulation may be effectually arrested.

With the exception of the popliteal, the axillary artery is perhaps more frequently lacerated than any other artery in the body by violent movements of the extremity, especially in those cases where its coats are diseased. It has occasionally been *ruptured* in attempts to reduce old dislocations of the shoulder-joint. This accident is most likely to occur during the preliminary breaking down of adhesions, in consequence of the artery having become fixed to the capsule of the joint. *Aneurism of the axillary artery* is of frequent occurrence, a large percentage of the cases being traumatic in their origin, due to the violence to which the vessel is exposed in the varied, extensive, and often violent movements of the limb.

The application of a ligature to the axillary artery may be required in cases of aneurism of the upper part of the brachial or as a distal operation for aneurism of the subclavian; and there are only two situations in which the vessel can be secured—viz., in the first and in the third parts of its course; for the axillary artery at its central part is so deeply seated, and, at the same time, so closely surrounded with large nerve trunks, that the application of a ligature to it in that situation would be almost impracticable.

In the *third part* of its course the operation is most simple, and may be performed in the following manner: The patient being placed on a bed and the arm separated from the side, with the hand supinated, an incision about two inches in length is made through the integument forming the floor of the axilla, the cut being a little nearer to the anterior than the posterior fold of the axilla. After carefully dissecting through the areolar tissue and fascia, the median nerve and axillary vein are exposed; the former having been displaced to the outer and the latter to the inner side of the arm, the elbow being at the same time bent, so as to relax the structures and facilitate their separation, the ligature may be passed around the artery from the ulnar to the radial side.

This portion of the artery is occasionally crossed by a muscular slip, the *axillary arch*, derived from the Latissimus dorsi, which may mislead the surgeon during an operation. The occasional existence of this muscle fasciculus was spoken of in the description of the muscles. It may easily be recognized by the transverse direction of its fibres.

The *first portion* of the axillary artery may be tied in cases of aneurism encroaching so far upward that a ligature cannot be applied in the lower part of its course. Notwithstanding that this operation has been performed in some few cases, and with success, its performance is attended with much difficulty and danger. The student will remark that in this situation it would be necessary to divide a thick muscle, and, after incising the costocoracoid membrane, the artery would be exposed at the bottom of a more or less deep space, with the cephalic and axillary veins in such relation with it as must render the application of a ligature to this part of the vessel particularly hazardous. Under such circumstances it is an easier, and at the same time more advisable, operation to tie the subclavian artery in the third part of its course.

The vessel in the first part of its course can best be secured through a curved incision the convexity of which is downward. This incision passes from a point half an inch external to the sternoclavicular joint to a point half an inch internal to the coracoid process. The limb is to be well abducted and the head inclined to the opposite side, and this incision is carried through the superficial structures, care being taken to avoid the cephalic vein at the outer angle of the incision. The clavicular origin of the Pectoralis major is then divided in the whole extent of the wound. The arm is now to be brought to the side, and the upper edge of the Pectoralis minor defined and drawn downward. The costocoracoid membrane is to be carefully divided close to the coracoid process, and the axillary sheath exposed; this is to be opened with especial care, on account of the vein overlapping the artery. The needle should be passed from below, so as to avoid wounding the vein.

In a case of wound of the vessel the general practice of cutting down upon and tying it above and below the wounded point should be adopted in all cases.

Branches.—The branches of the axillary artery are:

<i>From first part</i>	{ Superior thoracic. Acromiothoracic.	<i>From second part</i>	{ Long thoracic. Alar thoracic.
	<i>From third part</i>	{ Subscapular. Posterior circumflex. Anterior circumflex.	

The **superior thoracic** (*a. thoracalis suprema*) is a small artery which arises from the axillary separately or by a common trunk with the acromiothoracic. Running forward and inward along the upper border of the Pectoralis minor, it passes between it and the Pectoralis major to the side of the thorax. It supplies these muscles and the parietes of the thorax, anastomosing with the internal mammary and intercostal arteries.

The **acromiothoracic** (*a. thoracoacromialis*) is a short trunk which arises from the fore part of the axillary artery, its origin being generally overlapped by the upper edge of the Pectoralis minor. Projecting forward to the upper border of the Pectoralis minor, it divides into four sets of branches—**thoracic, acromial, descending, and clavicular.**

The **thoracic branches** (*rami pectorales*), two or three in number, are distributed to the Serratus magnus and Pectoral muscles, anastomosing with the intercostal branches of the internal mammary.

The **acromial branch** (*ramus acromialis*) is directed outward toward the acromion, supplying the Deltoid muscle, and anastomosing, on the surface of the acromion, with the suprascapular and posterior circumflex arteries.

The **descending or humeral branch** (*ramus deltoideus*) runs in the space between the Pectoralis major and Deltoid, in the same groove as the cephalic vein, and supplies both muscles.

The **clavicular branch** (*ramus clavicularis*), which is very small, runs upward to the Subclavius muscle.

The **long thoracic** or the **external mammary** (*a. thoracalis lateralis*) passes downward and inward along the lower border of the Pectoralis minor to the side of the thorax, supplying the Serratus magnus, the Pectoral muscles, and mammary gland, and sending branches across the axilla to the axillary nodes and Subscapularis; it anastomoses with the internal mammary and intercostal arteries.

The **alar thoracic** is a small branch which supplies the nodes and areolar tissue of the axilla. Its place is frequently supplied by branches from some of the other thoracic arteries.

The **subscapular** (*a. subscapularis*), the largest branch of the axillary artery, *arises* opposite the lower border of the Subscapularis muscle, and passes downward and backward along its lower margin to the inferior angle of the scapula, where it anastomoses with the long thoracic and intercostal arteries and with the posterior scapular branch of the transverse cervical, and terminates by supplying branches to the muscles in the neighborhood. About an inch and a half from its origin it gives off a large branch, the **dorsalis scapulae**.

The **dorsalis scapulae** (*a. circumflexa scapulae*) is generally larger than the continuation of the subscapular. It curves around the axillary border of the scapula, leaving the axilla through the space between the Teres minor above, the Teres major below, and the long head of the Triceps externally (Fig. 458), and enters the infraspinous fossa by passing under cover of the Teres minor, where it anastomoses with the posterior scapular and suprascapular arteries. In its course it gives off two branches: one (**infrascapular**) enters the subscapular fossa beneath the Subscapularis, which it supplies, anastomosing with the posterior scapular and suprascapular arteries; the other is continued along the axillary border of the scapula, between the Teres major and minor, and, at the dorsal surface of the inferior angle of the bone, anastomoses with the posterior scapular. In addition to these, small branches are distributed to the back part of the Deltoid muscle and the long head of the Triceps, anastomosing with an ascending branch of the superior profunda of the brachial.

The **circumflex arteries** wind around the surgical neck of the humerus. The **posterior circumflex** (*a. circumflexa humeri posterior*) (Fig. 458), the larger of the two, *arises* from the back part of the axillary opposite the lower border of the Subscapularis muscle, and, passing backward with the circumflex veins and nerve through the quadrangular space bounded by the Teres major and minor, the scapular head of the Triceps and the humerus, winds around the neck of that bone and is distributed to the Deltoid muscle and shoulder-joint, anastomosing with the anterior circumflex and acromial thoracic arteries, and with the superior profunda branch of the brachial artery. The **anterior circumflex** (*a. circumflexa humeri anterior*) (Figs. 458 and 460), considerably smaller than the preceding, *arises* nearly

FIG. 461.—The brachial artery.

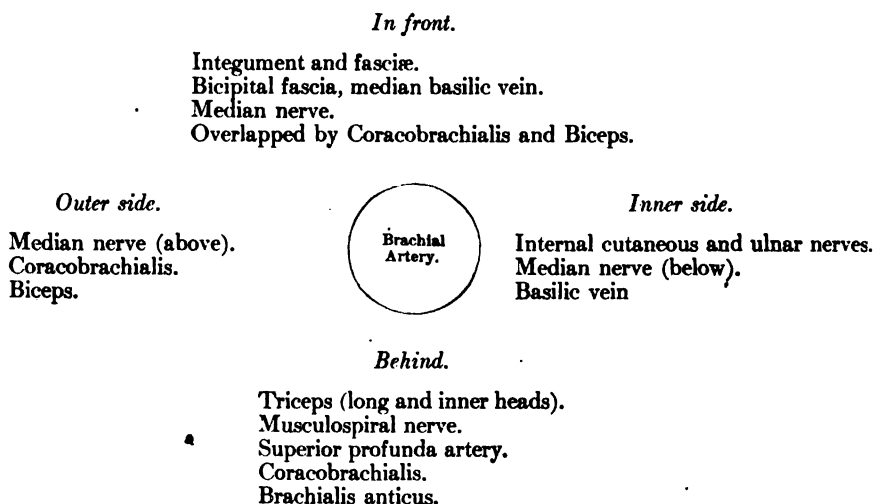

opposite that vessel from the outer side of the axillary artery. It passes horizontally outward beneath the Coracobrachialis and short head of the Biceps lying upon the fore part of the neck of the humerus, and, on reaching the bicipital groove, gives off an ascending branch which passes upward along the groove to supply the head of the bone and the shoulder-joint. The trunk of the vessel is then continued outward beneath the Deltoid, which it supplies, and anastomoses with the posterior circumflex artery.

The Brachial Artery (A. Brachialis) (Fig. 461).

The **brachial artery** (*a. brachialis*) commences at the lower margin of the tendon of the Teres major, and, passing down the inner and anterior aspect of the arm, terminates about half an inch below the bend of the elbow, where it divides into the **radial** and **ulnar arteries**. At first the brachial artery lies internal to the humerus, but as it passes down the arm it gradually gets in front of the bone, and at the bend of the elbow it lies midway between the two condyles.

Relations.—This artery is superficial throughout its entire extent, being covered, *in front*, by the integument, the superficial and deep fasciæ; the bicipital fascia separates it opposite the elbow from the median basilic vein; the median nerve crosses it at its middle; *behind*, it is separated from the long head of the Triceps by the musculospiral nerve and superior profunda artery. It then lies upon the inner head of the Triceps, next upon the insertion of the Coracobrachialis, and lastly on the Brachialis anticus. By its *outer side*, it is in relation with the commencement of the median nerve and the Coracobrachialis and Biceps muscles, the two muscles overlapping the artery to a considerable extent. By its *inner side*, its upper half is in relation with the internal cutaneous and ulnar nerves, its lower half with the median nerve. The basilic vein lies on the inner side of the artery, but is separated from it in the lower part of the arm by the deep fascia. The brachial artery is accompanied by two venæ comites, which lie in close contact with the artery, being connected at intervals by short transverse communicating branches.

PLAN OF THE RELATIONS OF THE BRACHIAL ARTERY.

THE ANATOMY OF THE BEND OF THE ELBOW (ANTECUBITAL FOSSA).

At the bend of the elbow the brachial artery sinks deeply into a triangular interval, the *antecubital fossa*, the *base* of which is directed upward, and may be represented by a line connecting the two condyles of the humerus; the *sides* are bounded, *externally*, by the inner edge of the Brachioradialis; *internally*, by the outer margin of the Pronator teres; its *floor* is formed by the Brachialis anticus and Supinator [brevis]. This space contains the brachial artery with its accompanying veins, the radial and ulnar arteries, the median and musculospiral nerves, and the tendon of the Biceps. The brachial artery occupies the middle line of this space, and divides opposite the neck of the radius into the radial and ulnar arteries; it is covered, *in front*, by the integument, the superficial fascia, and the median basilic vein, the vein being separated from direct contact with the artery by the bicipital fascia. *Behind*, it lies on the Brachialis anticus, which separates it from the elbow-joint. The median nerve lies on the inner side of the artery, close to it above, but separated from it below by the coronoid origin of the Pronator teres. The tendon of the Biceps lies to the outer side of the space, and the musculospiral nerve still more externally, situated upon the Supinator and partly concealed by the Brachioradialis.

Peculiarities of the Brachial Artery as Regards its Course.—The brachial artery, accompanied by the median nerve, may leave the inner border of the Biceps and descend toward the inner condyle of the humerus, where it usually curves around a prominence of bone, the supracondylar process. From this process, in most subjects, a fibrous arch is thrown over the artery. The vessel then inclines outward, beneath or through the substance of the Pronator teres muscle, to the bend of the elbow. The variation bears considerable homology to the normal condition of the artery in some of the carnivora; it has been referred to in the description of the humerus (page 181).

As Regards its Division.—Occasionally, the artery is divided for a short distance at its upper part into two trunks which are united above and below. A similar peculiarity occurs in the main vessel of the lower limb.

The vessels concerned in the high division of the brachial artery are three—viz., radial, ulnar, and interosseous. Most frequently the radial is given off high up, the other limb of the bifurcation consisting of the ulnar and interosseous. In some instances the ulnar arises from the brachial above the ordinary level, and the radial and interosseous form the other limb of the division; and occasionally the interosseous arises high up.

Sometimes long slender vessels, *vasa aberrantia*, connect the brachial or axillary arteries with one of the arteries of the forearm or a branch from them. These vessels usually join the radial.

Varieties in Muscular Relations.¹—The brachial artery is occasionally concealed in some part of its course by muscular or tendinous slips derived from the Coracobrachialis, Biceps, Brachialis anticus, and Pronator teres muscles.

Surface Marking.—The direction of the brachial artery is marked by a line drawn along the inner edge of the Biceps from the junction of the anterior and middle thirds of the axillary outlet to the middle of the front of the elbow-joint.

Applied Anatomy.—Compression of the brachial artery is required in cases of amputation and some other operations in the arm and forearm; and it will be observed that it may be effected in almost any part of the course of the artery. If pressure is made in the upper part of the limb, it should be directed from within outward, and if in the lower part, from before backward, as the artery lies on the inner side of the humerus above and in front of the humerus below. The most favorable situation is about the middle of the arm, where it lies on the tendon of the Coracobrachialis on the inner flat side of the humerus.

The application of a ligature to the brachial artery may be required in case of wound of the vessel and in some cases of wound of the palmar arch. It is also sometimes necessary in cases of aneurism of the brachial, the radial, ulnar, or interosseous arteries. The artery may be secured in any part of its course. The chief guides in determining its position are the surface markings produced by the inner margin of the Coracobrachialis and Biceps, the known

¹ See Struther's Anatomical and Physiological Observations.

course of the vessel, and its pulsation, which should be carefully felt for before any operation is performed, as the vessel occasionally deviates from its usual position in the arm. In whatever situation the operation is performed, great care is necessary, on account of the extreme thinness of the parts covering the artery and the intimate connection which the vessel has throughout its whole course with important nerves and veins. Sometimes a thin layer of muscle fibre is met with concealing the artery; if such is the case, it must be cut across in order to expose the vessel.

In the upper third of the arm the artery may be exposed in the following manner: The patient being placed supine upon a table, the affected limb should be raised from the side and the hand supinated. An incision about two inches in length should be made on the inner side of the Coracobrachialis muscle, and the subjacent fascia cautiously divided, so as to avoid wounding the internal cutaneous nerve or basilic vein, which sometimes runs on the surface of the artery as high as the axillary. The fascia having been divided, it should be remembered that the ulnar and internal cutaneous nerves lie on the inner side of the artery, the median on the outer side, the latter nerve being occasionally superficial to the artery in this situation, and that the venae comites are also in relation with the vessel, one on either side. These being carefully separated, the aneurism needle should be passed around the artery from the inner to the outer side.

In the case of a high division, the two arteries are usually placed side by side; and if they are exposed in an operation, the surgeon should endeavor to ascertain, by alternately pressing on each vessel, which of the two communicates with the wound or aneurism, when a ligature may be applied accordingly; or if pulsation or hemorrhage ceases only when both vessels are compressed, both vessels may be tied, as it may be concluded that the two communicate above the seat of disease or are reunited.

It should also be remembered that two arteries may be present in the arm in a case of high division, and that one of these may be found along the inner intermuscular septum, in a line toward the inner condyle of the humerus, or in the usual position of the brachial, but deeply placed beneath the common trunk; a knowledge of these facts will suggest the precautions necessary in every case, and indicate the measures to be adopted when anomalies are met with.

In the middle of the arm the brachial artery may be exposed by making an incision along the inner margin of the Biceps muscle. The forearm being bent so as to relax the muscle, it should be drawn slightly aside, and, the fascia being carefully divided, the median nerve will be exposed lying upon the artery (sometimes beneath); this being drawn inward and the muscle outward, the artery should be separated from its accompanying veins and secured. In this situation the inferior profunda may be mistaken for the main trunk, especially if enlarged, from the collateral circulation having become established; this may be avoided by directing the incision externally toward the Biceps, rather than inward or backward toward the Triceps.

The lower part of the brachial artery is of interest from a surgical point of view, on account of the relation which it bears to the veins most commonly opened in *venesection*. Of these vessels, the *median basilic* is the largest and most prominent, and, consequently, the one usually selected for the operation. It should be remembered that this vein runs parallel with the brachial artery, from which it is separated by the bicipital fascia, and that care should be taken in opening the vein not to carry the incision too deeply, so as to endanger the artery.

Collateral Circulation.—After the application of a ligature to the brachial artery in the upper third of the arm, the circulation is carried on by branches from the circumflex and subscapular arteries, anastomosing with ascending branches from the superior profunda. If the brachial is tied *below* the origin of the profunda arteries, the circulation is maintained by the branches of the profundæ, anastomosing with the recurrent radial, ulnar, and interosseous arteries.

Branches.—The branches of the brachial artery are:

Superior profunda.
Nutrient.

Inferior profunda.
Anastomotica magna.

Muscular.

The **superior profunda artery** (*a. profunda brachii*) arises from the inner and back part of the brachial, just below the lower border of the Teres major, and passes backward to the interval between the outer and inner heads of the Triceps muscle; accompanied by the musculospiral nerve it winds around the back part of the shaft of the humerus in the spiral groove, between the outer head of the Triceps and the bone, to the outer side of the humerus, where it reaches the external intermuscular septum and divides into two terminal branches. One of these pierces the external intermuscular septum, and descends, in company with the musculo-

spiral nerve, to the space between the Brachialis anticus and Brachioradialis, where it anastomoses with the recurrent branch of the radial artery; while the other, much the larger of the two, descends along the back of the external intermuscular septum to the back of the elbow-joint, where it anastomoses with the posterior interosseous recurrent, and across the back of the humerus with the posterior ulnar recurrent, the anastomotica magna, and inferior profunda (Fig. 465). The superior profunda supplies the Triceps muscle and gives off a nutrient artery which enters the bone at the upper end of the musculospiral groove. Near its commencement it sends off a branch which passes upward between the external and long heads of the Triceps muscle to anastomose with the posterior circumflex artery, and, while in the groove, a small branch which accompanies a branch of the musculospiral nerve through the substance of the Triceps muscle and ends in the Anconeus below the outer condyle of the humerus.

The **nutrient artery** (*a. nutritia humeri*) of the shaft of the humerus arises from the brachial, about the middle of the arm. Passing downward it enters the nutrient canal of that bone near the insertion of the Coracobrachialis muscle.

The **inferior profunda** (*a. collateralis ulnaris superior*), of small size, arises from the brachial, a little below the middle of the arm; piercing the internal intermuscular septum, it descends on the surface of the inner head of the Triceps muscle to the space between the inner condyle and olecranon, accompanied by the ulnar nerve, and terminates by anastomosing with the posterior ulnar recurrent and anastomotica magna. It sometimes supplies a branch to the front of the internal condyle, which anastomoses with the anterior ulnar recurrent.

The **anastomotica magna** (*a. collateralis ulnaris inferior*) arises from the brachial about two inches above the elbow-joint. It passes transversely inward upon the Brachialis anticus, and, piercing the internal intermuscular septum, winds

FIG. 462.—The radial and ulnar arteries.

around the back of the humerus between the Triceps and the bone, forming an arch above the olecranon fossa by its junction with the posterior articular branch of the superior profunda. As this vessel lies on the Brachialis anticus, branches ascend to join the inferior profunda, and others descend in front of the inner condyle to anastomose with the anterior ulnar recurrent. Behind the internal condyle an offset is given off which anastomoses with the inferior profunda and posterior ulnar recurrent arteries and supplies the Triceps.

The **muscular** (*rami musculares*) are three or four large branches, which are distributed to the muscles in the course of the artery. They supply the Coracobrachialis, Biceps, and Brachialis anticus muscles.

The Anastomosis around the Elbow-joint (Fig. 463).—The vessels engaged in this anastomosis may be conveniently divided into those situated *in front* and

FIG. 463.—Diagram of the anastomosis around the right elbow-joint.

behind the internal and external condyles. The branches anastomosing *in front* of the internal condyle are the anastomotica magna, the anterior ulnar recurrent, and the anterior terminal branch of the inferior profunda. Those *behind* the internal condyle are the anastomotica magna, the posterior ulnar recurrent, and the posterior terminal branch of the inferior profunda. The branches anastomosing *in front* of the external condyle are the radial recurrent and the anterior terminal branch of the superior profunda. Those *behind* the external condyle (perhaps more properly described as being situated between the external condyle and the olecranon) are the anastomotica magna, the interosseous recurrent, and the posterior terminal branch of the superior profunda. There is also a large arch of anastomosis above the olecranon, formed by the interosseous recurrent, joining with the anastomotica magna and posterior ulnar recurrent.

From this description it will be observed that the anastomotica magna is the vessel most engaged, the only part of the anastomosis in which it is not employed being that *in front* of the external condyle.

The Radial Artery (*A. Radialis*) (Figs. 462, 464).

The **radial artery** appears, from its direction, to be the continuation of the brachial, but in size it is smaller than the ulnar. It commences at the bifurcation of the brachial, just below the bend of the elbow, and passes along the radial side of the forearm to the wrist; it then winds backward, around the outer side of the carpus, beneath the Extensor tendons of the thumb, to the upper end of the

space between the metacarpal bones of the thumb and index finger, and finally passes forward, between the two heads of the First dorsal interosseous muscle, into the palm of the hand, where it crosses the metacarpal bones to the ulnar border of the hand, to form the **deep palmar arch**. At its termination it anastomoses with the profunda branch of the ulnar artery. The relations of this vessel may thus be conveniently divided into three parts—viz., in the forearm, at the back of the wrist, and in the hand.

Relations.—In the forearm this vessel extends from opposite the neck of the radius to the fore part of the styloid process, being placed to the inner side of the shaft of the bone above and in front of it below. It is overlapped in the upper part of its course by the fleshy belly of the Brachioradialis muscle; throughout the rest of its course it is superficial, being covered by the integument, the superficial and deep fasciæ. In its course downward it lies upon the tendon of the Biceps, the Supinator [brevis], the Pronator teres, the radial origin of the Flexor sublimis digitorum, the Flexor longus pollicis, the Pronator quadratus, and the lower extremity of the radius. In the upper third of its course it lies between the Brachioradialis and the Pronator teres; in the lower two-thirds, between the tendons of the Brachioradialis and the Flexor carpi radialis. The radial nerve lies close to the outer side of the artery in the middle third of its course, and some filaments of the musculocutaneous nerve, after piercing the deep fascia, run along the lower part of the artery as it winds around the wrist. The vessel is accompanied by venæ comites throughout its whole course.

PLAN OF THE RELATIONS OF THE RADIAL ARTERY IN THE FOREARM.

At the wrist, as it winds around the outer side of the carpus from the styloid process to the first interosseous space, it lies upon the external lateral ligament, and then upon the scaphoid bone and trapezium, being covered by the Extensor tendons of the thumb, subcutaneous veins, some filaments of the radial nerve, and the integument. It is accompanied by two veins and a filament of the musculocutaneous nerve.

In the hand it passes from the upper end of the first interosseous space, between the heads of the Abductor indicis or First dorsal interosseous muscle, transversely across the palm, to the base of the metacarpal bone of the little finger, where it anastomoses with the communicating branch from the ulnar artery, forming the **deep palmar arch**.

The **deep palmar arch** (*arcus volaris profundus*) (Fig. 464) lies upon the carpal extremities of the metacarpal bones and the Interossei muscles, being covered by the Adductor obliquus pollicis, the Flexor tendons of the fingers, the Lumbricales, the Opponens, and Flexor brevis minimi digiti. Alongside of it, but running in the opposite direction—that is to say, from within outward—is

the deep branch of the ulnar nerve. The branches of the deep palmar arch are the palmar interosseous, perforating and palmar recurrent vessels (page 650).

Peculiarities.—The origin of the radial artery, according to Quain, is, in nearly one case in eight, higher than usual; more frequently arising from the axillary or upper part of the brachial than from the lower part of this vessel. The variations in the position of this vessel in the arm and at the bend of the elbow have been already mentioned. In the forearm it deviates less frequently from its position than the ulnar. It has been found lying over the fascia instead of beneath it. It has also been observed superficial to the Brachioradialis, instead of under its inner border; and in turning around the wrist it has been seen lying over, instead of beneath, the Extensor tendons of the thumb.

Surface Marking.—The position of the radial artery in the forearm is represented by a line drawn from the outer border of the tendon of the Biceps in the centre of the hollow in front of the elbow-joint with a straight course to the inner side of the forepart of the styloid process of the radius.

Applied Anatomy.—The radial artery is much exposed to injury in its lower third, and is frequently wounded when the hand has been driven through a pane of glass, by the slipping of a knife or chisel held in the other hand, and similar accidents. The injury is often followed by a *traumatic aneurism*, for which the operation of extirpation or laying open the sac after securing the vessel above and below is required.

The operation of *tying the radial artery* is required in cases of wounds either of its trunk or of some of its branches, or for aneurism; and it will be observed that the vessel may be exposed in any part of its course through the forearm without the division of any muscle fibres. The operation in the middle or inferior third of the forearm is easily performed, but in the upper third, near the elbow, it is attended with some difficulty, from the greater depth of the vessel and from its being overlapped by the Brachioradialis muscle.

To tie the artery in the upper third an incision three inches in length should be made through the integument, in a line drawn from the centre of the bend of the elbow to the front of the styloid process of the radius, avoiding the branches of the median vein; the fascia of the arm being divided and the Brachioradialis drawn a little outward, the artery will be exposed. The *venae comites* should be carefully separated from the vessel, and the ligature passed from the radial to the ulnar side.

In the middle third of the forearm the artery may be exposed by making an incision of similar length on the inner margin of the Brachioradialis. In this situation the radial nerve lies in close relation with the outer side of the artery, and should, as well as the veins, be carefully avoided.

In the lower third the artery is easily secured by dividing the integument and fascia in the interval between the tendons of the Brachioradialis and Flexor carpi radialis muscles.

Branches (Figs. 462 and 464).—The branches of the radial artery may be divided into three groups, corresponding with the three regions in which the vessel is situated.

<i>In the Forearm</i>	{	Radial recurrent.	<i>At the Wrist</i>	{	Posterior radial carpal.
		Muscular.			First dorsal interosseous.
		Anterior radial carpal.			Dorsales pollicis.
		Superficialis volae.			Dorsalis indicis.
<i>In the Hand</i>		{	Princeps pollicis.		
			Radialis indicis.		
			Perforating.		
			Palmar interosseous.		
			Palmar recurrent.		

The **radial recurrent** (*a. recurrens radialis*) (Fig. 464) is given off immediately below the elbow. It ascends between the branches of the musculospiral nerve lying on the Supinator [brevis], and then between the Brachioradialis and Brachialis anticus, supplying these muscles and the elbow-joint, and anastomosing with the anterior terminal branch of the superior profunda.

The **muscular branches** (*rami musculares*) are distributed to the muscles on the radial side of the forearm.

The **anterior radial carpal** (*ramus carpeus volaris*) (Fig. 464) is a small vessel which *arises* from the radial artery near the lower border of the Pronator quadratus, and, running inward in front of the radius, anastomoses with the anterior carpal branch of the ulnar artery. In this way an arterial anastomosis, the **anterior carpal arch** (*rete carpi volare*) is formed in front of the wrist; it is joined by branches from the anterior interosseous above, and by recurrent branches from the deep palmar arch below, and gives off branches which descend to supply the articulations of the wrist and carpus.

The **superficialis volae** (*ramus volaris superficialis*) (Fig. 464) *arises* from the radial artery, just where this vessel is about to wind around the wrist. Running forward, it passes between, occasionally over, the muscles of the thumb, which it supplies, and sometimes anastomoses with the palmar portion of the ulnar artery, completing the superficial palmar arch. This vessel varies considerably in size; usually it is very small, and terminates in the muscles of the thumb; sometimes it is as large as the continuation of the radial.

The **posterior radial carpal** (*ramus carpeus dorsalis*) (Fig. 465) is a small vessel which *arises* from the radial artery beneath the Extensor tendons of the thumb; crossing the carpus transversely to the inner border of the hand, it anastomoses with the posterior carpal branch of the ulnar, forming the **posterior carpal arch** (*rete carpi dorsale*), which is joined by the termination of the anterior interosseous artery. From this arch are given off descending branches, the **dorsal interosseous arteries** (*aa. metacarpeae dorsales*) for the second, third, and fourth interosseous spaces, which run forward on the Second, Third, and Fourth dorsal interossei muscles, and divide into **dorsal digital branches** (*aa. digitales dorsales*), which supply the adjacent sides of the index, middle, ring, and little fingers, respectively, communicating with the digital arteries of the superficial palmar arch. The dorsal interosseous arteries anastomose with the perforating branches from the deep palmar arch.

The **first dorsal interosseous** *arises* beneath the Extensor tendons of the thumb, sometimes with the posterior radial carpal; running forward on the Second dorsal interosseous muscle, it divides into two dorsal digital branches, which supply the adjoining sides of the index and middle fingers; it forms anastomoses similar to those of the two other dorsal interosseous arteries.

The **dorsales pollicis** (Fig. 465) are two vessels which run along the sides of the dorsal aspect of the thumb. They usually *arise* separately, but occasionally by a common trunk, near the base of the first metacarpal bone.

The **dorsalis indicis** (Fig. 465), also a small branch, runs along the radial side of the back of the index finger, sending a few branches to the Abductor indicis.

The **princeps pollicis** (*a. princeps pollicis*) (Fig. 464) *arises* from the radial just as it turns inward to the deep part of the hand; it descends between the Abductor indicis and Adductor obliquus pollicis, then between the Adductor transversus pollicis and Adductor obliquus pollicis, along the ulnar side of the metacarpal bone of the thumb, to the base of the first phalanx, where it lies beneath the tendon of the Flexor longus pollicis and divides into two branches. These make their appearance between the inner and outer insertions of the Adductor obliquus pollicis, and run along the sides of the palmar aspect of the thumb, forming on the palmar surface of the last phalanx an arch, from which branches are distributed to the integument and subcutaneous tissue of the thumb.

The **radialis indicis** (*a. volaris indicis radialis*) (Fig. 464) *arises* close to the preceding, descends between the Abductor indicis and Adductor transversus pollicis, and runs along the radial side of the index finger to its extremity, where it anastomoses with the collateral digital artery from the superficial palmar arch. At the lower border of the Adductor transversus pollicis this vessel anastomoses with the princeps pollicis, and gives a communicating branch to the superficial palmar arch.

The **perforating arteries** (*rami perforantes*) (Fig. 464), three in number, pass backward from the deep palmar arch through the second, third, and fourth interosseous spaces and between the heads of the corresponding Interossei, to anastomose with the dorsal interosseous arteries.

The **palmar interosseous** (*aa. metacarpeae volares*) (Fig. 464), three or four in number, arise from the convexity of the deep palmar arch; they run downward upon the Interossei muscles, and anastomose at the clefts of the fingers with the digital branches of the superficial arch.

The **palmar recurrent branches** arise from the concavity of the deep palmar arch. They ascend in front of the wrist, supplying the carpal articulations and anastomosing with the anterior carpal arch.

The Ulnar Artery (*A. Ulnaris*) (Figs. 462, 464).

The **ulnar artery**, the larger of the two terminal branches of the brachial, commences a little below the bend of the elbow, and passes obliquely across the inner side of the forearm to a point about midway between the elbow and the wrist. It then runs along the ulnar border to the wrist, crosses the annular ligament on the radial side of the pisiform bone, and immediately beyond this bone divides into two branches which enter into the formation of the superficial and deep palmar arches.

FIG. 464.—Ulnar and radial arteries. Deep view.

covered by all the superficial Flexor muscles, excepting the Flexor carpi ulnaris; the median nerve is in relation with the inner side of the artery for about an inch and then crosses the vessel, being separated from it by the deep head of the Pronator teres; it lies upon the Brachialis anticus and Flexor profundus digitorum muscles. In the *lower half* of the forearm it lies upon the Flexor profundus, being covered by the integument, the superficial and deep fasciæ, and is placed between the Flexor carpi ulnaris and Flexor sublimis digitorum muscles. It is accompanied by two venæ comites; the ulnar nerve lies on its inner side for the lower two-thirds of its extent, and a small branch from the nerve descends on the lower part of the vessel to the palm of the hand.

Relations.—In the Forearm.—In its *upper half* it is deeply seated, being

 Ulnar nerve (lower two-thirds).

*Outer side.*

Flexor sublimis digitorum.

Behind.

Brachialis anticus.
 Flexor profundus digitorum.

At the wrist (Fig. 462) the ulnar artery is covered by the integument and fascia, and lies upon the anterior annular ligament. On its inner side is the pisiform bone, and somewhat behind the artery, the ulnar nerve. The nerve and artery are crossed by a band of fibres, which extends from the pisiform bone to the anterior annular ligament.

Peculiarities.—The ulnar artery has been found to vary in its origin nearly in the proportion of one in thirteen cases, in one case arising lower than usual, about two or three inches below the elbow, and in all other cases much higher, the brachial being a more frequent source of origin than the axillary.

Variations in the position of this vessel are more frequent than in the radial. When its origin is normal, the course of the vessel is rarely changed. When it arises high up it is almost invariably superficial to the Flexor muscles in the forearm, lying commonly beneath the fascia, more rarely between the fascia and integument. In a few cases its position was subcutaneous in the upper part of the forearm, subaponeurotic in the lower part.

Surface Marking.—On account of the curved direction of the ulnar artery the line on the surface of the body which indicates its course is somewhat complicated. *First*, draw a line from the front of the internal condyle of the humerus to the radial side of the pisiform bone; the lower two-thirds of this line represents the course of the middle and lower third of the ulnar artery. *Secondly*, draw a line from the centre of the antecubital space to the junction of the upper and middle third of the first line; this represents the course of the upper third of the artery.

Applied Anatomy.—The application of a ligature to this vessel is required in cases of wound of the artery or of its branches, or in consequence of aneurism. In the upper half of the forearm the artery is deeply seated beneath the Superficial Flexor muscles, and the application of a ligature in this situation is attended with some difficulty. An incision is to be made in the course of a line drawn from the front of the internal condyle of the humerus to the outer side of the pisiform bone, so that the centre of the incision is three fingers' breadth below the internal condyle. The skin and superficial fascia having been divided and the deep fascia exposed, the white line which separates the Flexor carpi ulnaris from the other Flexor muscles is to be sought for, and the fascia incised in this line. The Flexor carpi ulnaris is now to be carefully separated from the other muscles, when the ulnar nerve will be exposed, and must be drawn aside.

Some little distance below the nerve the artery will be found accompanied by its venæ comites, and it may be ligated by passing the needle from within outward. In the middle and lower third of the forearm this vessel may be easily secured by making an incision on the radial side of the tendon of the Flexor carpi ulnaris; the deep fascia being divided, and the Flexor carpi ulnaris and its companion muscle, the Flexor sublimis, being separated from each other, the vessel will be exposed, accompanied by its venæ comites, the ulnar nerve lying on its inner side.

The veins being separated from the artery, the ligature should be passed from the ulnar to the radial side, taking care to avoid the ulnar nerve.

Branches (Figs. 464 and 465).—The branches of the ulnar artery may be arranged in the following groups:

Forearm	{	Anterior ulnar recurrent.
		Posterior ulnar recurrent.
	{	Interosseous { Anterior interosseous.
		Posterior interosseous.
	{	Muscular.
Wrist	{	Anterior ulnar carpal.
		Posterior ulnar carpal.
Hand	{	Profunda.
		Superficial palmar arch.

The **anterior ulnar recurrent** (*a. recurrentes ulnaris anterior*) (Fig. 464) *arises* immediately below the elbow-joint, passes upward and inward between the Brachialis anticus and Pronator teres, supplies twigs to those muscles, and, in front of the inner condyle, anastomoses with the anastomotica magna and inferior profunda.

The **posterior ulnar recurrent** (*a. recurrentes ulnaris posterior*) (Figs. 464 and 465) is much larger, and *arises* somewhat lower than the preceding. It passes backward and inward, beneath the Flexor sublimis, and ascends behind the inner condyle of the humerus. In the interval between this process and the olecranon it lies beneath the Flexor carpi ulnaris, and ascending between the heads of that muscle, in relation with the ulnar nerve; it supplies the neighboring muscles and joint, and anastomoses with the inferior profunda, anastomotica magna, and interosseous recurrent arteries.

The **interosseous artery** (*a. interossea communis*) (Fig. 464) is a short trunk about half an inch in length, and of considerable size, which *arises* immediately below the tuberosity of the radius, and, passing backward to the upper border of the interosseous membrane, divides into two branches, the **anterior** and **posterior interosseous**.

The **anterior interosseous** (*a. interossea volaris*) (Fig. 464) passes down the forearm on the anterior surface of the interosseous membrane, to which it is connected by a thin aponeurotic arch. It is accompanied by the interosseous branch of the median nerve, and overlapped by the contiguous margins of the Flexor profundus digitorum and Flexor longus pollicis muscles, giving off in this situation *muscular* branches and the *nutrient* arteries of the radius and ulna. At the upper border of the Pronator quadratus a branch, **anterior communicating artery**, descends beneath the muscle to anastomose in front of the carpus with the anterior carpal arch. The continuation of the artery passes behind the Pronator quadratus, and, piercing the interosseous membrane, reaches the back of the forearm, and anastomoses with the posterior interosseous artery (Fig. 465). It then descends to the back of the wrist to join the posterior carpal arch. The anterior interosseous gives off a long, slender branch, the **comes nervi mediana artery** (*a. mediana*), which accompanies the median nerve and gives branches to its substance. This artery is sometimes much enlarged, and accompanies the nerve into the palm of the hand.

The **posterior interosseous artery** (*a. interossea dorsales*) (Figs. 464 and 465) passes backward through the interval between the oblique ligament and the upper border of the interosseous membrane. It appears between the contiguous borders of the Supinator [brevis] and the Extensor ossis metacarpi pollicis, and runs down the back part of the forearm, between the superficial and deep layer of muscles, to both of which it distributes branches (Fig. 465). Where it lies upon the Extensor ossis metacarpi pollicis and the Extensor brevis pollicis, it is accompanied by the posterior interosseous nerve. At the lower part of the forearm it anastomoses with the termination of the anterior interosseous artery and with the posterior carpal arch. Then, continuing its course over the head of the ulna,

it joins the posterior carpal branch of the ulnar artery. This artery gives off, near its origin, the **interosseous recurrent** branch.

The **interosseous recurrent artery** (*a. interossea recurrens*) (Fig. 465) is a large vessel which ascends to the interval between the external condyle and olecranon, on or through the fibres of the Supinator [brevis], but beneath the Anconeus, anastomosing with a branch from the superior profunda, and with the posterior ulnar recurrent and anastomotica magna.

The **muscular branches** (*rami musculares*) are distributed to the muscles along the ulnar side of the forearm.

The **anterior ulnar carpal** (*ramus carpeus volaris*) (Fig. 464) is a small vessel which crosses the front of the carpus beneath the tendons of the Flexor profundus and inosculates with a corresponding branch of the radial artery.

The **posterior ulnar carpal** (*ramus carpeus dorsalis*) (Fig. 465) arises immediately above the pisiform bone, and winds backward beneath the tendon of the Flexor carpi ulnaris; it passes across the dorsal surface of the carpus beneath the Extensor tendons to anastomose with a corresponding branch of the radial artery and complete the **posterior carpal arch** (*rete carpi dorsale*) (Fig. 465). Immediately after its origin it gives off a small branch, which runs along the ulnar side of the fifth metacarpal bone, and supplies the ulnar side of the dorsal surface of the little finger.

The **profunda branch** (*ramus volaris profundus*) (Fig. 464) passes deeply inward between the Abductor minimi digiti and Flexor brevis minimi digiti, near their origins; it anastomoses with the termination of the radial artery, completing the deep palmar arch.

The continuation of the trunk of the ulnar artery in the hand forms the greater part of the superficial palmar arch.

FIG. 465.—Arteries of the back of the forearm and hand.

The **superficial palmar arch** (*arcus volaris superficialis*) (Fig. 462) is formed by the ulnar artery in the hand, and is usually completed on the outer side by a branch from the *radialis indicis*, but sometimes by the *superficialis volae* of the *princeps pollicis* of the radial artery. The arch passes across the palm, describing a curve, with its convexity downward.

Relations.—The superficial palmar arch is covered by the skin, the *Palmaris brevis*, and the palmar fascia. It lies upon the annular ligament, the *Flexor brevis* and *Opponens minimi digiti*, the tendons of the *Flexor sublimis digitorum*, the *Lumbrical* muscles, and the divisions of the median and ulnar nerves.

PLAN OF THE RELATIONS OF THE SUPERFICIAL PALMAR ARCH.

In front.

Skin.

Palmar fascia.

Behind.

Annular ligament.
Flexor brevis minimi digiti.
Opponens minimi digiti.
Tendons of Flexor sublimis digitorum.
Lumbrical muscles.
Branches of median and ulnar nerves.

Branches.—The branches of the Superficial palmar arch are:

Four Digital Arteries.

Four digital arteries (*aa. digitales volares communes*) (Fig. 462) are given off from the convexity of this arch. The innermost accompanies the inner digital branch of the ulnar nerve, and runs along the ulnar side of the little finger; it is joined by a twig from the deep palmar arch or from the innermost palmar interosseous artery. The three outer run downward in front of the three inner interosseous spaces, superficial to the corresponding nerves and *Lumbrical* muscles. A little above the interdigital clefts they are joined by the palmar interosseous arteries, and by the inferior perforating branches of the dorsal interosseous arteries. Each then divides into **collateral digital arteries** (*aa. digitales volares propriae*) for the supply of the contiguous sides of the index, middle, ring, and little fingers. These collateral branches lie behind the corresponding digital nerves; they anastomose freely in the subcutaneous tissue of the finger tip and by smaller branches near the interphalangeal joints. Each supplies a couple of dorsal branches which anastomose with the dorsal digital arteries, and supply the soft parts on the back of the second and third phalanges, including the matrix of the finger nail.

Surface Marking.—The superficial palmar arch is represented by a curved line, starting from the outer side of the pisiform bone and carried downward as far as the middle third of the palm, and then curved outward on a level with the upper end of the cleft between the thumb and index finger. The deep palmar arch is situated about half an inch nearer to the carpus.

Applied Anatomy.—Wounds of the palmar arches are of special interest, and are always difficult to deal with. When the superficial arch is wounded it is generally possible, by enlarging the wound if necessary, to secure the vessel and tie it; or in cases where it is found impossible to

encircle the vessel with a ligature, a pair of hemostatic forceps may be applied and left on for twenty-four or forty-eight hours. Wounds of the deep arch are not so easily dealt with. It may be possible to secure the vessel by ligature or by forcipressure forceps, which may be left on; or, failing in this, the wound may be carefully plugged with gauze and an outside dressing carefully bandaged on. The plug should be allowed to remain untouched for three or four days. In wounds of the deep palmar arch a ligature may be applied to the bleeding points from the dorsum of the hand by resection of the upper part of the third metacarpal bone. It is useless in these cases to ligate one of the arteries of the forearm alone, and, indeed, simultaneous ligation of both radial and ulnar arteries above the wrist is often unsuccessful, on account of the anastomosis carried on by the carpal arches. Therefore, if unable to ligate the divided ends of the arch, upon the failure of pressure to arrest hemorrhage, it is expedient to apply a ligature to the brachial artery.

ARTERIES OF THE TRUNK.

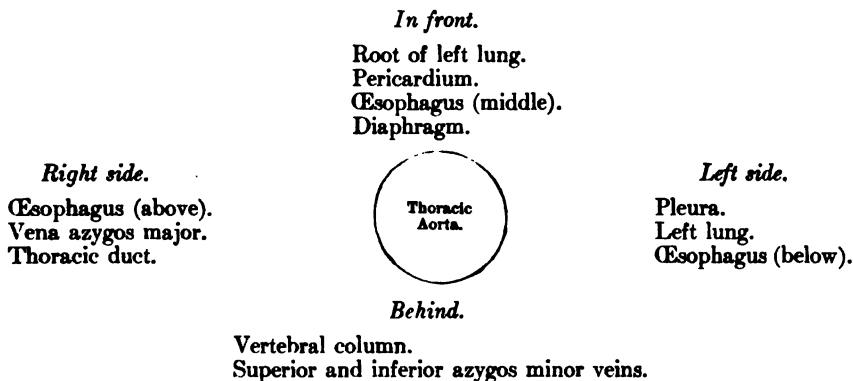

THE DESCENDING AORTA (Figs. 466, 467).

The descending aorta is divided into two portions, the thoracic and abdominal, in correspondence with the two great cavities of the trunk in which it is situated.

The Thoracic Aorta (*aorta thoracalis*) (Fig. 466).—The thoracic aorta is contained in the back part of the posterior mediastinum and commences at the lower border of the fourth thoracic vertebra, on the left side, and terminates at the aortic opening in the Diaphragm, in front of the lower border of the last thoracic vertebra. At its commencement it is situated on the left side of the vertebral column; it approaches the median line as it descends, and at its termination lies directly in front of the vertebral column. The direction of this vessel being influenced by the vertebral column, upon which it rests, it describes a curve which is concave forward in the thoracic region. As the branches given off from it are small, the diminution in the size of the vessel is inconsiderable.

Relations.—It is in relation, *in front*, from above downward, with the root of the left lung, the pericardium, the œsophagus, and the Diaphragm; *behind*, with the vertebral column and the azygos minor veins; on the *right side*, with the vena azygos major and thoracic duct; on the *left side*, with the left pleura and lung. The œsophagus, with its accompanying nerves, lies on the right side of the aorta *above*; but at the lower part of the thorax it passes in front of the aorta, and close to the Diaphragm is situated to its left side.

PLAN OF THE RELATIONS OF THE THORACIC AORTA.

Peculiarities.—The aorta is occasionally found to be obliterated at a particular spot—viz., at the junction of the arch with the thoracic aorta just below the ductus arteriosus. Whether this is the result of disease or of congenital malformation is immaterial to our present purpose; it affords an interesting opportunity of observing the resources of the collateral circulation.

The course of the anastomosing vessels, by which the blood is brought from the upper to the lower part of the artery, will be found well described in an account of two cases in the *Pathological Transactions*, vols. viii and x. In the former (p. 162) Mr. Sydney Jones thus sums up the detailed description of the anastomosing vessels: "The principal communications by which the circulation was carried on were: *First*, the internal mammary, anastomosing with the intercostal arteries, with the phrenic of the abdominal aorta by means of the musculophrenic and comes nervi phrenici, and largely with the deep epigastric. *Secondly*, the superior intercostal, anastomosing anteriorly by means of a large branch with the first aortic intercostal, and posteriorly with the posterior branch of the same artery. *Thirdly*, the inferior thyroid, by means of a branch about the size of an ordinary radial, formed a communication with the first aortic intercostal. *Fourthly*, the transverse cervical, by means of very large communications with the posterior branches of the intercostals. *Fifthly*, the branches (of the subclavian and axillary) going to the side of the thorax were large, and anastomosed freely with the lateral branches of the intercostals." In the second case also (vol. x, p. 97) Mr. Wood describes the anastomoses in a somewhat similar manner, adding the remark that "the blood which was brought into the aorta through the anastomoses of the intercostal arteries appeared to be expended principally in supplying the abdomen and pelvis, while the supply to the lower extremities had passed through the internal mammary and epigastrics."

Applied Anatomy.—The student should now consider the effects likely to be produced by *aneurism of the thoracic aorta*, a disease of common occurrence. When we consider the great depth of the vessel from the surface and the number of important structures which surround it on every side, it may easily be conceived what a variety of obscure symptoms may arise from disease of this part of the arterial system, and how they may be liable to be mistaken for those of other affections. Aneurism of the thoracic aorta most usually extends backward along the left side of the vertebral column, producing absorption of the bodies of the vertebræ, with curvature of the spine; while the irritation or pressure on the spinal cord will give rise to pain, either in the thorax, back, or loins, with radiating pain in the left upper intercostal spaces, from pressure on the intercostal nerves; at the same time the tumor may project backward on each side of the vertebral column, beneath the integument, as a pulsating swelling, simulating abscess connected with diseased bone, or it may displace the œsophagus and compress the lung on one or the other side. If the tumor extend forward, it may press upon and displace the heart, giving rise to palpitation and other symptoms of disease of that organ; or it may displace, or even compress, the œsophagus, causing pain and difficulty of swallowing, as in stricture of that tube; and ultimately even open into it by ulceration, producing fatal hemorrhage. If the disease extends to the right side, it may press upon the thoracic duct; or it may burst into the pleural cavity or into the trachea or lung; and, lastly, it may open into the posterior mediastinum. The diagnosis of thoracic aneurism is facilitated by the use of the x-rays.

Branches of the Thoracic Aorta.—

Visceral	{	Bronchial.	Parietal	{	Intercostal.
		Œsophageal.			Subcostal.
		Pericardial.			Superior phrenic.
		Mediastinal.			

The **bronchial arteries** (*aa. bronchiales*) are the nutrient vessels of the lungs, and vary in number, size, and origin. There is, as a rule, only one *right bronchial artery*, which *arises* from the first aortic intercostal, or from the left bronchial. The *left bronchial arteries*, usually two in number, *arise* from the thoracic aorta, one a little lower than the other. Each vessel runs along the back part of the corresponding bronchus, dividing and subdividing along the bronchial tubes, supplying them, the cellular tissue of the lungs, the bronchial nodes, and the œsophagus.

The **œsophageal arteries** (*aa. œsophageæ*), usually four or five in number, *arise* from the front of the aorta, and pass obliquely downward to the œsophagus, forming a chain of anastomoses along that tube, anastomosing with the œsophageal branches of the inferior thyroid arteries above, and with ascending branches from the phrenic and gastric arteries below.

The **pericardial** (*rami pericardiaci*) are a few small vessels, irregular in their origin, distributed to the pericardium.

The **mediastinal branches** (*rami mediastinales*) are numerous small vessels which supply the nodes and loose areolar tissue in the posterior mediastinum.

The **intercostal arteries** (*aa. intercostales*) (Fig. 466) arise from the back of the aorta. The aortic intercostals are usually nine in number on each side, the two superior intercostal spaces being supplied by the superior intercostal, a branch of the subclavian. The **right** aortic intercostals are longer than the left, on account of the position of the aorta on the left side of the vertebral column; they pass across the bodies of the vertebræ, behind the œsophagus, thoracic duct, and the vena azygos major, and are covered by the *right lung and pleura*. The **left** aortic intercostals run backward on the sides of the vertebræ and are covered by the *left lung and pleura*; the two upper are crossed by the left superior intercostal vein, the lower vessels by the azygos minor veins. Opposite the heads of the ribs the sympathetic cord passes downward in front of them, and the splanchnic nerves also descend in front of the lower arteries. Each artery crosses the corresponding intercostal space obliquely toward the angle of the upper rib and thence is continued forward in the subcostal groove. It is placed at first between the pleura and the posterior intercostal membrane, then pierces this membrane and lies between it and the External intercostal muscle as far as the rib angle; from this onward it runs between the External and Internal intercostal muscles and anastomoses with the anterior intercostal branches of the internal mammary or musculophrenic. Each intercostal artery is accompanied by a vein and nerve, the former being above, and the latter below, except in the upper intercostal spaces, where the nerve is at first above the artery. The first aortic intercostal anastomoses with the superior intercostal branch of the subclavian, and the last two intercostals continue anteriorly from the intercostal spaces into the abdominal wall, anastomosing with the superior epigastric, subcostal and lumbar arteries.

Branches.—Each intercostal artery gives off numerous muscular and cutaneous branches.

Posterior or dorsal.
Muscular.

Collateral intercostal.
Lateral cutaneous.

The **posterior or dorsal branch** (*ramus posterior*) runs with the posterior division of a spinal nerve and passes backward through a small opening which is bounded *above* and *below* by the necks of the ribs and adjacent transverse processes, *internally* by the vertebral body, and *externally* by the anterior costotransverse ligament. It gives off a **spinal branch**, which enters the vertebral canal through the intervertebral foramen, is distributed to the spinal cord and its membranes,

FIG. 466.—Thoracic aorta. (Testut.)

and to the bodies of the vertebræ in the same manner as the lateral spinal branches from the vertebral.

The **collateral intercostal branch** comes off from the intercostal artery near the angle of the rib, and descends to the upper border of the rib below, along which it courses to anastomose with the anterior intercostal branch of the internal mammary.

FIG. 467.—The abdominal aorta and its branches.

Muscular branches (*rami musculares*) are given to the Intercostal and Pectoral muscles and to the Serratus magnus; they anastomose with the superior and long thoracic branches of the axillary artery.

The **lateral cutaneous branches** (*rami cutanei laterales*) accompany the lateral cutaneous branches of the intercostal nerves, and divide into anterior and posterior branches.

Mammary branches are given off by the intercostal arteries in the third, fourth, and fifth spaces. They supply the mammary gland, and increase considerably in size during the period of lactation.

Applied Anatomy.—The position of the intercostal vessels should be borne in mind in performing the operation of *paracentesis thoracis*. The puncture should never be made nearer the middle line posteriorly than the angle of the rib, as the artery crosses the space internal to this point. In the lateral portion of the thorax, where the puncture is usually made, the artery lies at the upper part of the intercostal space, and therefore the puncture should be made just above the upper border of the rib forming the lower boundary of the space.

The Abdominal Aorta (*aorta abdominalis*) (Fig. 467).—The abdominal aorta commences at the aortic opening of the Diaphragm, in front of the lower border of the body of the last thoracic vertebra, and, descending a little to the left side of the vertebral column, terminates on the body of the fourth lumbar vertebra, commonly a little to the left of the middle line,¹ by dividing into the two common iliac arteries. It diminishes rapidly in size, in consequence of the many large branches which it gives off. As it lies upon the bodies of the vertebræ, the curve which it describes is convex forward, the greatest convexity corresponding to the third lumbar vertebra, which is a little above and to the left side of the umbilicus.

Relations.—It is covered, *in front*, by the lesser omentum and stomach, behind which are the branches of the celiac axis and the solar plexus; below these, by the splenic vein, the pancreas, the left renal vein, the transverse portion of the duodenum, the mesentery, and aortic plexus. *Behind*, it is separated from the lumbar vertebræ and intervening disks by the anterior common ligament and left lumbar veins. On the *right side* it is in relation with the inferior vena cava (the right crus of the Diaphragm being interposed above), the vena azygos major, thoracic duct, and right semilunar ganglion; on the *left side*, with the gangliated cord of the sympathetic and left semilunar ganglion.

Vertebral column.

Surface Marking.—In order to map out the abdominal aorta on the surface of the abdomen, a line must be drawn from the middle line of the body, on a level with the costal extremity of the seventh costal cartilage, downward and slightly to the left, so that it just skirts the umbilicus, to a zone drawn around the body opposite the highest point of the crest of the ilium. This point

¹ Lord Lister, having accurately examined 30 bodies in order to ascertain the exact point of termination of this vessel, found it "either absolutely, or almost absolutely, mesal in 15, while in 13 it deviated more or less to the left, and in 2 was slightly to the right" (System of Surgery, edited by T. Holmes, 2d ed., vol. v, p. 652).

is generally half an inch below and to the left of the umbilicus, but as the position of this structure varies with the obesity of the individual, it is not a reliable landmark as to the situation of the bifurcation of the aorta.

Applied Anatomy.—*Aneurisms of the abdominal aorta* near the cœliac axis communicate in nearly equal proportion with the anterior and posterior parts of the artery.

When an aneurismal sac is connected with the back part of the abdominal aorta, it usually produces absorption of the bodies of the vertebræ, and forms a pulsating tumor that presents itself in the left hypochondriac or epigastric regions, and is accompanied by symptoms of disturbance in the alimentary canal. Pain is invariably present, and is usually of two kinds—a fixed and constant pain in the back, caused by the tumor pressing on or displacing the branches of the solar plexus and splanchnic nerves; and a sharp lancinating pain, radiating along those branches of the lumbar nerves which are pressed on by the tumor; hence the pain in the loins, the testes, the hypogastrium, and in the lower limb (usually of the left side). This form of aneurism usually bursts into the peritoneal cavity or behind the peritoneum in the left hypochondriac region; or it may form a large aneurismal sac, extending down as low as Poupart's ligament; hemorrhage in these cases being generally very extensive, but slowly produced, and not rapidly fatal.

When an aneurismal sac is connected with the front of the aorta near the cœliac axis it forms a pulsating tumor in the left hypochondriac or epigastric region, usually attended with symptoms of disturbance of the alimentary canal, as nausea, dyspepsia, or constipation, and is accompanied by pain, which is constant, but nearly always fixed in the loins, epigastrium, or some part of the abdomen; the radiating pain being rare, as the lumbar nerves are seldom implicated. This form of aneurism may burst into the peritoneal cavity or behind the peritoneum, between the layers of the mesentery, or, more rarely, into the duodenum; it seldom extends backward so as to affect the vertebral column.

The abdominal aorta has been tied several times, and although none of the patients permanently recovered, still, as Prof. Keen's lived forty-eight days, the possibility of the reëstablishment of the circulation is proved. In the lower animals this artery has been often successfully tied. The chief difficulty in the dead subject consists in isolating the artery in consequence of its great depth; but in the living the embarrassment resulting from the proximity of the aneurismal tumor, and the great probability of disease in the vessel itself, add to the dangers and difficulties of this formidable operation.

The collateral circulation would be carried on by the anastomosis between the internal mammary and the deep epigastric; by the free communication between the superior and inferior mesenterics if the ligature were placed above the latter vessel; or by the anastomosis between the inferior mesenteric and the internal pudic when (as is more common) the point of ligation is below the origin of the inferior mesenteric; and possibly by the anastomoses of the lumbar arteries with the branches of the internal iliac.

Branches.—The branches of the abdominal aorta may be divided into three sets—visceral, parietal, and terminal.

Visceral Branches.

Cœliac Axis { Gastric:
Hepatic.
Splenic.

Superior mesenteric.

Inferior mesenteric.

Suprarenal.

Renal.

Spermatic or ovarian.

Parietal Branches.

Inferior phrenic.

Lumbar.

Middle sacral.

Terminal Branches.

Common iliac.

The **cœliac axis**, or **artery** (*a. coeliaca*) (Figs. 468 and 469), is a short, thick trunk, about half an inch in length, which *arises* from the aorta, close to the margin of the opening in the Diaphragm, behind the posterior parietal peritoneum, above the pancreas, and below the twelfth thoracic vertebra, and, passing nearly horizontally forward (in the erect posture), divides into three large branches, the **gastric**, **hepatic**, and **splenic**, occasionally giving off one of the phrenic arteries.

Relations.—It is covered by the lesser omentum. On the *right side* it is in relation with the right semilunar ganglion and the Spigelian lobe of the liver; on the *left side*, with the left semilunar ganglion and cardiac end of the stomach. *Below*, it rests upon the upper border of the pancreas.

FIG. 468.—The celiac axis and its branches, the liver having been raised and the lesser omentum removed.

The **gastric or coronary artery** (*a. gastrica sinistra*) (Figs. 468 and 469), the smallest of the three branches of the celiac axis, passes upward and to the left side, behind the peritoneum of the lesser peritoneal cavity. It continues this course until it nearly reaches the lesser curvature of the stomach just below the cardia. It then turns to the front and curves forward, distributing branches to the œsophagus which anastomose with the aortic œsophageal arteries; others supply the cardiac end of the stomach, anastomosing with branches of the splenic artery; it then passes from left to right, along and upon the lesser curvature of the stomach and beneath the peritoneum to the pylorus, lying in its course between the layers of the lesser omentum, and sometimes dividing into two vessels, which run along each side of the lesser curvature. One vascular arch gives branches to the antero-superior wall of the stomach and the other to the postero-inferior wall; at its termination it anastomoses with the pyloric branches of the hepatic. The **œsophageal branches** (*rami œsophagei*) anastomose with the œsophageal branches from the thoracic aorta and the inferior phrenic. Occasionally the gastric artery gives off an hepatic branch of variable size, which is usually distributed to the left lobe of the liver.

The **hepatic artery** (*a. hepatica*) (Figs. 468 and 469) in the adult is intermediate in size between the gastric and splenic; in the fetus it is the largest of the three

branches of the cœliac axis. It runs forward and to the right, to be distributed to the upper margin of the pyloric end of the stomach; in its course it forms the lower boundary of the foramen of Winslow. It then passes upward between the layers of the lesser omentum, and in front of the foramen of Winslow, to the transverse fissure of the liver, where it divides into two branches, right and left, which supply the corresponding lobes of that organ, accompanying the ramifications of the portal vein and hepatic duct. The hepatic artery, in its course along the right border of the lesser omentum, is in relation with the common bile duct and portal vein, the duct lying to the right of the artery and the portal vein behind.

Its branches (Figs. 468 and 469) are:

Pyloric.

Gastroduodenal { Right gastroepiploic.
Superior pancreaticoduodenal.

Cystic.

FIG. 469.—The celiac axis and its branches, the stomach having been raised and the transverse mesocolon removed (semidiagrammatic).

The **pyloric** (*a. gastrica dextra*) arises from the hepatic, above the pylorus, descends between the layers of the lesser omentum to the pyloric end of the stomach, and passes from right to left along its lesser curvature, supplying it with branches and anastomosing with the terminal branches of the gastric artery.

The **gastroduodenal** (*a. gastroduodenalis*) (Fig. 469) is a short but large branch, which descends near the pylorus, behind the first portion of the duodenum, and

divides at the lower border of this viscus into two branches, the **right gastroepiploic** (*a. gastroepiploica dextra*) and the **superior pancreaticoduodenal**. Previous to its division, it gives off two or three small **inferior pyloric branches**, to the pyloric end of the stomach and pancreas.

The **right gastroepiploic** runs from right to left along the greater curvature of the stomach, between the layers of the great omentum, anastomosing about the middle of the lower border of the stomach with the left gastroepiploic from the splenic artery. This vessel gives off numerous branches, some of which ascend to supply both surfaces of the stomach, while others descend to supply the great omentum (*rami epiploici*).

The **superior pancreaticoduodenal** (*a. pancreaticoduodenalis superior*) descends between the contiguous margins of the duodenum and pancreas. It supplies the head of the pancreas by means of the *rami pancreatica*, and the duodenum by means of the *rami duodenalis*, and anastomoses with the inferior pancreaticoduodenal branch of the superior mesenteric artery and with the pancreatic branches of the splenic.

The **cystic artery** (*a. cystica*) (Fig. 468), usually a branch of the right hepatic, passes downward and forward along the cystic duct to the gall-bladder and divides into two branches, one of which ramifies on its free surface beneath the peritoneum, the other between the gall-bladder and the substance of the liver.

The **splenic artery** (*a. lienalis*) (Figs. 468 and 469), in the adult, is the largest of the three branches of the celiac axis, and is remarkable for the extreme tortuosity of its course. It passes horizontally to the left side, behind the peritoneum and along the upper border of the pancreas, accompanied by the splenic vein, which lies below it; it crosses in front of the upper part of the left kidney, and on arriving near the spleen divides into branches, some of which enter the hilum of that organ between the two layers of the lienorenal ligament to be distributed to its structure; some branches, given off along its course, are distributed to the pancreas, while others pass to the greater curvature of the stomach between the two layers of the gastrosplenic omentum. Its **branches** are:

Pancreatic.

Left gastroepiploic.

Vasa brevia.

The **pancreatic branches** (*rami pancreatici*) are numerous small branches derived from the splenic as it runs behind the upper border of the pancreas, supplying its middle and left parts. One of these, larger than the rest, is sometimes given off from the splenic near the left extremity of the pancreas; it runs from left to right near the posterior surface of the gland, following the course of the pancreatic duct, and is called the **pancreatica magna**. These vessels anastomose with the pancreatic branches of the pancreaticoduodenal arteries, derived from the hepatic on the one hand and the superior mesenteric on the other.

The **vasa brevia** (*aa. gastricae breves*) consist of from five to seven small branches, which *arise* either from the end of the splenic artery or from its terminal branches. They pass from left to right, between the layers of the gastrosplenic omentum, are distributed to the greater curvature of the stomach, anastomosing with branches of the gastric and left gastroepiploic arteries.

The **left gastroepiploic** (*a. gastroepiploica sinistra*), the largest branch of the splenic, runs from left to right along but distinctly below the greater curvature of the stomach, between the layers of the great omentum, and anastomoses with the right gastroepiploic. In its course it distributes several ascending branches to both surfaces of the stomach; others descend to supply the greater omentum.

Applied Anatomy.—The operation of *pylorectomy* can be made an almost bloodless procedure by tying the gastric, the pyloric, and the right and left gastroepiploic arteries. "The

gastric is doubly tied about one inch below the cardiac orifice at a point where it joins the lesser curvature and is divided between the ligatures. The superior pyloric is doubly tied and divided. The fingers are passed beneath the pylorus, raising the gastrocolic omentum from the transverse mesocolon, and in this way safe ligation behind the pylorus of the right gastroepiploic artery, or in most cases its parent vessel, the gastroduodenal, is secured. The left gastroepiploic is now tied at an appropriate point, and the necessary amount of gastrocolic omentum doubly tied and cut."¹ Embolism of branches of the splenic artery is not uncommon in heart disease, the embolus coming from the left side of the heart. It is characterized by the occurrence of a sudden sharp pain or "stitch" in the splenic region, with subsequent local enlargement of the spleen from the formation of an infarct in its substance.

The **superior mesenteric artery** (*a. mesenterica superior*) (Figs. 467 and 471) is a vessel of large size which supplies the whole length of the small intestine, except the first part of the duodenum; it also supplies the cecum and the ascending and transverse parts of the colon. It *arises* from the front of the aorta about half an inch below the cœliac axis, and is covered at its origin by the splenic vein and the neck of the pancreas. It passes downward and forward in front of the lower part of the head of the pancreas—processus uncinatus—and the third portion of the duodenum, and descends between the layers of the mesentery to the right iliac fossa, where, considerably diminished in size, it anastomoses with one of its own branches—viz., the ileocolic. In its course it forms an arch, the convexity of which is directed forward and downward to the left side, the concavity backward and upward to the right. It is accompanied by the superior mesenteric vein, and is surrounded by the superior mesenteric plexus of nerves.

Dissection.—In order to expose the superior mesenteric artery raise the great omentum and transverse colon, draw down the small intestines, and cut through the peritoneum where the transverse mesocolon and mesentery join; the artery will then be exposed just as it issues from over the unciform process of the head of the pancreas.

Branches.—Its branches are:

Inferior pancreaticoduodenal.
Vasa intestini tenuis.

Ileocolic.
Right colic.

Middle colic.

The **inferior pancreaticoduodenal** (*a. pancreaticoduodenalis inferior*) is given off from the superior mesenteric, or from its first intestinal branch behind the pancreas. It courses to the right between the head of the pancreas and duodenum, and then ascends to anastomose with the superior pancreaticoduodenal artery. It distributes branches to the head of the pancreas and to the second and third portions of the duodenum.

The **vasa intestini tenuis** (*aa. intestinales*) arise from the convex side of the superior mesenteric artery. They are usually from twelve to fifteen in number, and are distributed to the jejunum (*aa. jejunales*) and ileum (*aa. ileae*). They run parallel with one another between the layers of the mesentery, each vessel dividing into two branches, which unite with similar branches on each side, forming a series of arches the convexities of which are directed toward the intestine. From this first set of arches branches arise, which again unite with similar branches from either side, and thus a second series of arches is formed; and from these latter, a third and a fourth, or even a fifth, series of arches is constituted, diminishing in size the nearer they approach the intestine. From the terminal arches numerous small straight vessels arise which encircle the intestine, upon which they are distributed, ramifying between its coats. Throughout their course small branches are given off to the nodes and other structures between

¹ William J. Mayo, *Annals of Surgery*, March, 1904.

the layers of the mesentery. (See the description of the vascular loops in the section upon the Intestines.)

The **ileocolic artery** (*a. ileocolica*) is the lowest branch given off from the concavity of the superior mesenteric artery. It descends between the layers of the mesentery to the right iliac fossa, where it divides into two branches. Of these, the *inferior division* anastomoses with the termination of the superior mesenteric artery, forming with it an arch, from the convexity of which branches proceed to supply the termination of the ileum, the cecum, the vermiform appendix, and the ileocecal valve. The *superior division* anastomoses with the right colic and supplies the commencement of the colon.

FIG. 470.—Arteries and veins of the cecum and vermiform appendix seen from behind. (Poirier and Charpy.)

The descending branch of the ileocolic runs toward the upper border of the ileocecal junction and gives off the following branches:

(a) **Colic**, which passes upward on the ascending colon; (b) **anterior and posterior cecal** (or *ileocecal*), which are distributed to the front and back of the cecum; (c) **appendicular** (*a. appendicularis*), which passes downward behind the terminal part of the ileum and runs in the mesoappendix close to its free margin for the supply of the appendix; and (d) **ileal**, which runs upward and to the left on the terminal part of the ileum and anastomoses with the termination of the superior mesenteric (Fig. 470).

The **right colic artery** (*a. colica dextra*) arises from about the middle of the concavity of the superior mesenteric artery; it passes to the right behind the peritoneum to the middle of the ascending colon, and divides into two branches—a **descending branch**, which anastomoses with the ileocolic, and an **ascending branch**, which anastomoses with the middle colic. These branches form arches, from the convexity of which vessels are distributed to the ascending colon.

The **middle colic artery** (*a. colica media*) arises from the upper part of the concavity of the superior mesenteric, and, passing downward and forward between the layers of the transverse mesocolon, divides into two branches, the one on the right side anastomosing with the right colic; that on the left side, with the left colic, a branch of the inferior mesenteric. From the arches formed by their anastomosis branches are distributed to the transverse colon. The branches of this vessel lie between the two layers of the transverse mesocolon.

The **inferior mesenteric artery** (*a. mesenterica inferior*) (Figs. 467 and 472) supplies the descending colon, the sigmoid flexure of the colon, and the greater part of the rectum. It is smaller than the superior mesenteric, and *arises* from the front and toward the left side of the aorta, between one and two inches above the division of that vessel into the common iliacs. It passes downward to the left iliac fossa, and then descends between the layers of the mesorectum, into the pelvis, under the name of the **superior hemorrhoidal artery**. It lies at first in close relation with the left side of the aorta, and then passes as the superior hemorrhoidal in front of the left common iliac artery.

FIG. 471.—The superior mesenteric artery and its branches.

Dissection.—In order to expose the inferior mesenteric artery draw the small intestines and mesentery over to the right side of the abdomen, raise the transverse colon toward the thorax, and divide the peritoneum covering the front of the aorta.

Branches.—Its branches are:

Left colic.

Superior hemorrhoidal.

Sigmoid.

The **left colic artery** (*a. colica sinistra*) passes behind the peritoneum, in front of the left kidney, to reach the descending colon; it divides into an ascending

branch which anastomoses with the middle colic, and a descending branch which anastomoses with the upper sigmoid artery. From the arches formed by these anastomoses, branches are distributed to the descending colon.

The **sigmoid arteries** (*aa. sigmoideae*) run obliquely downward and outward behind the peritoneum across the Psoas muscle to the sigmoid flexure of the colon. They divide into branches which supply the lower part of the descending colon and the sigmoid flexure, anastomosing above with the left colic, and below with the superior hemorrhoidal artery.

FIG. 472.—The inferior mesenteric and its branches.

The **superior hemorrhoidal artery** (*a. haemorrhoidalis superior*) (Figs. 472 and 473), the continuation of the inferior mesenteric, descends into the pelvis between the layers of the mesorectum, crossing, in its course, the left ureter and left common iliac vessels. Opposite the middle of the sacrum it divides into two branches, which descend one on either side of the rectum, and about five inches from the anus break up into several small branches, which pierce the muscular coat of the bowel and run downward, as straight vessels, placed at regular intervals from each other in the wall of the intestine between its muscular and mucous coat, to the level of the Internal sphincter; here they form a series of loops around the lower end of the rectum, and communicate with the middle hemorrhoidal arteries, which are branches of the internal iliac, and with the inferior hemorrhoidal branches of the internal pudic.

The **suprarenal artery** (*a. suprarenalis media*) (Fig. 467), or **capsular artery**, arises, one from each side of the aorta, opposite the superior mesenteric artery. It is a small vessel which passes obliquely upward and outward, over the corresponding crus of the Diaphragm, to the under surface of the suprarenal gland, to which it is distributed, anastomosing with capsular branches from the phrenic and renal arteries. In the adult these arteries are of small size; in the fetus they are as large as the renal arteries.

The **renal arteries** (*aa. renales*) (Fig. 467) are two large trunks which arise from the sides of the aorta immediately below the superior mesenteric artery. Each is directed outward across the corresponding crus of the Diaphragm, so as to form nearly a right angle with the aorta. The right is longer than the left, on account of the position of the aorta; it passes behind the inferior vena cava. The left is somewhat higher than the right. Before reaching the hilum of the kidney, each artery usually divides into four branches. Two of these vessels enter the anterior portion and two the posterior portion of the kidney. There may be but one renal artery; there may be two, three, four, or five branches. The greater number of the branches generally lie between the renal vein and ureter, the vein being in front of the arteries, the ureter behind. The anterior branches supply three-fourths of the kidney, the posterior supply one-fourth. Each vessel gives off a small branch to the suprarenal gland (*a. suprarenalis inferior*) and branches to the ureter, **ureteral branches**, and to the surrounding cellular tissue and muscles, **perirenal branches**. Hyrtl, in 1870, pointed out that the renal artery gives off a branch which divides and supplies the dorsal or posterior portion of the kidney and ureteral pelvis, and a branch which divides and supplies the ventral or anterior portion of the kidney and the pelvis. The two circulations are distinct and do not anastomose even at the periphery. Between these two sets of vessels is a nearly bloodless zone, the **exsanguinated renal zone of Hyrtl**, which does not correspond to the lateral border, but is one-half inch dorsal to the lateral longitudinal renal border. The ventral or anterior segment is much the larger. In very rare instances the bloodless zone corresponds to the lateral border (Kümmel). An incision of the middle third of the kidney exactly at the junction of the two segments does not divide large vessels. As the incision approaches either pole there is danger of cutting a large branch (Schede). Frequently there is a second renal artery, which is given off from the abdominal aorta either above or below the renal artery proper, the former being the more common position. Instead of entering the kidney at the hilum, an accessory renal artery often pierces the upper or the lower part of the gland.

The **spermatic arteries** (*aa. spermaticae internae*) (Fig. 467) are distributed to the testes. They are two slender vessels of considerable length, which arise from the front of the aorta a little below the renal arteries. Each artery passes obliquely outward and downward behind the peritoneum, resting on the Psoas muscle, the right spermatic lying in front of the inferior vena cava, the left behind the sigmoid flexure of the colon. It then crosses obliquely over the ureter (to which it sends a few branches) and the lower part of the external iliac artery to reach the internal abdominal ring, through which it passes, and accompanies the other constituents of the spermatic cord along the inguinal canal to the scrotum, where it becomes tortuous and divides into several branches. Two or three of these accompany the vas deferens, anastomosing with the artery of the vas deferens, and are distributed to the epididymis; others pierce the back part of the tunica albuginea and supply the substance of the testis. The spermatic artery in the inguinal canal gives off **cremasteric branches** to supply the Cremaster muscle. In the canal and scrotum the artery lies behind the pampiniform plexus and in front of the vas deferens.

The **ovarian arteries** (*aa. ovaricae*) (Fig. 474) in the female correspond to the spermatic arteries in the male. They supply the ovaries, and are shorter than the spermatic. The origin and course of the first part of each artery are the same as the spermatic in the male, but on arriving at the margin of the pelvis the ovarian artery passes inward, between the two layers of the broad ligament of the uterus, to be distributed to the ovary. Small branches go to the Fallopian tube, the ureter, and the broad ligament; and one passes on to the side of the uterus and anastomoses with the uterine artery. Other offsets are continued along the round ligament through the inguinal canal, to the integument of the labium and groin.

At an early period of fetal life, when the testes or ovaries lie at the side of the vertebral column below the kidneys, the spermatic or ovarian arteries are short; but as these organs descend from the abdomen into the scrotum or pelvis, the arteries gradually become lengthened.

The **inferior phrenic arteries** (*aa. phrenicae inferiores*) (Fig. 467) are two small vessels which present much variety in their origin. They may *arise* separately from the front of the aorta, immediately above the celiac axis, or by a common trunk, which may spring either from the aorta or from the celiac axis. Sometimes one is derived from the aorta, and the other from one of the renal arteries. In only one out of thirty-six cases examined did these arteries arise as two separate vessels from the aorta. They diverge from one another across the crura of the Diaphragm, and then pass obliquely upward and outward upon the under surface of the Diaphragm. The **left phrenic** passes behind the œsophagus and runs forward on the left side of the œsophageal opening. The **right phrenic** passes behind the inferior vena cava, and ascends along the right side of the aperture for transmitting that vein. Near the back part of the central tendon each vessel divides into two branches. The **internal branch** runs forward to the front of the thorax, supplying the Diaphragm, and anastomosing with its fellow of the opposite side, and with the musculophrenic and comes nervi phrenici branches of the internal mammary. The **external branch** passes toward the side of the thorax and anastomoses with the intercostal arteries and with the musculophrenic. The internal branch of the right phrenic gives off a few vessels to the inferior vena cava, and the left one some branches to the œsophagus. Each vessel also sends **glandular branches** (*rami suprarenales superior*) to the suprarenal glands of its own side. The spleen and the liver also receive a few branches from the left and right vessels respectively.

The **lumbar arteries** (*aa. lumbales*) are in series with the intercostals. They are usually four in number on either side, and *arise* from the back part of the aorta opposite the bodies of the upper four lumbar vertebræ. A fifth pair, small in size, is occasionally present; it *arises* from the middle sacral artery. They run outward and backward on the bodies of the lumbar vertebræ, behind the sympathetic cord, to the intervals between the adjacent transverse processes, and are then continued into the abdominal wall. The arteries of the right side pass behind the inferior vena cava, and the upper two on each side run behind the corresponding crus of the Diaphragm. The arteries of both sides pass beneath the tendinous arches which give origin to the Psoas magnus, and are then continued behind this muscle and the lumbar plexus. They now cross the Quadratus lumborum, the upper three arteries running behind, the last usually in front of the muscle. At the outer border of the Quadratus lumborum they pierce the posterior aponeurosis of the Transversalis abdominis and are carried forward between this muscle and the Internal oblique. They anastomose with the lower intercostals, the subcostal, the iliolumbar, the deep circumflex iliac, and the deep epigastric arteries.

Branches.—In the interval between the adjacent transverse processes each lumbar artery gives off a **dorsal branch** (*ramus dorsalis*), which is continued backward between the transverse processes and is distributed to the muscles and skin

of the back. It gives off a **spinal branch** (*ramus spinalis*) which enters the vertebral canal and is distributed in a similar manner to the lateral spinal branches of the vertebral (page 622). **Muscular branches** are supplied from each lumbar artery and from its dorsal branch to the neighboring muscles.

The **middle sacral artery** (*a. sacralis media*) (Fig. 473) is a small vessel, which *arises* from the back part of the aorta just at its bifurcation. It descends upon the last lumbar vertebra, and along the middle line of the front of the sacrum, to the upper part of the coccyx, where it anastomoses with the lateral sacral arteries, and terminates in the coccygeal body. From it minute branches arise which run through the mesorectum to supply the posterior surface of the rectum. Other branches are given off on each side, which anastomose with the lateral sacral arteries, and send branches into the anterior sacral foramina. It is crossed by the left common iliac vein, and is accompanied by a pair of *venae comites*; these unite to form a single vessel which opens into the left common iliac vein.

This artery and its lateral branches probably represent fused segmental arteries (see page 766).

THE COMMON ILIAC ARTERIES (AA. ILIACAE COMMUNES) (Figs. 467, 473).

The **abdominal aorta** divides on the left side of the body of the fourth lumbar vertebra into the two **common iliac arteries**. Each is about two inches in length. They diverge from the termination of the aorta, pass downward and outward to the margin of the pelvis, and divide, opposite the intervertebral disk, between the last lumbar vertebra and the sacrum, into two branches, the **internal** and **external iliac arteries**, the *latter* supplying the lower extremity; the *former*, the viscera and parietes of the pelvis.

The **right common iliac** is somewhat longer than the left, and passes more obliquely across the body of the last lumbar vertebra. In *front* of it are the peritoneum, the small intestines, branches of the sympathetic cord, and, at its point of division, the ureter. *Behind*, it is separated from the bodies of the fourth and fifth lumbar vertebrae, and the intervening intervertebral disk, by the two common iliac veins. On its *outer side*, it is in relation above with the inferior vena cava and the right common iliac vein; and *below*, with the Psoas magnus muscle. On its *inner side*, above, is the left common iliac vein.

The **left common iliac** is in relation, *in front*, with the peritoneum, small intestines, branches of the sympathetic cord, and the superior hemorrhoidal artery; and is crossed at its point of bifurcation by the ureter. It rests on the bodies of the fourth and fifth lumbar vertebrae, with the intervening disk. The left common iliac vein lies partly on the *inner side*, and partly behind the corresponding artery; on its *outer side*, the artery is in relation with the Psoas magnus muscle.

PLAN OF THE RELATIONS OF THE COMMON ILIAC ARTERIES.

Branches.—The common iliac arteries give off small branches to the peritoneum, Psoas magnus, ureters, and the surrounding cellular tissue, and occasionally give origin to the iliolumbar or to the accessory renal arteries.

Peculiarities.—The *point of origin* varies according to the bifurcation of the aorta. In three-fourths of a large number of cases the aorta bifurcated either upon the fourth lumbar vertebra or upon the intervertebral disk between it and the fifth, the bifurcation being, in one case out of nine below, and in one out of eleven above, this point. In ten out of every thirteen cases the vessel bifurcated within half an inch above or below the level of the crest of the ilium, more frequently below than above.

The *point of division* is subject to great variety. In two-thirds of a large number of cases it was between the last lumbar vertebra and the upper border of the sacrum, being above that point in one case out of eight and below it in one case out of six. The left common iliac artery divides lower down more frequently than the right.

The *relative lengths*, also, of the two common iliac arteries vary. The right common iliac was the longer in sixty-three cases, the left in fifty-two, while they were both equal in fifty-three. The length of the arteries varied in five-sevenths of the cases examined from an inch and a half to three inches; in about half of the remaining cases the artery was longer and in the other half shorter, the minimum length being less than half an inch, the maximum four and a half inches. In two instances the right common iliac has been found wanting, the external and internal iliacs arising directly from the aorta.

Surface Marking.—Draw a line between the highest points of the iliac crests; this is usually half an inch below the umbilicus; in this line take a point half an inch to the left of the middle line. From this draw two lines to points midway between the anterior superior spines of the ilium and the symphysis pubis. These two diverging lines will represent the course of the common and external iliac arteries. Draw a second line corresponding to the level of the anterior superior spines of the ilium; the portion of the diverging lines between these two levels will represent the course of the common iliac artery; the portion below the lower zone, that of the external iliac artery.

Applied Anatomy.—The application of a ligature to the common iliac artery may be required on account of aneurism or hemorrhage implicating the external or internal iliacs. The abdomen is opened by an incision in either the semilunar line or the linea alba; the intestines are drawn to one side and the peritoneum covering the artery divided. The sheath is then opened, and the needle passed from within outward. On the right side great care must be exercised in passing the needle, since both the common iliac veins lie behind the artery. After the vessel has been tied the incision in the peritoneum over the artery should be sutured. In amputation of the hip-joint the common iliac can be compressed most certainly and safely by opening the abdomen and compressing the vessel by means of the fingers against the Psoas muscle (McBurney's method).

Collateral Circulation.—The principal agents in carrying on the collateral circulation after the application of a ligature to the common iliac are the anastomoses of the hemorrhoidal branches of the internal iliac with the superior hemorrhoidal from the inferior mesenteric; the anastomoses of the uterine and ovarian arteries and of the vesical arteries of opposite sides; of the lateral sacral with the middle sacral artery; of the epigastric with the internal mammary inferior intercostal, and lumbar arteries; of the circumflex iliac with the lumbar arteries; of the iliolumbar with the last lumbar artery; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the deep epigastric.

The Internal Iliac Artery (Figs. 467, 473).

The **internal iliac** or **hypogastric artery** (*a. hypogastrica*) supplies the walls and viscera of the pelvis, the buttock, the generative organs, and inner side of the thigh. It is a short thick vessel, smaller in the adult than the external iliac, and about an inch and a half in length. It *arises* at the bifurcation of the common iliac, opposite the lumbosacral articulation, and, passing downward to the upper margin of the great sacrosacral foramen, divides into two large trunks, an **anterior** and a **posterior**. From its anterior division a partially impervious cord, a part of the **fetal hypogastric artery**, extends forward to the bladder.

Relations.—*In front*, with the ureter, which is between the artery and the peritoneum. *Behind*, with the internal iliac vein, the lumbosacral cord, and Piriformis muscle. On its *outer side*, near its origin with the external iliac vein, which lies between it and the Psoas magnus muscle; lower down, with the obturator nerve.

PLAN OF THE RELATIONS OF THE INTERNAL ILIAC ARTERY.

In front.
Peritoneum.
Ureter.

Outer side.
Psoas magnus.

Behind.
Internal iliac vein.
Lumbosacral cord.
Pyriformis muscle.

FIG. 473.—Arteries of the pelvis.

In the fetus the hypogastric artery is twice as large as the external iliac, and appears to be the continuation of the common iliac. Instead of dipping into the pelvis, it passes forward to the bladder, and ascends along the sides of that viscus to its summit, to which it gives branches; it then passes upward along the back part of the anterior wall of the abdomen to the umbilicus, converging toward its fellow of the opposite side. Having passed through the umbilical opening,

the two arteries, now termed **umbilical**, enter the umbilical cord, where they are coiled around the umbilical vein and ultimately ramify in the placenta.

At birth, when the placental circulation ceases, the portion of the hypogastric artery which extends from the summit of the bladder to the umbilicus, contracts, and ultimately dwindles to a solid fibrous cord, the **impervious hypogastric artery** (*lig. umbilicale laterale*), but the lower portion, extending from its origin (in what is now the internal iliac artery) for about an inch and a half to the wall of the bladder, and thence to the summit of that organ, is not totally impervious, though it becomes considerably reduced in size, and serves to convey blood to the bladder under the name of the **superior vesical artery**.

Peculiarities as Regards Length.—In two-thirds of a large number of cases the length of the internal iliac varied between an inch and an inch and a half; in the remaining third it was more frequently longer than shorter, the maximum length being three inches, the minimum half an inch.

The lengths of the common and internal iliac arteries bear an inverse proportion to each other, the internal iliac artery being long when the common iliac is short, and *vice versa*.

As Regards its Place of Division.—The place of division of the internal iliac varies between the upper margin of the sacrum and the upper border of the sacrosciatic foramen.

The arteries of the two sides in a series of cases often differed in length, but neither seemed constantly to exceed the other.

Applied Anatomy.—The application of a ligature to the internal iliac artery may be required in cases of aneurism or hemorrhage affecting one of its branches. The best method of tying the internal iliac artery is by an abdominal section in the median line and reaching the vessel through the peritoneal cavity. This plan has been advocated by Dennis, of New York, on the following grounds: (1) It in no way increases the danger of the operation; (2) it prevents a series of accidents which have occurred during ligature of the artery by the older methods; (3) it enables the surgeon to ascertain the exact extent of disease in the main arterial trunk, and select his spot for the application of the ligature; and (4) it occupies much less time.

Collateral Circulation.—The circulation after ligature of the internal iliac artery¹ is carried on by the anastomoses of the uterine and ovarian arteries; of the opposite vesical arteries; of the hemorrhoidal branches of the internal iliac with those from the inferior mesenteric; of the obturator artery, by means of its pubic branch, with the vessel of the opposite side and with the epigastric and internal circumflex; of the circumflex and perforating branches of the profunda femoris with the sciatic; of the gluteal with the posterior branches of the sacral arteries; of the ilio-lumbar with the last lumbar; of the lateral sacral with the middle sacral; and of the circumflex iliac with the ilio-lumbar and gluteal.

Branches (Fig. 473).—The branches of the internal iliac are:

From the Anterior Trunk.

Superior vesical.
Middle vesical.
Inferior vesical.
Middle hemorrhoidal.
Obturator.
Internal pudic.
Sciatic.
Uterine }
Vaginal } *In the female.*

From the Posterior Trunk.

Ilio-lumbar.
Lateral sacral.
Gluteal.

The **superior vesical** (*a. vesicalis superior*) (Fig. 473) is the terminal part of the previous portion of the fetal hypogastric artery. It extends to the side of the bladder, distributing numerous branches to the apex and body of the organ. From one of these a slender vessel is derived which accompanies the vas deferens in its course to the testis, where it anastomoses with the spermatic artery. This is the **artery of the vas deferens**. Other branches supply the ureter.

¹ For a description of a case in which Owen made a dissection ten years after ligature of the internal iliac artery, see *Medico-Chirurgical Transactions*, vol. xvi.

The **middle vesical** (*a. vesicalis medialis*) (Fig. 473), usually a branch of the superior, is distributed to the base of the bladder and under surface of the seminal vesicles.

The **inferior vesical** (*a. vesicalis inferior*) (Fig. 473) frequently *arises* in common with the middle hemorrhoidal, and is distributed to the base of the bladder, the prostate gland, and seminal vesicles. The branches distributed to the prostate communicate with the corresponding vessel of the opposite side.

The **middle hemorrhoidal artery** (*a. hemorrhoidalis media*) (Fig. 473) usually *arises* together with the preceding vessel. It is distributed to the rectum, anastomosing with the superior and inferior hemorrhoidal arteries. It gives branches to the seminal vesicle and prostate gland.

FIG. 474.—The arteries of the internal organs of generation of the female, seen from behind. (After Hyrtl.)

The **uterine artery** (*a. uterina*) (Fig. 474) *arises* from the anterior division of the internal iliac and runs inward on the Levator ani to the neck of the uterus. About three-quarters of an inch from the cervix it crosses the front of the ureter, to which it supplies a small branch. Ascending in a tortuous course on the side of the uterus, between the layers of the broad ligament, it distributes branches to its substance and to the round ligament and the Fallopian tube (*ramus tubarius*), anastomosing near its termination with the ovarian artery. It gives a branch to the ovary (*ramus ovarii*), which anastomoses with a branch from the ovarian branches to the cervix of the uterus, **cervicouterine**, and a branch which descends on the vagina, the **cervicovaginal**, and, joining with branches from the vaginal arteries, form a median longitudinal vessel both in front and behind; these descend on the anterior and posterior surfaces of the vagina, and are named the **azygos arteries of the vagina**.

The **vaginal artery** (*a. vaginalis*) usually corresponds to the inferior vesical in the male; it descends upon the vagina, supplying its mucous membrane, and sends branches to the bulb of the vestibule, the neck of the bladder, and the contiguous

part of the rectum. It assists in forming the *azygos arteries* of the vagina, which are anterior and posterior vessels, running longitudinally, and due to anastomoses of the branches of the vaginal from each side and the cervicovaginal artery. The vaginal artery is frequently represented by two or three branches.

Luschka, Hyrtl, Waldeyer, Robinson, and others, instead of describing the ovarian and uterine arteries as two distinct vessels, regard them as constituting the chief parts of one vessel, the *arteria uterina ovarica*. What has been called "the circle of Robinson" is composed of a spiral segment (the *arteria uterina ovarica*), with a portion of the abdominal aorta, common iliacs, and internal iliacs.

Robinson¹ has made a careful study of this vascular circle; he shows that it is of great importance in certain surgical procedures, and that its remarkable "capacity for extension" saves it from damage when the uterus is enormously distended by pregnancy, or when it is "drawn through the pudendum with traction forceps for palpation, inspection, or repair."

The author just quoted says further that the utero-ovarian artery has three origins, because it develops from the Wolffian body: The *ovarian segment arises* from the abdominal aorta. The *uterine segment arises* from the anterior branch of the internal iliac artery. The *artery of the round ligament arises* from the deep epigastric. The *arteria uterina ovarica* secures nutrition to the uterus by bringing blood from three sources. It is spiral throughout its entire course, in certain parts is convoluted or looped, and it is accompanied by the pampiniform plexus of veins.

The three origins of this vessel are freely united by anastomoses, and rami laterales are given off, which unite the bilateral vessels in the median line. Robinson describes three bifurcations of the utero-ovarian artery. The *distal bifurcation*, which is "about midway between the uterus and the pelvic wall," forms an acute angle with the main vessel. This bifurcation indicates the point of division of the external from the internal genitals. The cervicovaginal artery supplies the external genitals. The *proximal bifurcation* marks the situation of the ovary. The artery bifurcates at an acute angle into two branches to supply the ovary and Fallopian tube. The *middle bifurcation* consists of (1) the division of the uterine segment at the angle formed by the uterus and oviduct ("forming the *ramus oviductus* and *ramus ovarii*"), and (2) "the bifurcation of the *ramus oviductus* forming the *ramus oviductus* and the *ramus ligamenti teretis*, or the segment of the round ligament."

Applied Anatomy.—As pointed out by Robinson, the source of bleeding after vaginal hysterectomy is usually the torn and unclamped cervicovaginal artery.

As previously pointed out, the spiral and convoluted course of the utero-ovarian artery allows the uterus, ovary, and tube to be drawn into the vagina without injury to the vessels. Robinson points out that in vaginal hysterectomy the genital circle is not divided and only the rami laterales which go to the uterus are cut, the ovaries retaining a normal blood supply and continuing to functionate.

The *obturator artery* (*a. obturatoria*) (Fig. 473) passes forward and downward on the lateral wall of the pelvis, to the upper part of the obturator foramen, and, escaping from the pelvic cavity through a short canal, formed by a groove on the under surface of the ascending ramus of the os pubis and the arched border of the obturator membrane, it divides into an *internal* and *external branch*. In the pelvic cavity this vessel is in relation, *externally*, with the obturator fascia; *internally*, with the ureter, vas deferens, and peritoneum; while a little below it is the obturator nerve.

Branches.—*Within the pelvis*, the obturator artery gives off an *iliac branch* (*ramus iliacus*) to the iliac fossa, which supplies the bone and the Iliacus muscle, and anastomoses with the iliolumbar artery; a *vesical branch* (*ramus vesicalis*), which runs backward to supply the bladder; and a *pubic branch* (*ramus pubicus*), which is given off from the vessel just before it leaves the pelvic cavity. The pubic branch ascends upon the back of the pubis, communicating with offshoots from the deep epigastric artery and with the corresponding vessel of the opposite side; it is sometimes placed on the inner side of the femoral ring.

Outside the pelvis, the obturator artery divides into an internal and an external branch, which are deeply situated beneath the Obturator externus.

¹ F. Byron Robinson. The Utero-ovarian Artery, or the Genital Vascular Circle, 1903.

² Ibid.

The **internal branch** (*ramus anterior*) curves downward along the inner margin of the obturator foramen, lying beneath the Obturator externus muscle; it distributes branches to the Obturator externus, Pectineus, Adductors and Gracilis, and anastomoses with the external branch, and with the internal circumflex artery.

The **external branch** (*ramus posterior*) curves around the outer margin of the obturator foramen, also lying beneath the Obturator externus muscle, to the space between the Gemellus inferior and Quadratus femoris, where it divides into two branches. One, the smaller, courses inward around the lower margin of the foramen and anastomoses with the internal branch and with the internal circumflex; the other inclines outward in the groove below the acetabulum (*a. acetabulis*), and supplies the muscles attached to the tuberosity of the ischium and anastomoses with the sciatic artery. It sends through the cotyloid notch a branch to the hip-joint, which ramifies on the round ligament as far as the head of the femur.

Peculiarities (Fig. 475).—The obturator artery sometimes arises from the main stem or from the posterior trunk of the internal iliac, from the deep epigastric (28 per cent.), or it may arise from the external iliac (1.2 per cent.).

FIG. 475.—Variations in origin and course of the obturator artery.

When the obturator artery arises at the front of the pelvis from the deep epigastric, it descends almost vertically to the upper part of the obturator foramen. The artery in this course usually lies in contact with the external iliac vein and on the outer side of the femoral ring (Fig. 475, A); in such cases it would not be endangered in the operation for femoral hernia. Occasionally, however, it curves inward along the free margin of Gimbernat's ligament (Fig. 475, B), and under such circumstances would almost completely encircle the neck of the hernial sac, and would be in great danger of being wounded if an operation were performed for strangulation.

The **internal pudic artery** (*a. pudenda interna*) (Figs. 476 and 477) is the smaller of the two terminal branches of the anterior trunk of the internal iliac, and supplies the external organs of generation. Though the course of the artery is the same in the two sexes, the vessel is much smaller in the female than in the male, and the distribution of its branches somewhat different. The description of its arrangement in the male will first be given, and subsequently the differences which it presents in the female will be mentioned.

The **internal pudic artery in the male** passes downward and outward to the lower border of the great sacrosclatic foramen, and emerges from the pelvis between the Piriformis and Coccygeus muscles; it then crosses the spine of the ischium and enters the pelvis through the lesser sacrosclatic foramen. The artery now crosses the Obturator internus muscle along the outer wall of the ischio-rectal fossa, being situated about an inch and a half above the lower margin of the ischial tuberosity. It gradually approaches the margin of the ramus of the ischium, passes forward between the two layers of the triangular ligament of the perineum; it then runs forward along the inner margin of the ramus of the pubis and about half an inch behind the subpubic ligament it pierces the superficial layer of the triangular ligament and divides into its two terminal branches, the dorsal artery of the penis and the artery of the corpus cavernosum.

Relations.—Within the pelvis, it lies in front of the Piriformis muscle and sacral plexus of nerves, and the sciatic artery, and on the outer side of the rectum (on the left side). As it crosses the spine of the ischium it is covered by the Gluteus maximus and overlapped by the great sacrosciatic ligament. Here the pudic nerve lies to the inner side and the nerve to the Obturator internus to the outer side of the vessel. In the pelvis it lies on the outer side of the ischiorectal fossa, upon the surface of the Obturator internus muscle, contained in a fibrous canal (**Alcock's canal**), formed by the splitting of the obturator fascia. It is accompanied by the pudic veins and the pudic nerve.

Peculiarities.—The internal pudic is sometimes smaller than usual, or fails to give off one or two of its usual branches; in such cases the deficiency is supplied by branches derived from an additional vessel, the **accessory pudic**, which generally arises from the internal pudic artery before its exit from the great sacrosciatic foramen. It passes forward along the lower part of the bladder and across the side of the prostate gland to the root of the penis, where it perforates the triangular ligament and gives off the branches usually derived from the pudic artery. The deficiency most frequently met with is that in which the internal pudic ends as the artery of the bulb, the artery of the corpus cavernosum and dorsal artery of the penis being derived from the accessory pudic. Or the pudic may terminate as the superficial perineal, the artery of the bulb being derived, with the other two branches, from the accessory vessel. Occasionally the accessory pudic artery is derived from one of the other branches of the internal iliac, most frequently the inferior vesical or the obturator.

Branches.—The branches of the internal pudic artery are:

Muscular.	Artery of the bulb.
Inferior hemorrhoidal.	Urethral artery.
Superficial perineal.	Artery of the corpus cavernosum.
Transverse perineal.	Dorsal artery of the penis.

The **muscular branches** consist of two sets—one given off in the pelvis, the other as the vessel crosses the ischial spine. The former are several small offshoots which supply the Levator ani, the Obturator internus, the Piriformis, and the Coccygeus muscles. The branches given off outside the pelvis are distributed to the adjacent part of the Gluteus maximus and External rotator muscles. They anastomose with branches of the sciatic artery.

The **inferior hemorrhoidal artery** (*a. haemorrhoidalis inferior*) arises from the internal pudic as it passes above the tuberosity of the ischium. Crossing the ischiorectal fossa it is distributed by two or three terminal branches to the muscles and integument of the anal region. Instead of one inferior hemorrhoidal artery two or three small vessels may arise from the internal pudic.

The **superficial perineal artery** (*a. perinei*) (Fig. 476) supplies the scrotum and the muscles and integument of the perineum. It arises from the internal pudic in front of the preceding branches, and turns upward, crossing either over or under the Transversus perinei superficialis muscle, and runs forward, parallel to the pubic arch, in the interspace between the Accelerator urinae (*m. bulbocavernosus*) and Erector penis (*m. ischiocavernosus*) muscles, both of which it supplies, and is finally distributed to the skin and dartos of the scrotum. In its passage through the perineum it lies beneath the superficial perineal fascia.

The **transverse perineal artery** is a small branch which arises either from the internal pudic or from the superficial perineal artery as it crosses the Transversus perinei muscle. It runs transversely inward along the cutaneous surface of the Transversus perinei superficialis muscle and anastomoses with the like vessel of the opposite side, and with the superficial perineal and inferior hemorrhoidal arteries. It supplies the Transversus perinei and the structures between the anus and bulb of the urethra.

The **artery of the bulb** (*a. bulbi urethrae*) is a short vessel of large caliber which arises from the internal pudic between the two layers of the triangular ligament; it passes nearly transversely inward, through the fibres of the Compressor urethrae muscle, pierces the superficial layer of the triangular ligament, and gives off

branches which ramify in the bulb of the urethra. It is then continued forward in the corpus spongiosum to the glans penis. It gives off a small branch to Cowper's gland.

The **urethral artery** (*a. urethralis*) is a small vessel which passes to the corpus spongiosum at the angle of the converging crura of the penis. It reaches the glans penis and anastomoses with the artery of the corpus cavernosum and the dorsal artery of the penis. This vessel is quite often absent.

The **artery of the corpus cavernosum** (*a. profunda penis*), one of the terminal branches of the internal pudic, arises just after that vessel has perforated the superficial triangular ligament, and, quickly entering the crus penis obliquely, runs forward in the centre of the corpus cavernosum, to which its branches are distributed.

FIG. 476.—The superficial muscles and vessels of the perineum.

The **dorsal artery of the penis** (*a. dorsalis penis*) ascends between the crus and pubic symphysis, and passes between the two layers of the suspensory ligament of the penis, and runs forward on the dorsum of the penis to the glans, where it divides into two branches which supply the glans and prepuce. On the dorsum of the penis it lies immediately beneath the integument, between the dorsal nerve and the deep dorsal vein, the former being on its outer side. It supplies the integument and fibrous sheath of the corpus cavernosum, sending branches through the sheath to anastomose with the preceding vessel.

The **internal pudic artery in the female** is smaller than in the male. Its origin and course are similar, and there is considerable analogy in the distribution of its branches. The superficial perineal artery supplies the labia pudendi; the artery of the bulb supplies the bulbi vestibuli and the erectile tissue of the vagina; the artery of the corpus cavernosum (*a. profunda clitoridis*) supplies the cavernous body of the clitoris; and the dorsal artery of the clitoris (*a. dorsalis clitoridis*) supplies the dorsum of that organ, and terminates in the glans and in the membranous fold corresponding to the prepuce of the male.

The **sciatic artery** (*a. glutea inferior*) (Fig. 477), the larger of the two terminal branches of the anterior trunk of the internal iliac, is distributed chiefly on the buttock and back of the thigh. It passes down to the lower part of the great sacrosciatic foramen behind the internal pudic artery, resting on the sacral plexus of nerves and Piriformis muscle, and escapes from the pelvis through this foramen between the Piriformis and Coccygeus. It then descends in the interval between the trochanter major and tuberosity of the ischium, accompanied by the sciatic nerves, and covered by the Gluteus maximus, and is continued down the back of the thigh supplying the skin, and anastomosing with branches of the perforating arteries.

Within the pelvis it distributes branches to the Piriformis, Coccygeus, and Levator ani muscles; some hemorrhoidal branches, which supply the rectum, and occasionally take the place of the middle hemorrhoidal artery; and vesical branches to the base and neck of the bladder, seminal vesicles, and prostate gland. Outside the pelvis it gives off the following branches:

- Muscular.
- Coccygeal.
- Comes nervi ischiadici.
- Anastomotic.
- Articular.
- Cutaneous.

The **muscular branches** supply the Gluteus maximus, anastomosing with the gluteal artery in the substance of the muscle; the External rotators, anastomosing with the internal pudic artery; and the muscles attached to the tuberosity of the ischium, anastomosing with the external branch of the obturator and the internal circumflex arteries.

The **coccygeal branch** runs inward, pierces the great sacrosciatic ligament, and supplies the Gluteus maximus, the integument, and other structures on the back of the coccyx.

The **comes nervi ischiadici** (*a. comitans n. ischiadici*) is a long, slender vessel which accompanies the great sciatic nerve for a short distance; it then penetrates it and runs in its substance to the lower part of the thigh.

FIG. 477.—The arteries of the gluteal and posterior femoral regions.

The **anastomotic artery** is directed downward across the External rotators and assists in forming the so-called **crucial anastomosis** by anastomosing with the superior perforating and the internal and external circumflex arteries.

The **articular branch**, generally derived from the anastomotic, is distributed to the capsule of the hip-joint.

The **cutaneous branches** are distributed to the skin of the buttock and back of the thigh.

The **iliolumbar artery** (*a. iliolumbalis*), given off from the posterior trunk of the internal iliac, turns upward and outward between the obturator nerve and lumbosacral cord, to the inner margin of the Psoas muscle, behind which it divides into a **lumbar** and an **iliac branch**.

The **lumbar branch** (*ramus lumbalis*) supplies the Psoas and Quadratus lumborum muscles, anastomosing with the last lumbar artery, and sends a small **spinal branch** (*ramus spinalis*) through the intervertebral foramen, between the last lumbar vertebra and the sacrum, into the vertebral canal, to supply the cauda equina.

The **iliac branch** (*ramus iliacus*) descends to supply the Iliacus muscle; some offshoots, running between the muscle and the bone, anastomose with the iliac branch of the obturator; one of these enters an oblique canal to supply the diploë, while others run along the crest of the ilium, distributing branches to the Gluteal and Abdominal muscles, and anastomose in their course with the gluteal circumflex iliac, and external circumflex arteries.

The **lateral sacral arteries** (*a. sacralis lateralis*) (Fig. 473) are usually two in number—**superior** and **inferior**.

The **superior**, which is of large size, passes inward, and, after anastomosing with branches from the middle sacral, enters the first or second anterior sacral foramen, supplies branches to the contents of the sacral canal, and, escaping by the corresponding posterior sacral foramen, is distributed to the skin and muscles on the dorsum of the sacrum, anastomosing with the gluteal.

The **inferior** passes obliquely across the front of the Piriformis muscle and sacral nerves to the inner side of the anterior sacral foramina, descends on the front of the sacrum, and anastomoses over the coccyx with the middle sacral and opposite lateral sacral artery. In its course it gives off branches which enter the anterior sacral foramina (*rami spinales*); these, after supplying the contents of the sacral canal, escape by the posterior sacral foramina, and are distributed to the muscles and skin on the dorsal surface of the sacrum, anastomosing with the gluteal.

The **gluteal artery** (*a. glutea superior*) (Fig. 477) is the largest branch of the internal iliac, and appears to be the continuation of the posterior division of that vessel. It is a short, thick trunk which runs backward between the lumbosacral cord and the first sacral nerve, and, passing out of the pelvis above the upper border of the Piriformis muscle, immediately divides into a **superficial** and a **deep branch**. Within the pelvis it gives off a few muscular branches to the Iliacus, Piriformis, and Obturator internus, and, just previous to emerging from that cavity, a nutrient artery which enters the ilium.

The **superficial branch** enters the deep surface of the Gluteus maximus, and divides into numerous branches, some of which supply the muscle, while others perforate its tendinous origin, and supply the integument covering the posterior surface of the sacrum, anastomosing with the posterior branches of the sacral arteries.

The **deep branch** lies under the Gluteus medius and almost immediately subdivides into two. Of these, the **superior division** (*ramus superior*), continuing the original course of the vessel, passes along the upper border of the Gluteus minimus to the anterior superior spine of the ilium, anastomosing with the circumflex iliac and ascending branches of the external circumflex artery. The **inferior division** (*ramus inferior*) crosses the Gluteus minimus obliquely to the trochanter

major, distributing branches to the Gluteus muscles, and anastomoses with the external circumflex artery. Some branches pierce the Gluteus minimus to supply the hip-joint.

Surface Marking.—The position of the three main branches of the internal iliac, the sciatic, internal pudic, and gluteal, which may occasionally be the object of surgical interference, is indicated on the surface in the following way: A line is to be drawn from the posterior superior iliac spine to the posterior superior angle of the great trochanter, with the limb slightly flexed and rotated inward; the point of emergence of the gluteal artery from the upper part of the sciatic notch will correspond with the junction of the upper with the middle third of this line. A second line is to be drawn from the same point to the outer part of the tuberosity of the ischium; the junction of the lower with the middle third marks the point of emergence of the sciatic and pudic arteries from the great sciatic notch.

Applied Anatomy.—Any of these three vessels may require ligating for a wound or for aneurism, which is generally traumatic. The gluteal artery is ligated by turning the patient two-thirds over on his face and making an incision from the posterior superior spine of the ilium to the upper and posterior angle of the great trochanter. This must expose the Gluteus maximus muscle, and its fibres are to be separated through the whole thickness of the muscle and pulled apart with retractors. The contiguous margins of the Gluteus medius and Pyramiformis are now to be separated from each other, and the artery will be exposed emerging from the sciatic notch. In ligation of the sciatic artery, the incision should be made parallel with that for ligation of the gluteal, but one inch and a half lower down. After the fibres of the Gluteus maximus have been separated, the vessel is to be sought for at the lower border of the Pyramiformis; the great sciatic nerve, which lies just above it, forms the chief guide to the artery. The internal pudic can be reached through the incision used to reach the sciatic.

The External Iliac Artery (*A. Iliaca Externa*) (Fig. 473).

The external iliac artery is larger in the adult than is the internal iliac. It passes obliquely downward and outward along the inner border of the Psoas muscle, from the bifurcation of the common iliac to a point beneath Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, where it enters the thigh and becomes the femoral artery.

Relations.—*In front*, the artery is in relation with the peritoneum, subperitoneal areolar tissue, the termination of the ileum on the right side, and the sigmoid flexure on the left, and a thin layer of fascia derived from the iliac fascia, which surrounds the artery and vein. At its origin it is crossed by the ovarian artery in the female, and occasionally by the ureter. The spermatic vessels descend for some distance upon it near its termination, and it is crossed in this situation by the genital branch of the genitofemoral nerve and the deep circumflex iliac vein; the vas deferens in the male, and the round ligament in the female, curve down along its inner side. *Behind*, it is in relation with the inner border of the Psoas muscle, from which it is separated by the iliac fascia. At the upper part of its course, the external iliac vein lies partly behind it, but lower down lies entirely to its inner side. *Externally*, it rests against the Psoas muscle, from which it is separated by the iliac fascia. Numerous lymphatic vessels and nodes are found lying on the front and inner side of the vessel.

PLAN OF THE RELATIONS OF THE EXTERNAL ILIAC ARTERY.

Surface Marking.—The surface line indicating the course of the external iliac artery has been already given (see page 671).

Applied Anatomy.—The application of a *ligature* to the external iliac may be required in cases of aneurism of the femoral artery or for a wound of the artery. This vessel may be secured in any part of its course, excepting near its upper end, which is to be avoided on account of the proximity of the internal iliac, and near its lower end, which should also be avoided, on account of the proximity of the deep epigastric and circumflex iliac vessels. The patient having been placed in the supine position, an incision should be made, commencing below at a point about three-quarters of an inch above Poupart's ligament, and a little external to its middle, and running upward and outward, parallel to Poupart's ligament, to a point one inch internal and one inch above the anterior superior spine of the ilium. When the artery is deeply seated more room will be required, and may be obtained by curving the incision from the point last named inward toward the umbilicus for a short distance. Another mode of ligating the vessel is the plan advocated by Sir Astley Cooper, by making an incision close to Poupart's ligament from about half an inch outside of the external abdominal ring to one inch internal to the anterior superior spine of the ilium. This incision, being made in the course of the fibres of the aponeurosis of the External oblique, is less likely to be followed by a ventral hernia, but there is danger of wounding the epigastric artery, and only the lower end of the vessel can be ligated. Abernethy, who first tied this artery, made his incision in the course of the vessel. The Abdominal muscles and transversalis fascia having been cautiously divided, the peritoneum should be separated from the iliac fossa and raised toward the pelvis; and on introducing the finger to the bottom of the wound, the artery may be felt pulsating along the inner border of the Psoas muscle. The external iliac vein is generally found on the inner side of the artery, and must be cautiously separated from it by the finger nail or handle of the knife, and the aneurism needle should be introduced on the inner side, between the artery and the vein.

Ligation of the external iliac artery is performed by a transperitoneal method. An incision four inches in length is made in the semilunar line, commencing about an inch below the umbilicus and carried through the abdominal wall into the peritoneal cavity. The intestines are then pushed upward and held out of the way by a broad abdominal retractor, and an incision is made through the peritoneum at the brim of the pelvis in the course of the artery, and the vessel is secured in any part of its course which may seem desirable to the operator. The advantages of this operation appear to be that if it is found necessary, the common iliac artery can be ligated instead of the external iliac without extension or modification of the incision; and secondly, that the vessel can be ligated without in any way interfering with the coverings of the sac of an aneurism. Possibly a disadvantage may exist in the greater risk of hernia after this method.

Collateral Circulation.—The principal anastomoses in carrying on the collateral circulation, after the application of a ligature to the external iliac, are the ilio-lumbar with the circumflex iliac; the gluteal with the external circumflex; the obturator with the internal circumflex; the sciatic with the superior perforating and circumflex branches of the profunda artery; and the internal pudic with the external pudic. When the obturator arises from the epigastric it is supplied with blood by branches, either from the internal iliac, the lateral sacral, or the internal pudic. The epigastric receives its supply from the internal mammary and inferior intercostal arteries, and from the internal iliac by the anastomoses of its branches with the obturator.¹

Branches.—Besides several small branches to the Psoas muscle and the neighboring lymph nodes, the external iliac gives off two branches of considerable size—the **deep epigastric** and **deep circumflex iliac arteries**.

The **deep epigastric artery** (*a. epigastrica inferior*) (Fig. 473) arises from the external iliac above Poupart's ligament. It curves forward below the peritoneum, and then ascends obliquely along the inner margin of the internal abdominal ring, lying between the transversalis fascia and peritoneum; continuing its course upward, it pierces the transversalis fascia, and passing over the semilunar fold of Douglas, ascends between the Rectus and the posterior lamella of its aponeurotic sheath. It finally divides into numerous branches which anastomose, above the umbilicus, with the superior epigastric branch of the internal mammary and with the lower intercostal arteries (Fig. 459). As the deep epigastric artery passes obliquely upward and inward from its origin it lies along the lower and inner margin of the internal abdominal ring and behind the commencement of the spermatic cord. This part of the vessel is crossed by the vas deferens in the male and the round ligament of the uterus in the female.

¹ Sir Astley Cooper describes the dissection of a limb eighteen years after successful ligation of the external iliac artery in Vol. I of Guy's Hospital Reports.

Branches.—The branches of this vessel are: The **cremasteric** (*a. spermatica externa in the male, a. ligamenti teretis uteri in the female*), which accompanies the spermatic cord, and supplies the Cremaster muscle and other coverings of the spermatic cord, anastomosing with the spermatic artery in the male, and which accompanies the round ligament in the female; a **pubic branch** (*ramus pubicus*), which runs along Poupart's ligament, and then descends behind the os pubis to the inner side of the femoral ring, and anastomoses with offshoots from the obturator artery; **muscular branches**, some of which are distributed to the Abdominal muscles and peritoneum, anastomosing with the lumbar and circumflex iliac arteries; **cutaneous branches**, which perforate the tendon of the External oblique, and supply the integument, anastomosing with branches of the superficial epigastric.

FIG. 478.—Femoral sheath laid open to show its three compartments. Iliac portion of fascia lata removed.

Peculiarities.—The origin of the deep epigastric may take place from any part of the external iliac between Poupart's ligament and two inches and a half above it, or it may arise below this ligament, from the common femoral or from the deep femoral. It frequently arises from the external iliac by a common trunk with the obturator. Sometimes the epigastric arises from the obturator, the latter vessel being furnished by the internal iliac, or the epigastric may be formed by two branches, one derived from the external iliac, the other from the internal iliac.

Applied Anatomy.—The deep epigastric artery follows a line drawn from the middle of Poupart's ligament toward the umbilicus; but shortly after this line crosses the linea semilunaris the direction changes, and the course of the vessel is directly upward in the line of junction of the inner third with the outer two-thirds of the Rectus muscle. It has important surgical relations, in addition to the fact that it is one of the principal means, through its anastomosis with the internal mammary, in establishing the collateral circulation after ligation of either the common or external iliac arteries. It lies close to the internal abdominal ring, and is therefore *internal* to an oblique inguinal hernia, but *external* to a direct inguinal hernia, as the hernia

emerges from the abdomen. It forms the outer boundary of Hesselbach's triangle. It is in close relationship with the spermatic cord, which lies in front of it in the inguinal canal, separated only by the transversalis fascia. The vas deferens curves round its outer side.

The **deep circumflex iliac artery** (*a. circumflexa ilium profunda*) (Fig. 472) arises from the outer side of the external iliac nearly opposite the epigastric artery. It ascends obliquely outward behind Poupart's ligament, contained in a fibrous sheath formed by the junction of the transversalis and iliac fasciæ, to the anterior superior spinous process of the ilium. It then runs along the inner surface of the crest of the ilium to about its middle, where it pierces the Transversalis, and runs backward between that muscle and the Internal oblique, to anastomose with the iliolumbar and gluteal arteries. Opposite the anterior superior spine of the ilium it gives off a large branch which ascends between the Internal oblique and Transversalis muscles, supplying them, and anastomosing with the lumbar and epigastric arteries. It also gives off cutaneous branches.

FIG. 479.—Structures which pass beneath the crural arch.

ARTERIES OF THE LOWER EXTREMITY.

The artery which supplies the greater part of the lower extremity is the direct continuation of the external iliac. It continues as a single trunk from Poupart's ligament to the lower border of the Popliteus muscle, and here divides into two branches, the anterior and posterior tibial. For convenience of description, the upper part of the main trunk is named **femoral**, the lower part, **popliteal**.

THE FEMORAL ARTERY (A. FEMORALIS) (Figs. 481 and 482).

The **femoral artery** commences immediately behind Poupart's ligament, midway between the anterior superior spine of the ilium and the symphysis pubis, and, passing down the fore part and inner side of the thigh, terminates at the opening in the Adductor magnus, at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. The vessel, at the upper part of the thigh, lies in front of the hip-joint, on a line with the innermost part of the head of the femur; in the lower part of its course it is in close relation with the inner side of the shaft of the bone, and between these two parts the vessel is some distance from the bone. The first inch and a half of the vessel is enclosed, together with the femoral vein, in a fibrous sheath—the **femoral sheath**. In the upper third of the thigh it is contained in a triangular space called **Scarpa's triangle**, and in this space it gives off its largest branch, the **deep femoral**. In the middle third of the thigh it is contained in an aponeurotic canal called **Hunter's canal**. That portion of the femoral artery which extends from Poupart's ligament to the origin of the deep femoral is sometimes called the **common femoral**; its continuation is the **superficial femoral**.

FIG. 480.—The relations of the femoral and internal abdominal rings, seen from within the abdomen. Right side.

The **femoral or crural sheath** (Fig. 479) is a continuation downward of the fasciæ that line the abdomen, the **transversalis fascia** passing down in front of the femoral vessels, and the **iliac fascia** descending behind them; these fasciæ are directly continuous on the iliac side of the femoral artery, but a small space exists between the femoral vein and the point where they are continuous on the pubic side of that vessel, which constitutes the **femoral or crural canal** (Fig. 479). The femoral sheath is closely adherent to the contained vessels about an inch below the saphenous opening, being blended with the areolar sheath of the vessels, but opposite Poupart's ligament it is much larger than is required to contain them; hence the funnel-shaped form which it presents. The outer border of the sheath is perforated by the femoral nerve. Its inner border is pierced by the internal saphenous vein and numerous lymphatic vessels. In front it is covered by the iliac portion of the fascia lata; and behind it is the pubic portion of the same fascia.

The anterior wall of the sheath is a thickened band of fascia continuous above Poupart's ligament with the transversalis fascia, called the **deep crural arch**. From it stretch two septa, one between the femoral artery and the vein, the other lying just internal to the vein, and cutting off a small space between the vein and the inner wall of the sheath. The septa are stretched between the anterior and posterior walls of the sheath, so that each vessel is enclosed in a separate compartment. The interval left between the vein and the inner wall of the sheath is not

FIG. 481.—Scheme of the femoral artery. (Poirier and Charpy.)

filled up by any structure, excepting a little loose areolar tissue, a few lymphatic vessels, and occasionally by a small lymph node; this is the **femoral or crural canal** through which the intestine descends in femoral hernia.

The **femoral or crural canal** (*canalis femoralis*) (Figs. 479 and 480) is the narrow interval between the femoral vein and the inner wall of the femoral sheath. It exists as a distinct canal only when the sheath has been separated from the vein by dissection or by the pressure of a hernia or tumor. Its length is from a quarter

to half an inch, and it extends from the femoral ring to the upper part of the saphenous opening.

This canal has two orifices—an upper one, the **femoral or crural ring**, closed by the **septum crurale**; and a lower one, the **saphenous opening**, closed by the cribriform fascia.

The **femoral or crural ring** (*annulus femoralis*) (Figs. 463 and 464) is the upper opening of the femoral canal, and leads into the cavity of the abdomen. It is of an oval form; its long diameter, directed transversely, measures about half an inch, and it is larger in the female than in the male, which is one of the reasons of the greater frequency of femoral hernia in the former sex.

Scarpa's triangle (*trigonum femorale*) corresponds to the depression seen immediately below the fold of the groin. It is a triangular space, the *apex* of which is directed downward, and the sides formed *externally* by the Sartorius, *internally* by the inner margin of the Adductor longus, and *above* by Poupart's ligament. The floor of the space is formed from without inward by the Iliacus, Psoas, Pectineus (in some cases a small part of the Adductor brevis), and the Adductor longus muscles; and it is divided into two nearly equal parts by the femoral vessels, which extend from the middle of its base to its apex, the artery giving off in this situation its superficial and profunda branches, the vein receiving the deep femoral and internal saphenous. On the outer side of the femoral artery is the femoral nerve dividing into its branches. In the outer corner of the space is the external cutaneous nerve. Within the sheath of the artery, and lying upon the outer side of the vessel, is the femoral branch of the genitofemoral nerve. At the base of the triangle the vein is to the inner side of the artery; at the apex of the triangle it is passing behind the artery. Besides the vessels and nerves, this space contains some fat and lymphatics.

Hunter's canal, or the **adductor canal** (*canalis adductorius* [*Hunteri*]) (Fig. 383), is the aponeurotic space in the middle third of the thigh, extending from

FIG. 482.—The femoral artery.

the apex of Scarpa's triangle to the femoral opening in the Adductor magnus muscle. It is bounded, *externally*, by the Vastus internus; *internally*, by the Adductors longus and magnus muscles; and is *covered* in by a strong aponeurosis which extends transversely from the Vastus internus across the femoral vessels to the Adductor longus and magnus; lying on which aponeurosis is the Sartorius muscle. It contains the femoral artery and vein enclosed in their own sheath of areolar tissue, the vein being behind and on the outer side of the artery, and the internal or long saphenous nerve lying at first on the outer side and then in front of the vessels.

Relations.—The relations of the artery differ along its course. In *Scarpa's triangle* the femoral artery is very superficial, being covered by the skin and superficial fascia, superficial inguinal lymph nodes, the iliac portion of the fascia lata, and the anterior part of the femoral sheath. The femoral branch of the genitofemoral nerve courses for a short distance within the outer compartment of the femoral sheath and lies at first in front and then on the outer side of the artery. Near the apex of Scarpa's triangle the internal cutaneous nerve crosses the artery from without inward.

Behind the artery are the posterior part of the femoral sheath, the pubic portion of the fascia lata, the inner part of the tendon of the Psoas, the Pectineus and Adductor longus. The artery is separated from the capsule of the hip-joint by the tendon of the Psoas, from the Pectineus by the femoral vein and profunda vessels, and from the Adductor longus by the femoral vein. The nerve to the Pectineus passes inward behind the artery. On the *outer* side of the artery, but separated from it by some fibres of the Psoas, is the femoral nerve. The femoral vein is on the inner side of the upper part of the artery, but is behind the vessel in the lower part of Scarpa's triangle.

PLAN OF THE RELATIONS OF THE FEMORAL ARTERY IN SCARPA'S TRIANGLE.

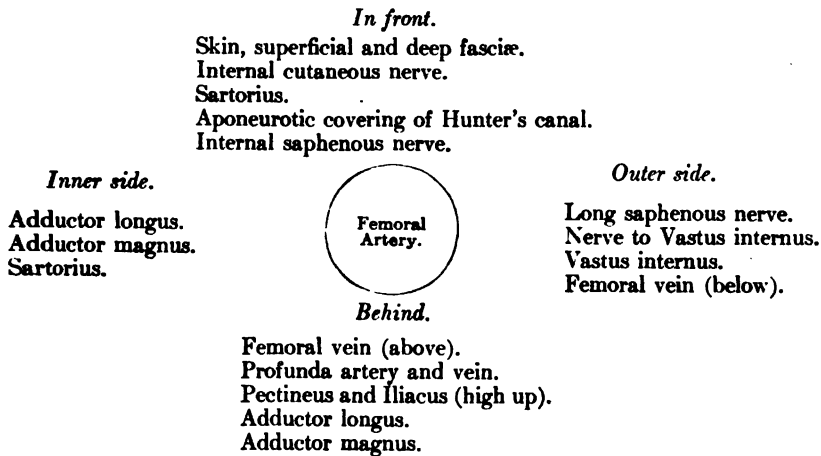

In *Hunter's canal* the femoral artery is more deeply situated, being *covered* by the integument, the superficial and deep fasciæ, the Sartorius and the fibrous roof of the canal; it is *crossed* from without inward by the long saphenous nerve. *Behind* the artery are the Adductores longus et magnus; in *front* and to its outer side is the Vastus internus. The femoral vein lies behind the upper part, and on the outer side of the lower part of the artery. As the artery passes out of Scarpa's

triangle into Hunter's canal, the Iliacus and Pectineus muscles lie behind it for a short distance (Fig. 482).

That portion of the femoral artery which extends from Poupart's ligament to the origin of the profunda is sometimes named the **common femoral**.

PLAN OF THE RELATIONS OF THE FEMORAL ARTERY IN HUNTER'S CANAL.

Peculiarities, Double Femoral Reunited.—Several cases are recorded in which the femoral artery divided into two trunks below the origin of the profunda, and became reunited near the opening of the Adductor magnus so as to form a single popliteal artery. One of them occurred in a patient operated upon for popliteal aneurism.

Change of Position.—A few cases have been recorded in which the femoral artery was situated at the back of the thigh, the vessel being continuous above with the internal iliac, escaping from the pelvis through the great sacrosciatic foramen, and accompanying the great sciatic nerve to the popliteal space, where its division occurred in the usual manner. The external iliac in these cases was small, and terminated in the profunda.

Position of the Vein.—The femoral vein is occasionally placed along the inner side of the artery, throughout the entire extent of Scarpa's triangle, or it may be divided so that a large vein is placed on each side of the artery for a greater or less extent.

Surface Marking.—The upper two-thirds of a line drawn from a point midway between the anterior superior spine of the ilium and the symphysis pubis to the adductor tubercle on the inner condyle of the femur, with the thigh abducted and rotated outward, will indicate the course of the femoral artery.

Applied Anatomy.—*Compression* of the femoral artery, which is constantly requisite in amputations and other operations on the lower limbs, and also for the cure of popliteal aneurisms, is most effectually made immediately below Poupart's ligament. In this situation the artery is very superficial, and is merely separated from the ascending ramus of the os pubis by the Psoas muscle; so that the surgeon, by means of his thumb or a compressor, may effectually control the circulation through it. This vessel may also be compressed in the middle third of the thigh by placing a compress over the artery, beneath the tourniquet, and directing the pressure from within outward, so as to compress the vessel against the inner side of the shaft of the femur.

The **application of a ligature** to the femoral artery may be required in the cases of wound or aneurism of the arteries of the leg, of the popliteal or femoral; and the vessel may be exposed and tied in any part of its course. The great depth of this vessel at its lower part, its close connection with important structures, and the density of its sheath render the operation in this situation one of much greater difficulty than the application of a ligature at its upper part, where it is more superficial.

Ligation of the common femoral artery is usually considered unsafe, on account of the connection of large branches with it—viz., the deep epigastric and the deep circumflex iliac arising just above Poupart's ligament; on account of the number of small branches which arise from it in its short course; and on account of the uncertainty of the origin of the profunda femoris, which, if it arise high up, would be too close to the ligature for the formation of a firm coagulum. The profunda sometimes arises higher than the point above mentioned, and rarely

¹ Ligation of the femoral artery has been also recommended and performed for elephantiasis of the leg and acute inflammation of the knee-joint (Maunder, Clin. Soc. Trans., vol. ii, p. 37).

between two or three inches (in one case four) below Poupart's ligament. It would appear, then, that the most favorable situation for the application of a ligature to the femoral is on the superficial femoral at the apex of Scarpa's triangle. In order to expose the artery in this situation, an incision between three and four inches long should be made in the course of the vessel, the patient lying in the recumbent position, with the limb slightly flexed and abducted, and rotated outward. A large vein is frequently met with, passing in the course of the artery to join the internal saphenous vein; this must be avoided, and the fascia lata having been cautiously divided and the Sartorius exposed, that muscle must be drawn outward in order to expose fully the sheath of the vessels. The finger being introduced into the wound and the pulsation of the artery felt, the sheath should be opened on the outer side of the vessel to a sufficient extent to allow of the introduction of the ligature, but no farther; otherwise the nutrition of the coats of the vessel may be interfered with, or muscular branches which arise from the vessel at irregular intervals may be divided. In this part of the operation the long saphenous nerve and the nerve to the Vastus internus, which is in close relation with the sheath, should be avoided. The aneurism needle must be carefully introduced and kept close to the artery, to avoid the femoral vein, which lies behind the vessel in this part of its course.

To expose the artery in Hunter's canal, an incision should be made between three and four inches in length, a finger's breadth internal to the line of the artery, in the middle of the thigh—i. e., midway between the groin and the knee. The integument is first divided. The fascia lata having been divided, and the outer border of the Sartorius muscle exposed, it should be drawn inward, when the strong fascia which is stretched across from the Adductors to the Vastus internus will be exposed, and must be freely divided; the sheath of the vessels is now seen, and must be opened, and the artery secured by passing the aneurism needle between the vein and artery in the direction from without inward. The femoral vein in this situation lies on the outer side of the artery and the long saphenous nerve on the anterior and outer side of the artery.

It has been seen that the femoral artery occasionally divides into two trunks below the origin of the profunda. If in the operation for tying the femoral two vessels are met with, the surgeon should alternately compress each, in order to ascertain which vessel is connected with the aneurismal tumor or with the bleeding from the wound, and that one only should be tied which controls the pulsation or hemorrhage. If, however, it is necessary to compress both vessels before the circulation in the tumor is controlled, both should be tied, as it would be probable that they became reunited, as in the instances referred to above.

In wounds of the femoral artery the question of the mode of treatment is of considerable importance. If the wound in the superficial structures is a large one, the injured vessel must be exposed and tied; but if the wound is a punctured one and the bleeding has ceased, the question will arise whether to cut down upon the artery or to trust to pressure. Mr. Cripps advises that if the wound is in the "upper part of the thigh—that is to say, in a position where the femoral artery is comparatively superficial—the surgeon may enlarge the opening with a good prospect of finding the wounded vessel without an extensive or prolonged operation. If the wound be in the lower half of the thigh, owing to the greater depth of the artery and the possibility of its being the popliteal that is wounded, the search is rendered a far more severe and hazardous operation, and it should not be undertaken until a thorough trial of pressure has proved ineffectual."

Great care and attention are necessary for the successful application of pressure. The limb should be carefully bandaged from the foot upward to the wound, which is not covered, and then onward to the groin. The wound is then dusted with iodoform or boracic powder and a conical pad applied over the wound. Rollers the thickness of the index finger are then placed along the course of the vessel above and below the wound, and the whole carefully bandaged to a back splint with a foot piece.

Collateral Circulation.—After ligation of the femoral artery, the main channels for carrying on the circulation are the anastomoses between (1) the gluteal and sciatic branches of the internal iliac with the internal and external circumflex and superior perforating branches of the profunda femoris; (2) the obturator branch of the internal iliac with the internal circumflex of the profunda; (3) the internal pudic of the internal iliac with the superficial and deep external pudic of the common femoral; (4) the deep circumflex iliac of the external iliac with the external circumflex of the profunda and the superficial circumflex iliac of the femoral; and (5) the sciatic and comes nervi ischiadici of the internal iliac with the perforating branches of the profunda.

Branches (Figs. 481 and 482).—The branches of the femoral artery are:

Superficial epigastric.		Muscular.
Superficial circumflex iliac.		External circumflex.
Superficial external pudic.	Profunda femoris	Internal circumflex.
Deep external pudic.		Three perforating.
	Anastomotica magna.	

The **superficial epigastric** (*a. epigastrica superficialis*) arises from the femoral about half an inch below Poupart's ligament, and, passing through the saphenous opening in the fascia lata, ascends on the abdomen in the superficial fascia covering the External oblique muscle, nearly as high as the umbilicus. It distributes branches to the superficial inguinal nodes, the superficial fascia, and the integument, anastomosing with branches of the deep epigastric.

The **superficial circumflex iliac** (*a. circumflexa ilium superficialis*), the smallest of the cutaneous branches, arises close to the preceding, and, piercing the fascia lata, runs outward, parallel with Poupart's ligament, as far as the crest of the ilium, dividing into branches which supply the integument of the groin, the superficial fascia, and the superficial inguinal lymph nodes, anastomosing with the deep circumflex iliac and with the gluteal and external circumflex arteries.

The **superficial external pudic** (*a. pudenda externa superficialis*) arises from the inner side of the femoral artery, close to the preceding vessels, and, after passing through the saphenous opening, courses inward, across the spermatic cord or round ligament, to be distributed to the integument on the lower part of the abdomen, the penis and scrotum in the male, and the labium majus in the female, anastomosing with branches of the internal pudic.

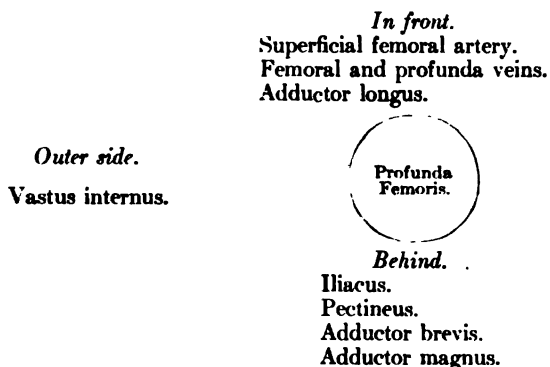

The **deep external pudic** (*a. pudenda externa profunda*), more deeply seated than the preceding, passes inward across the Pectineus and Adductor longus muscles, covered by the fascia lata, which it pierces at the inner border of the thigh, its branches being distributed, in the male, to the integument of the scrotum and perineum; and in the female to the labium majus, anastomosing with branches of the superficial perineal artery.

Muscular branches (*rami musculares*) are supplied by the femoral to the Sartorius, Vastus internus, and Adductors.

The **deep femoral**, or the **profunda femoris** (*a. profunda femoris*) (Figs. 471 and 472), is a large vessel arising from the outer and back part of the femoral artery, from one to two inches below Poupart's ligament. It at first lies on the outer side of the superficial femoral, and then passes behind it and the femoral vein to the inner side of the femur, and, passing downward beneath the Adductor longus, terminates at the lower third of the thigh in a small branch which pierces the Adductor magnus (and from this circumstance is sometimes called the **fourth perforating artery**), and is distributed to the Flexor muscles on the back of the thigh, anastomosing with branches of the popliteal and inferior perforating arteries. The deep femoral supplies all the tissues on the back and outer side of the thigh not supplied by the sciatic and gluteal arteries.

Relations.—*Behind*, it lies first upon the Iliacus, and then on the Pectineus, Adductor brevis, and Adductor magnus muscles. *In front*, it is separated from the superficial femoral artery, above by the femoral and profunda veins, and below by the Adductor longus. On its *outer side* the origin of the Vastus internus separates it from the femur.

PLAN OF THE RELATIONS OF THE PROFUNDA ARTERY.

Peculiarities of Origin of the Profunda.—This vessel occasionally arises from the inner side, and, more rarely, from the back of the common trunk; but the more important peculiarity, from a surgical point of view, is that which relates to the height at which the vessel arises from the femoral. In three-fourths of a large number of cases it arose between one to two inches below Poupart's ligament; in a few cases the distance was less than an inch; more rarely, opposite the ligament; and in one case, above Poupart's ligament, from the external iliac. Occasionally, the distance between the origin of the vessel and Poupart's ligament exceeds two inches, and in one case it was found to be as much as four inches.

Branches.—The profunda gives off the following-named branches:

External circumflex.
Internal circumflex.

Four perforating.
Muscular.

The **external circumflex artery** (*a. circumflexa femoris lateralis*) supplies the muscles on the front of the thigh. It arises from the outer side of the profunda, passes horizontally outward, between the divisions of the femoral nerve and behind the Sartorius and Rectus muscles, and divides into three sets of branches—**ascending, transverse, and descending.**

The **ascending branch** (*ramus ascendens*) passes upward, beneath the Tensor fasciae femoris muscle, to the outer side of the hip, anastomosing with the terminal branches of the gluteal and deep circumflex iliac arteries. It sends out muscular branches.

The **descending branch** (*ramus descendens*) passes downward, behind the Rectus, upon the Vasti muscles, to which its branches are distributed, one or two passing beneath the Vastus externus as far as the knee, anastomosing with the superior articular branches of the popliteal artery. These are accompanied by the branch of the femoral nerve to the Vastus externus.

The **transverse branch**, the smallest, passes outward over the Crureus, pierces the Vastus externus, and winds around the femur to its back part, just below the great trochanter, anastomosing at the back of the thigh with the internal circumflex, sciatic, and superior perforating arteries.

The **internal circumflex artery** (*a. circumflexa femoris medialis*), smaller than the external, arises from the inner and back part of the profunda, and winds around the inner side of the femur, between the Pectineus and Psoas muscles. On reaching the upper border of the Adductor brevis it gives off two **muscular branches**, one of which passes inward to be distributed to the Adductor muscles, the Gracilis, and Obturator externus, anastomosing with the obturator artery; the other descends, and passes beneath the Adductor brevis, to supply it and the great Adductor; while the continuation of the vessel passes backward and divides into an ascending and a transverse branch (Fig. 389). The **ascending branch** (*ramus profundus*) passes obliquely upward upon the tendon of the Obturator externus and under cover of the Quadratus femoris toward the digital fossa, where it anastomoses with twigs from the gluteal and sciatic arteries. The **transverse branch** (*ramus superficialis*), larger than the ascending, appears between the Quadratus femoris and upper border of the Adductor magnus, anastomosing with the sciatic, external circumflex, and superior perforating arteries, the **crucial anastomosis**. Opposite the hip-joint the artery gives off an **articular vessel** (*ramus acetabuli*), which enters the joint beneath the transverse ligament; and, after supplying the adipose tissue, passes along the round ligament to the head of the bone.

The **perforating arteries** (Figs. 472 and 473), usually three in number, are so called from their perforating the tendon of the Adductor magnus muscle to reach the back of the thigh. They pass backward close to the linea aspera of the femur, under cover of small tendinous arches in the Adductor magnus. The **first** is given off above the Adductor brevis, the **second** in front of that muscle, and the **third** immediately below it.

The **first perforating artery** (*a. perforans prima*) passes backward between the Pectineus and Adductor brevis (sometimes perforates the latter); it then pierces the Adductor magnus close to the *linea aspera*. It gives off branches which supply the Adductor brevis, the Adductor magnus, the Biceps, the Gluteus maximus muscles, and anastomoses with the sciatic, internal and external circumflex, and second perforating arteries.

The **second perforating artery** (*a. perforans secunda*), larger than the first, pierces the tendons of the Adductor brevis and Adductor magnus muscles, and divides into ascending and descending branches, which supply the Flexor muscles of the thigh, anastomosing with the first and third perforating arteries. The second artery frequently arises in common with the first. The **nutrient artery of the femur** (*a. nutricia femoris*) is usually given off from this branch.

The **third perforating artery** (*a. perforans tertia*) is given off below the Adductor brevis; it pierces the Adductor magnus, and divides into branches which supply the Flexor muscles of the thigh; anastomosing above with the higher perforating arteries, and below with the terminal branches of the profunda and the muscular branches of the popliteal.

A **fourth perforating artery** is represented by the termination of the profunda femoris artery.

Numerous **muscular branches** arise from the profunda; some of these end in the Adductor muscles, others pierce the Adductor magnus, give branches to the Hamstring muscles, and anastomose with the internal circumflex artery and with the upper muscular branches of the popliteal.

The **anastomotica magna** (*a. genu suprema*) (Figs. 481 and 482) arises from the femoral artery just before it passes through the tendinous opening in the Adductor magnus muscle, and immediately divides into a **superficial** and **deep branch**.

The **superficial branch** (*ramus saphenus*) pierces the aponeurotic covering of Hunter's canal, and accompanies the long saphenous nerve to the inner side of the thigh. It passes between the Sartorius and Gracilis muscles, and, piercing the fascia lata, is distributed to the integument of the upper and inner part of the leg, anastomosing with the inferior internal articular artery.

The **deep branch** (*ramus musculoarticularis*) descends in the substance of the Vastus internus, lying in front of the tendon of the Adductor magnus, to the inner side of the knee, where it anastomoses with the superior internal articular artery and the anterior recurrent branch of the anterior tibial. A branch from this vessel crosses outward above the articular surface of the femur, forming an anastomotic arch with the superior external articular artery, and supplies branches to the knee-joint.

THE POPLITEAL ARTERY (A. POPLITEA) (Figs. 477 and 481).

The popliteal artery commences at the termination of the femoral at the opening in the Adductor magnus, and, passing obliquely downward and outward behind the knee-joint to the lower border of the Popliteus muscle, divides into the **anterior** and **posterior tibial arteries**. A portion of the artery lies in the popliteal space; but above and below, to a considerable extent, it is covered by the muscles which form the boundaries of the space, and is therefore beyond the confines of the space.

The Popliteal Space (Fig. 483).

Dissection.—A vertical incision about eight inches in length should be made along the back part of the knee-joint, connected above and below by a transverse incision from the inner to the outer side of the limb. The flaps of integument included between these incisions should be reflected in the direction shown in Fig. 386, p. 518.

Boundaries.—The **popliteal space** is a lozenge-shaped space, widest at the back part of the knee-joint, and deepest above the articular end of the femur. It is bounded *externally, above the joint*, by the Biceps, and *below the joint* by the Plantaris and external head of the Gastrocnemius. *Internally, above the joint*, by the Semimembranosus, Semitendinosus, Gracilis, and Sartorius; *below the joint*, by the inner head of the Gastrocnemius.

Above, it is limited by the apposition of the inner and outer Hamstring muscles; *below*, by the junction of the two heads of the Gastrocnemius. The floor is formed by the lower part of the posterior surface of the shaft of the femur, the posterior ligament of the knee-joint, the upper end of the tibia, and the fascia covering the Popliteus muscle, and the space is covered in by the fascia lata.

Contents.—It contains the popliteal vessels and their branches, together with the termination of the external saphenous vein, the internal and external popliteal nerves and some of their branches, the lower extremity of the small sciatic nerve, the articular branch from the obturator nerve, a few small lymph nodes, and a considerable quantity of loose adipose tissue.

Position of Contained Parts.—The internal popliteal nerve descends in the middle line of the space lying superficial and crossing the artery from without inward. The external popliteal nerve descends on the outer side of the upper part of the space, lying close to the tendon of the Biceps muscle. More deeply at the bottom of the space are the popliteal vessels, the vein lying superficial to the artery, to which it is closely united by dense areolar tissue; it is a thick-walled vessel, and lies at first to the outer side of the artery, and then crosses it to gain the inner side below; sometimes the vein is double, the artery lying between the two venae comites, which are usually connected by short transverse branches. More deeply and, at its upper part, close to the surface of the bone is the popliteal artery, and passing off from it at right angles are its articular branches. The articular branch from the obturator nerve descends upon the popliteal artery to supply the knee, and occasionally there is found deep in the space an articular filament from the great sciatic nerve.

The popliteal lymph nodes, four or five in number, are found surrounding the artery; one usually lies superficial to the vessel;

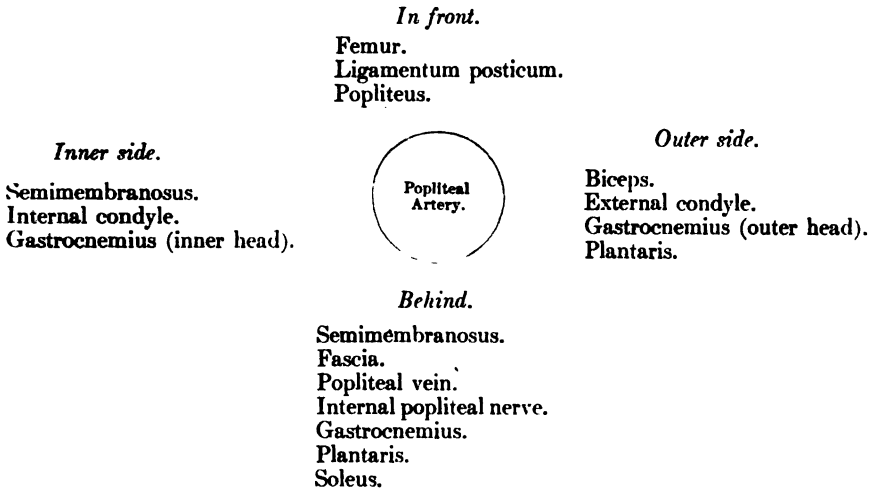

FIG. 483.—The popliteal, posterior tibial, and peroneal arteries.

another is situated between it and the bone, and the rest are placed on either side of it.

The **popliteal artery**, in its course downward from the aperture in the Adductor magnus to the lower border of the Popliteus muscle, rests first on the inner surface of the femur, and is then separated by a little fat from the hollowed popliteal surface of the bone; in the middle of its course it rests on the posterior ligament of the knee-joint, and below on the fascia covering the Popliteus muscle. *Superficially*, it is covered above by the Semimembranosus; in the middle of its course, by a quantity of fat, which separates it from the deep fascia and integument; and below it is overlapped by the Gastrocnemius, Plantaris, and Soleus muscles, the popliteal vein, and the internal popliteal nerve. The popliteal vein, which is intimately attached to the artery, lies superficial and external to it above; it then crosses it and lies to its inner side. The internal popliteal nerve is still more superficial and external above, but below the joint it crosses the artery and lies on its inner side. *Laterally*, the artery is bounded by the muscles which are situated on either side of the popliteal space.

PLAN OF THE RELATIONS OF THE POPLITEAL ARTERY.

Peculiarities in Point of Division.—Occasionally the popliteal artery divides prematurely into its terminal branches; this unusual division occurs most frequently opposite the knee-joint. The anterior tibial under these circumstances may pass in front of the Popliteus muscle.

Unusual Branches.—The artery sometimes divides into the anterior tibial and peroneal, the posterior tibial being wanting or very small. Occasionally the popliteal is found to divide into three branches, the anterior and posterior tibial and peroneal.

Surface Marking.—The course of the upper part of the popliteal artery is indicated by a line drawn from the outer border of the Semimembranosus muscle at the junction of the middle and lower third of the thigh obliquely downward to the middle of the popliteal space, exactly behind the knee-joint. From this point it passes vertically downward to the level of a line drawn through the lower part of the tubercle of the tibia.

Applied Anatomy.—The popliteal artery is not infrequently the seat of injury. It may be torn by direct violence, as by the passage of a cart-wheel over the knee or by hyperextension of the knee; and in the dead body, at all events, the middle and internal coats may be ruptured by extreme flexion. It may also be lacerated by fracture of the lower part of the shaft of the femur or by antero-posterior dislocation of the knee-joint. It has been torn in breaking down adhesions in cases of fibrous ankylosis of the knee, and is in danger of being wounded, and, in fact, has been wounded, in performing Macewen's operation for osteotomy of the lower end of the femur for genu valgum. In addition, Spencer records a case in which the popliteal artery was wounded from in front by a stab just below the knee, the knife passing through the interosseous space.

The popliteal artery is more frequently the seat of aneurism than is any other artery in the body, with the exception of the thoracic aorta. This is due, no doubt, in a great measure, to the amount of movement to which it is subjected, and to the fact that it is supported by loose and lax tissue only, and not by muscles, as is the case with most arteries.

Ligation of the popliteal artery is required in cases of wound of that vessel, but for aneurism of the posterior tibial it is preferable to tie the superficial femoral. The popliteal may be tied in the upper or lower part of its course; but in the middle of its course the operation is attended with considerable difficulty, from the great depth of the artery and from the extreme degree of tension of the lateral boundaries of the space.

In order to expose the vessel in the upper part of its course, the patient should be placed in the supine position, with the knee flexed and the thigh rotated outward, so that it rests on its outer surface; an incision three inches in length, beginning at the junction of the middle and lower third of the thigh, is to be made parallel to and immediately behind the tendon of the Adductor magnus, and the skin, superficial and deep fascia divided. The tendon of the muscle is thus exposed, and is to be drawn forward and the Hamstring tendons backward. A quantity of fatty tissue will now be exposed, in which the artery will be felt pulsating. This is to be separated with the point of a director until the artery is exposed. The vein and nerve will not be seen, as they lie to the outer side of the artery. The sheath is to be opened and the aneurism needle passed from before backward, keeping its point close to the artery for fear of injuring the vein. The only structure to avoid is the long saphenous vein in the superficial incision. The upper part of the popliteal artery may also be tied by an incision on the back of the limb, along the outer margin of the Semimembranosus, but the operation is a more difficult one, as the internal popliteal nerve and the popliteal vein are first exposed, and great care has to be exercised in separating them from the artery.

To expose the vessel in the lower part of its course, where the artery lies between the two heads of the Gastrocnemius, the patient should be placed in the prone position with the limb extended. An incision should then be made through the integument in the middle line, commencing opposite the bend of the knee-joint, care being taken to avoid the external saphenous vein and nerve. After dividing the deep fascia and separating some dense cellular membrane, the artery, vein, and nerve will be exposed, descending between the two heads of the Gastrocnemius. Some muscular branches of the popliteal should be avoided if possible, or, if divided, tied immediately. The leg being now flexed, in order the more effectually to separate the two heads of the Gastrocnemius, the nerve should be drawn inward and the vein outward, and the aneurism needle passed between the artery and vein from without inward.

Branches.—The branches of the popliteal artery are:

Muscular	{ Superior. Inferior or sural.
Cutaneous.	
Superior internal articular.	

Superior external articular.
Azygos articular.
Inferior internal articular.
Inferior external articular.

The **superior muscular branches**, two or three in number, *arise* from the upper part of the popliteal artery, and are distributed to the lower part of the Adductor magnus and Flexor muscles of the thigh, anastomosing with the fourth perforating branch of the profunda.

The **inferior muscular or sural** (*aa. surales*) are two large branches which are distributed to the two heads of the Gastrocnemius and to the Plantaris muscle. They *arise* from the popliteal artery opposite the knee-joint.

The **cutaneous branches** *arise* separately from the popliteal artery or from some of its branches; they descend between the two heads of the Gastrocnemius muscle, and, piercing the deep fascia, are distributed to the integument of the calf. One branch usually accompanies the short, or external, saphenous vein, the **superficial sural artery**.

The **superior articular arteries**, two in number, *arise* one on each side of the popliteal, and wind around the femur immediately above its condyles to the front of the knee-joint. The **internal branch** (*a. genu superior medialis*) winds inward beneath the Hamstring muscles, to which it supplies branches, above the inner head of the Gastrocnemius, and, passing beneath the tendon of the Adductor magnus, divides into two branches, one of which supplies the Vastus internus,

anastomosing with the anastomotica magna and inferior internal articular; the other ramifies close to the surface of the femur, supplying it and the knee-joint, and anastomosing with the superior external articular artery. This branch is frequently of small size, a condition which is associated with an increase in the size of the anastomotica magna. The **external branch** (*a. genu superior lateralis*) passes above the outer condyle, beneath the tendon of the Biceps, and divides into a superficial and deep branch; the superficial branch supplies the Vastus externus, and anastomoses with the descending branch of the external circumflex and the inferior external articular arteries; the deep branch supplies the lower part of the femur and knee-joint, and forms an anastomotic arch across the bone with the anastomotica magna and the inferior internal articular arteries.

The **azygos articular** (*a. genu media*) is a small branch arising from the popliteal artery opposite the bend of the knee-joint. It pierces the posterior ligament, and supplies the ligaments and synovial membrane in the interior of the articulation.

FIG. 484. — Circumpatellar anastomosis.

The **inferior articular arteries**, two in number, arise from the popliteal beneath the Gastrocnemius, and wind around the head of the tibia below the joint. The **internal branch** (*a. genu inferior medialis*) first descends along the upper margin of the Popliteus muscle, to which it gives branches; it then passes below the inner tuberosity, beneath the internal lateral ligament, at the anterior border of which it ascends to the front and inner side of the joint, to supply the head of the tibia and the articulation of the knee, anastomosing with the inferior external articular and superior internal articular arteries. The **external branch** (*a. genu inferior lateralis*) passes outward above the head of the fibula, to the front of the knee-joint, passing in its course beneath the outer head of the Gastrocnemius, the

external lateral ligament, and the tendon of the Biceps muscle, and divides into branches which anastomose with the inferior internal articular artery, the superior external articular artery, and the anterior recurrent branch of the anterior tibial.

Circumpatellar Anastomosis. —

Around and above the patella, and on the contiguous ends of the femur and tibia, is a large network of vessels, forming a superficial and a deep plexus. The superficial plexus is situated between the fascia and skin around about the patella; the deep plexus, which forms a close network of vessels, lies on the surface of the lower end of the femur and upper end of the tibia around their articular surfaces, and sends numerous offshoots into the interior of the joint. The arteries from which this plexus is formed are the two internal and two external articular branches of the popliteal, the anastomotica magna, the terminal branch of the profunda, the descending branch from the external circumflex, and the anterior recurrent branch of the anterior tibial.

FIG. 485.—Applied anatomy of the anterior tibial and dorsalis pedis arteries.

The Anterior Tibial Artery (A. Tibialis Anterior) (Fig. 485).

The anterior tibial artery commences at the bifurcation of the popliteal at the lower border of the Popliteus muscle, passes forward between the two heads of the Tibialis posticus, and through the large oval aperture above the upper border of the interosseous membrane to the deep part of the front of the leg; it here lies close to the inner side of the neck of the fibula; it then descends on the anterior surface of the interosseous membrane, gradually approaching the tibia; and at the lower part of the leg lies on this bone, and then on the anterior ligament of the ankle to the bend of the ankle-joint, where it lies more superficially, and becomes the **dorsalis pedis**.

Relations.—In the upper two-thirds of its extent it rests upon the interosseous membrane, to which it is connected by delicate fibrous arches thrown across it; in the lower third, upon the front of the tibia and

the anterior ligament of the ankle-joint. In the upper third of its course it lies between the *Tibialis anticus* and *Extensor longus digitorum*; in the middle third, between the *Tibialis anticus* and *Extensor proprius hallucis*. At the bend of the ankle it is crossed by the tendon of the *Extensor proprius hallucis*, and lies between it and the innermost tendon of the *Extensor longus digitorum*. It is covered, in the upper two-thirds of its course, by the muscles which lie on either side of it and by the deep fascia; in the lower third, by the integument anterior annular ligament and fascia.

The anterior tibial artery is accompanied by two veins, *venae comites*, which lie one on each side of the artery; the anterior tibial nerve, coursing around the outer side of the neck of the fibula, comes into relation with the outer side of the artery shortly after it has passed through the opening in the interosseous membrane; about the middle of the leg it is placed superficial to it; at the lower part of the artery the nerve is generally again on the outer side.

PLAN OF THE RELATIONS OF THE ANTERIOR TIBIAL ARTERY.

Interosseous membrane.

Tibia.

Anterior ligament of ankle-joint.

Peculiarities in Size.—This vessel may be very small, may be deficient to a greater or less extent, or may be entirely wanting, its place being supplied by perforating branches from the posterior tibial or by the anterior division of the peroneal artery.

Course.—The artery occasionally deviates in its course toward the fibular side of the leg, regaining its usual position beneath the annular ligament at the front of the ankle. In two instances the vessel has been found to approach the surface in the middle of the leg, being covered merely by the integument and fascia below that point.

Surface Marking.—Draw a line from the inner side of the head of the fibula to midway between the two malleoli. In this line take a point one inch and a quarter below the head of the fibula, and the portion of the line below this point will mark the course of the artery.

Applied Anatomy.—The anterior tibial artery may be tied in the upper or lower part of the leg. In the upper part the operation is attended with great difficulty, on account of the depth of the vessel from the surface. An incision, about four inches in length, should be made through the integument, midway between the tubercle of the tibia and the outer margin of the fibula, and the deep fascia exposed. The wound must now be carefully dried, its edges retracted, and the white line separating the *Tibialis anticus* from the *Extensor longus digitorum* sought for. When this has been clearly defined, the deep fascia is to be divided in this line, and the *Tibialis anticus* separated from the adjacent muscles with the handle of the scalpel or a director until the interosseous membrane is reached. The foot is to be flexed in order to relax the muscles, and upon drawing them apart the artery will be found lying on the interosseous membrane with the nerve on its outer side or on top of the artery. The nerve should be drawn outward, and the *venae comites* separated from the artery and the needle passed around it.

To tie the vessel in the lower third of the leg above the ankle-joint an incision about three inches in length should be made through the integument between the tendons of the *Tibialis anticus* and *Extensor proprius hallucis* muscles, the deep fascia being divided to the same extent. The tendon on either side should be held aside, when the vessel will be seen lying upon the tibia, with the nerve on the outer side and one of the *venae comites* on either side.

Branches.—The branches of the anterior tibial artery are:

Posterior recurrent tibial.

Superior fibular.

Anterior recurrent tibial.

Muscular.

Internal malleolar.

External malleolar.

The **posterior recurrent tibial** (*a. recurrens tibialis posterior*) is not a constant branch, and is given off from the anterior tibial before that vessel passes through the interosseous space. It ascends beneath the Popliteus muscle, which it supplies, and anastomoses with the lower articular branches of the popliteal artery, giving an offshoot to the superior tibiofibular joint.

The **superior fibular** is sometimes given off from the anterior tibial, sometimes from the posterior tibial. It passes outward, around the neck of the fibula, through the Soleus, which it supplies, and ends in the substance of the Peroneus longus.

The **anterior recurrent tibial** (*a. recurrens tibialis anterior*) arises from the anterior tibial as soon as that vessel has passed through the interosseous space; it ascends in the Tibialis anticus muscle, and ramifies on the front and sides of the knee-joint, anastomosing with the articular branches of the popliteal, with the anastomotica magna, and the external articular branches of the popliteal assisting in the formation of the circumpatellar plexus.

The **muscular branches** are numerous; they are distributed to the muscles which lie on each side of the vessel, some **cutaneous branches** piercing the deep fascia to supply the integument, others passing through the interosseous membrane, and anastomosing with branches of the posterior tibial and peroneal arteries.

The **internal malleolar branch** (*a. malleolaris anterior medialis*) arises about two inches above the articulation, and passes beneath the tendons of the Extensor proprius hallucis and Tibialis anticus to the inner ankle, upon which it ramifies, anastomosing with branches of the posterior tibial and internal plantar arteries and with the internal calcanean from the posterior tibial.

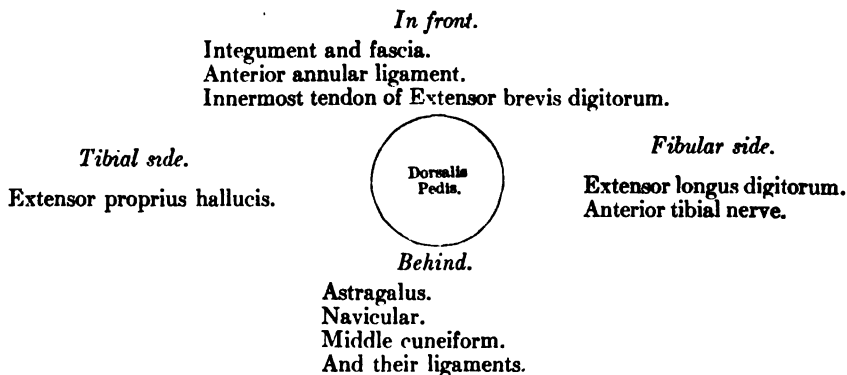

The **external malleolar branch** (*a. malleolaris anterior lateralis*) passes beneath the tendons of the Extensor longus digitorum and Peroneus tertius, and supplies the outer ankle, anastomosing with the anterior peroneal artery and with ascending branches from the tarsal branch of the dorsalis pedis.

The Dorsalis Pedis Artery (A. Dorsalis Pedis) (Figs. 485, 486).

The **dorsalis pedis**, the continuation of the anterior tibial, passes forward from the ankle along the tibial side of the foot to the back part of the first intermetatarsal space, where it divides into two branches, the **dorsalis hallucis** and **communicating**.

Relations.—This vessel, in its course forward, rests upon the astragalus, navicular, and middle cuneiform bones and the ligaments connecting them, being covered by the integument and fascia, anterior annular ligament, and crossed near its termination by the innermost tendon of the Extensor brevis digitorum. On its *tibial side* is the tendon of the Extensor proprius hallucis; on its *fibular side*, the innermost tendon of the Extensor longus digitorum, and the termination of the anterior tibial nerve. The nerve is, however, quite as often upon the tibial side of the artery. The artery is accompanied by two veins.

PLAN OF THE RELATIONS OF THE DORSALIS PEDIS ARTERY.

Peculiarities in Size.—The dorsal artery of the foot may be larger than usual, to compensate for a deficient plantar artery; or it may be deficient in its terminal branches to the toes, which are then derived from the internal plantar; or its place may be supplied altogether by a large anterior peroneal artery.

Position.—This artery frequently curves outward, lying external to the line between the middle of the ankle and the back part of the first interosseous space.

Surface Marking.—The dorsalis pedis artery is indicated on the surface of the dorsum of the foot by a line drawn from the centre of the space between the two malleoli to the back of the first intermetatarsal space.

Applied Anatomy.—This artery may be tied, by making an incision through the integument between two and three inches in length, on the fibular side of the tendon of the Extensor proprius hallucis, in the interval between it and the inner border of the short Extensor muscle. The incision should not extend farther forward than the back part of the first intermetatarsal space, as the artery divides in that situation. The deep fascia being divided to the same extent, the artery will be exposed, the nerve lying upon its outer side.

Branches. — The branches of the dorsalis pedis are:

- Cutaneous.
- Tarsal.
- Metatarsal — Interosseous.
- Dorsalis hallucis.
- Communicating.

Cutaneous branches go to the skin of the dorsum and inner surface of the foot.

The **tarsal artery** (*a. tarsea lateralis*) arises from the dorsalis pedis, as that vessel crosses the navicular bone; it passes in an arched direction outward, lying upon the tarsal bones, and covered by the Extensor brevis digitorum; it supplies

that muscle and the articulations of the tarsus, and anastomoses with branches from the metatarsal, external malleolar, peroneal, and external plantar arteries.

The **metatarsal** (*a. arcuata*) arises a little anterior to the preceding; it passes outward to the outer part of the foot, over the bases of the metatarsal bones, beneath the tendons of the short Extensor, its direction being influenced by its point of origin; and it anastomoses with the tarsal and external plantar arteries. This vessel gives off three branches, the **dorsal interosseous arteries** (*aa. metatarsae dorsales*), which pass forward upon the three outer Dorsal interossei muscles, and, in the clefts between the toes, divide into two dorsal collateral branches for the adjoining toes (*aa. digitales dorsales*). At the back part of each interosseous space these vessels receive the posterior perforating branches from the plantar arch, and at the fore part of each interosseous space they are joined by

FIG. 486.—Diagram of the arteries of the dorsal surface of the foot. (Poirier and Charpy.)

the anterior perforating branches from the digital arteries. The outermost interosseous artery gives off a branch which supplies the outer side of the little toe.

The **dorsalis hallucis**, or the **first dorsal interosseous** (*a. dorsalis hallucis*), is one of the terminal branches of the dorsalis pedis. It runs forward along the outer border of the first metatarsal bone, and at the cleft between the first and second toes divides into two branches, one of which passes inward, beneath the tendon of the Extensor proprius hallucis, and is distributed to the inner border of the great toe; the outer branch bifurcates, to supply the adjoining sides of the great and second toes.

The **communicating artery** (*ramus plantaris profundus*), the other terminal branch of the dorsalis pedis, dips down into the sole of the foot, between the two heads of the First dorsal interosseous muscle, and anastomoses with the termination of the external plantar artery, to complete the plantar arch. It here gives off its plantar digital branch, which is named the **arteria magna hallucis**, or the **princeps hallucis**. This artery passes forward along the first interosseous space, and, after sending a branch along the inner side of the great toe, bifurcates for the supply of the adjacent sides of the great and second toes.

The Posterior Tibial Artery (**A. Tibialis Posterior**) (Fig. 483).

The **posterior tibial** is an artery of large size, which extends obliquely downward from the lower border of the Popliteus muscle, along the tibial side of the leg, to the fossa between the inner malleolus and the heel, where it divides beneath the origin of the Abductor hallucis, on a level with a line drawn from the point of the internal malleolus to the centre of the convexity of the heel, into the **internal** and **external plantar arteries**. At its origin it lies opposite the interval between the tibia and fibula; as it descends, it approaches the inner side of the leg, lying behind the tibia, and, in the lower part of its course, is situated midway between the inner malleolus and the tuberosity of the os calcis.

Relations.—The posterior tibial artery lies successively upon the Tibialis posticus, the Flexor longus digitorum, the tibia, and the back part of the ankle-joint. It is covered by the deep transverse fascia, which separates it above from the Gastrocnemius and Soleus muscles; at its termination it is covered by the Abductor hallucis muscle. In the lower third, where it is more superficial, it is covered only by the integument and fascia, and runs parallel with the inner border of the tendo Achillis. It is accompanied by two veins and by the posterior tibial nerve, which lies at first to the inner side of the artery, but soon crosses it, and is, in the greater part of its course, on its outer side.

PLAN OF THE RELATIONS OF THE POSTERIOR TIBIAL ARTERY.

<i>In front.</i>		
Tibialis posticus.		
Flexor longus digitorum.		
Tibia.		
Ankle-joint.		
<i>Inner side.</i>		<i>Outer side.</i>
Posterior tibial nerve, upper third.		Posterior tibial nerve, lower two-thirds.
<i>Behind.</i>		
Integument and fascia.		
Gastrocnemius.		
Soleus.		
Deep transverse fascia.		
Posterior tibial nerve.		
Abductor hallucis.		

Behind the inner malleolus the tendons and bloodvessels are arranged, under cover of the internal annular ligament, in the following order, from within outward: First, the tendons of the *Tibialis posticus* and *Flexor longus digitorum*, lying in the same groove, behind the inner malleolus, the former being the most internal. External to these is the posterior tibial artery, having a vein on either side, and, still more externally, the posterior tibial nerve. About half an inch nearer the heel is the tendon of the *Flexor longus hallucis*.

Peculiarities in Size.—The posterior tibial is not infrequently smaller than usual, or absent, its place being supplied by a large peroneal artery which passes inward at the lower end of the tibia, and either joins the small tibial artery or continues alone to the sole of the foot.

Surface Marking.—The course of the posterior tibial artery is indicated by a line drawn from a point one inch below the centre of the popliteal space to midway between the tip of the internal malleolus and the centre of the convexity of the heel.

Applied Anatomy.—The application of a ligature to the posterior tibial may be required in cases of wound of the sole of the foot attended with great hemorrhage, when the vessel should be tied at the inner ankle. In cases of wound of the posterior tibial it will be necessary to enlarge the opening so as to expose the vessel at the wounded point, excepting where the vessel is injured by a punctured wound from the front of the leg. In cases of aneurism from wound of the artery low down, the vessel should be tied in the middle of the leg. But in aneurism of the posterior tibial high up it would be better to tie the femoral artery.

To tie the posterior tibial artery at the ankle, a semilunar incision, convex backward, should be made through the integument, about two inches and a half in length, midway between the heel and the inner ankle or a little nearer the latter. The subcutaneous cellular tissue having been divided, a strong and dense fascia, the internal annular ligament, is exposed. This ligament is continuous above with the deep fascia of the leg, covers the vessels and nerves, and is intimately adherent to the sheaths of the tendons. This having been cautiously divided upon a director, the sheath of the vessels is exposed, and, being opened, the artery is seen with one of the *venae comites* on each side. The aneurism needle should be passed around the vessel from the heel toward the ankle, in order to avoid the posterior tibial nerve, care being taken at the same time not to include the *venae comites*.

The vessel may also be tied in the lower third of the leg by making an incision, about three inches in length, parallel with the inner margin of the *tendo Achillis*. The internal saphenous vein being carefully avoided, the two layers of fascia must be divided upon a director, when the artery is exposed along the outer margin of the *Flexor longus digitorum*, with one of its *venae comites* on either side and the nerve lying external to it.

To tie the posterior tibial in the middle of the leg is a very difficult operation, on account of the great depth of the vessel from the surface. The patient being placed in the recumbent position, the injured limb should rest on its outer side, the knee being partially bent and the foot extended, so as to relax the muscles of the calf. An incision about four inches in length should then be made through the integument a finger's breadth behind the inner margin of the tibia, taking care to avoid the internal saphenous vein. The deep fascia having been divided, the margin of the *Gastrocnemius* is exposed, and must be drawn aside, and the tibial attachment of the *Soleus* divided, a director being previously passed beneath it. The artery may now be felt pulsating beneath the deep fascia about an inch from the margin of the tibia. The fascia having been divided, and the limb placed in such a position as to relax the muscles of the calf as much as possible, the veins should be separated from the artery, and the aneurism needle passed around the vessel from without inward, so as to avoid wounding the posterior tibial nerve.

Branches.—The branches of the posterior tibial artery are:

Peroneal.	Cutaneous.
Nutrient.	Communicating.
Muscular.	Internal calcaneal.
Malleolar cutaneous.	

The **peroneal artery** (*a. peronaea*) (Fig. 483) lies, deeply seated, along the back part of the fibular side of the leg. It arises from the posterior tibial about an inch below the lower border of the *Popliteus* muscle, passes obliquely outward to the fibula, and then descends along the inner border of that bone, contained in a fibrous canal between the *Tibialis posticus* and the *Flexor longus hallucis*, or in the substance of the latter muscle to the lower third of the leg, where it gives off the **anterior peroneal**. It then passes across the articulation between the tibia and fibula to the outer side of the *os calcis*, where it gives off its terminal branches, the **external calcaneal**.

Relations.—This vessel rests at first upon the Tibialis posticus, and then, for the greater part of its course, in a fibrous canal between the origins of the Flexor longus hallucis and Tibialis posticus, covered or surrounded by the fibres of the Flexor longus hallucis. It is *covered*, in the upper part of its course, by the Soleus and deep transverse fascia; *below*, by the Flexor longus hallucis.

PLAN OF THE RELATIONS OF THE PERONEAL ARTERY.

Peculiarities in Origin.—The peroneal artery may arise three inches below the Popliteus, or from the posterior tibial high up, or even from the popliteal.

Its size is more frequently increased than diminished; and then it either reinforces the posterior tibial by its junction with it, or altogether takes the place of the posterior tibial in the lower part of the leg and foot, the latter vessel only existing as a short muscular branch. In those rare cases where the peroneal artery is smaller than usual a branch from the posterior tibial supplies its place, and a branch from the anterior tibial compensates for the diminished anterior peroneal artery. In one case the peroneal artery has been found entirely wanting.

The anterior peroneal is sometimes enlarged, and takes the place of the dorsal artery of the foot.

Branches.—The branches of the peroneal are:

Muscular.	Communicating.
Nutrient.	Posterior peroneal.
Anterior peroneal.	External calcaneal.

Muscular Branches.—The peroneal artery in its course gives off branches to the Soleus, Tibialis posticus, Flexor longus hallucis, and Peronei muscles.

The **nutrient artery** (*a. nutricia fibulae*) supplies the fibula.

The **anterior peroneal** (*ramus perforans*) (Fig. 486) pierces the interosseous membrane, about two inches above the outer malleolus, to reach the fore part of the leg, and, passing down beneath the Peroneus tertius to the outer ankle, ramifies on the front and outer side of the tarsus, anastomosing with the external malleolar and tarsal arteries.

The **communicating** (*ramus communicans*) is given off from the peroneal about an inch from its lower end, and, passing inward, joins the communicating branch of the posterior tibial.

The **posterior peroneal** passes down behind the outer ankle to the back of the external malleolus, to terminate in branches which ramify on the outer surface and back of the os calcis.

The **external calcaneal** (*ramus calcaneus lateralis*) are the terminal branches of the peroneal artery; they pass to the outer side of the heel, and communicate with the external malleolar, and, on the back of the heel, with the internal calcaneal arteries.

Cutaneous branches come from the posterior tibial and supply the skin of the inner side and back of the leg.

The **nutrient artery** of the tibia (*c. nutricia tibiae*) arises from the posterior tibial near its origin, and, after supplying a few muscular branches, enters the

nutrient canal of that bone, which it traverses obliquely from above downward. This is the largest nutrient artery of bone in the body.

The **muscular branches** of the posterior tibial are distributed to the Soleus and deep muscles along the back of the leg.

The **communicating branch** (*ramus communicans*), to join a similar branch of the peroneal, runs transversely across the back of the tibia, about two inches above its lower end, passing beneath the Flexor longus hallucis.

The **malleolar** or **internal malleolar** (*a. malleolaris posterior medialis*) lies upon the tibia, sends branches over the inner ankle, and anastomoses with the inner malleolar branch of the anterior tibial.

The **internal calcaneal** (*rami calcanei mediales*) are several large arteries which *arise* from the posterior tibial just before its division; they are distributed to the fat and integument behind the tendo Achillis and about the heel, and to the muscles on the inner side of the sole, anastomosing with the peroneal and internal malleolar, and, on the back of the heel, with the external calcaneal arteries.

FIG. 487.—The plantar arteries. Superficial view.

FIG. 488.—The plantar arteries. Deep view.

The **internal plantar artery** (*a. plantaris medialis*) (Figs. 487 and 488), much smaller than the external, passes forward along the inner side of the foot. It is at first situated above¹ the Abductor hallucis, and then between it and the Flexor brevis digitorum, both of which it supplies. At the base of the first metatarsal bone, where it has become much diminished in size, it passes along the inner border of the great toe, anastomosing with its digital branch. Small superficial digital branches (*ramus superficialis*) accompany the digital branches of the medial plantar nerve and join the plantar digital arteries of the three inner spaces. In addition, this vessel gives off numerous cutaneous branches.

The **external plantar artery** (*a. plantaris lateralis*) (Figs. 487 and 488), much larger than the internal, passes obliquely outward and forward to the base of the

¹ This refers to the erect position of the body. In the ordinary position for dissection the artery is deeper than the muscle.

fifth metatarsal bone. It then turns obliquely inward to the interval between the bases of the first and second metatarsal bones, where it anastomoses with the communicating branch from the *dorsalis pedis* artery, thus completing the **plantar arch** (*arcus plantaris*) (Fig. 488). As this artery passes outward, it is first placed between the *os calcis* and *Abductor hallucis*, and then between the *Flexor brevis digitorum* and *Flexor accessorius*, and as it passes forward to the base of the little toe it lies more superficially between the *Flexor brevis digitorum* and *Abductor minimi digiti*, covered by the deep fascia and integument. The remaining portion of the vessel is deeply situated; it extends from the base of the metatarsal bone of the little toe to the back part of the first interosseous space, and forms the plantar arch; it is convex forward, lies below or on the plantar aspect of the tarsal ends of the second, third, and fourth metatarsal bones and the corresponding Interosseous muscles and upon the *Adductor obliquus hallucis*.

Surface Marking.—The course of the internal plantar artery is represented by a line drawn from the mid-point between the tip of the internal malleolus and the centre of the convexity of the heel to the middle of the under surface of the great toe; the external plantar by a line from the same point to within a finger's breadth of the tuberosity of the fifth metatarsal bone. The plantar arch is indicated by a line drawn from this point—i. e., a finger's breadth internal to the tuberosity of the fifth metatarsal bone transversely across the foot to the back of the first interosseous space.

Applied Anatomy.—Wounds of the plantar arch are always serious, on account of the depth of the vessel and the important structures which must be interfered with in an attempt to ligate it. They must be treated on similar lines to those of wounds of the palmar arches (see page 654). Delorme has shown that the plantar arch may be ligated from the dorsum of the foot in almost any part of its course by removing a portion of one of the three middle metatarsal bones.

Branches.—The plantar arch, besides distributing numerous branches to the muscles, integument, and fasciæ in the sole, gives off the following branches:

Posterior perforating.

Digital.

The **posterior perforating** (*rami perforantes posteriores*) are three small branches which ascend through the back part of the three outer interosseous spaces, between the heads of the *Dorsal interossei* muscles, and anastomose with the interosseous branches from the metatarsal artery.

The **digital branches** (*aa. metatarsæ plantares*) are four in number, and supply the three outer toes and half the second toe. It will be remembered that the *arteria princeps hallucis* is the plantar digital branch of the communicating rami in the first interosseous space and supplies the adjacent sides of the great and second toes. The *first digital branch* of the plantar arch passes outward from the outer side of the plantar arch, and is distributed to the outer side of the little toe, passing in its course beneath the *Abductor* and short *Flexor* muscles. The *second, third, and fourth* run forward along the interosseous spaces, and on arriving at the clefts between the toes each divides into **collateral digital branches** (*aa. digitales plantares*), which supply the adjacent sides of the three outer toes and the outer side of the second. At the bifurcation of the toes each digital artery sends upward, through the fore part of the corresponding interosseous space, a small branch which anastomoses with the interosseous branches of the metatarsal artery. These are the **anterior perforating branches** (*rami perforantes anteriores*).

From the description given it will be seen that both sides of the three outer toes and the outer side of the second toe are supplied by branches from the plantar arch; both sides of the great toe and the inner side of the second are supplied by the communicating branch of the *dorsalis pedis* (*princeps hallucis*).

THE VEINS.

THE **Veins** convey the blood from the capillaries of the different parts of the body toward the heart. They consist of two distinct sets of vessels, the **pulmonary** and **systemic veins**, and an appendage to the systemic, the **portal system**.

The **Pulmonary Veins** are concerned in the circulation of the blood through the lungs. Unlike other vessels of this kind, they contain arterial blood, which they return from the lungs to the left auricle of the heart.

FIG. 489.—Valves of a vein. In the lower part of the figure are seen the parietal valves; the upper part shows the mouth of a vein guarded by a valve. (Poirier and Charpy.)

FIG. 490.—Collateral anastomosis of veins. The arrows indicate the direction of the flow of blood (schematic). (Poirier and Charpy.)

The **Systemic Veins** are concerned in the general circulation; they return the venous blood from the body generally to the right auricle of the heart.

The **Portal Vein** and its radicles constitute the portal system. The portal system is in reality an appendage to the systemic venous system, and is confined to the abdominal cavity, returning the venous blood from the viscera of the digestive system, and carrying it to the liver by a single trunk of large size, the **portal vein**. This vessel ramifies in the substance of the liver and breaks up into a minute network of capillaries. These capillaries then re-collect to form the **hepatic veins**, by which the blood is conveyed to the inferior vena cava.

The veins, like the arteries, are found in nearly every tissue of the body. They commence by minute plexuses which receive the blood from the capillaries. The

branches which have their commencement in these plexuses unite into trunks, and these, in their passage toward the heart, constantly increase in size as they receive tributaries or join other veins. The veins are larger and altogether more numerous than the arteries; hence the capacity of the venous system is much greater than that of the arterial, the pulmonary veins excepted, which only slightly exceed in capacity the pulmonary arteries. From the combined area of the smaller venous tributaries being greater than the main trunks, it results that the venous system represents a cone, the summit of which corresponds to the heart, its base to the periphery of the body. In form the veins are cylindrical, like the arteries, their walls being collapsed when empty, and the uniformity of their surface being interrupted at intervals by slight dilatations, which indicate the existence of valves in their interior (Fig. 489). They usually retain, however, about the same calibre as long as they receive no tributaries, but not so uniformly as do the arteries.

The veins communicate very freely with one another (Fig. 491), especially in certain regions of the body, and this communication exists between the larger trunks as well as between the smaller tributaries. Thus, in the cavity of the cranium and between the veins of the neck, where obstruction would be attended with imminent danger to the cerebral venous system, we find that the sinuses and larger veins have large

FIG. 491.—The venous circle of Braune (schematic). The arrows indicate the direction of the blood current. (Poirier and Charpy.)

FIG. 492.—Part of a cross-section of the vena cava inferior of a dog. (Szymonowicz.)

and very frequent anastomoses (Fig. 490). The same free communication exists throughout the whole extent of the vertebral canal, and between the veins composing the various venous plexuses in the abdomen and pelvis, as the spermatic, uterine, vesical, and prostatic.

Veins have thinner walls than arteries, the difference in thickness being due to the small amount of elastic and muscular tissues which the veins contain. The superficial veins usually have thicker coats than the deep veins, and the veins of the lower limb are thicker than those of the upper.

Histology of the Veins.—As previously stated, capillaries enter into **venules** or **post-capillary veins**. The venules empty into larger veins. Vein walls are much thinner than arterial walls. A vein has a much thinner **media** and much less elastic tissue than an artery,

and a very strongly developed **adventitia**. The **intima** is a connective-tissue layer containing a small number of elastic fibres and lined with endothelium. The internal elastic lamina is usually poorly developed. The valves are duplications of the intima. The **media** consists chiefly of white fibrous tissue containing some circular muscle fibres and some fine elastic fibres. In some veins the media is thoroughly well developed (veins of the lower extremities), in others it is practically absent (veins of the retina, of the pia, of bone, the superior vena cava). The **adventitia** is dense and strong, and is composed of fibroelastic tissue and non-striated muscle fibres longitudinally placed. Fig. 492 shows a transverse section of part of the wall of a vein. The large veins and the veins of medium size possess vasa vasorum, in the adventitia and to some extent in the media. The walls of veins contain vasomotor nerves. Lymph capillaries often surround the smaller bloodvessels and sometimes by spaces lined with endothelium and which are in communication with the lymphatic system; these spaces are called **perivascular lymph spaces**.

The systemic veins are subdivided into three sets—**superficial**, **deep**, and **sinuses**.

The **Superficial** or **Outaneous Veins** are found between the layers of the superficial fascia, immediately beneath the integument; they return the blood from these structures, and communicate with the deep veins by perforating the deep fascia.

The **Deep Veins** accompany the arteries, and are usually enclosed in the same sheath with those vessels. With the smaller arteries—as the radial, ulnar, brachial, tibial, and peroneal—they exist generally in pairs, one lying on each side of the vessel, and are called **venae comites**. The larger arteries—as the axillary, subclavian, popliteal, and femoral—have usually only one accompanying vein. In certain organs of the body, however, the deep veins do not accompany the arteries; for instance, the veins in the skull and vertebral canal, the hepatic veins in the liver, and the larger veins returning blood from the osseous tissue.

Sinuses are venous channels which, in their structure and mode of distribution, differ altogether from the veins. They are found only in the interior of the skull, and consist of channels formed by a separation of the two layers of the dura, their outer coat consisting of fibrous tissue, their inner of an endothelial layer continuous with the lining membrane of the veins.

THE PULMONARY VEINS (V. PULMONALES) (Fig. 493).

The **pulmonary veins** return the arterialized blood from the lungs to the left auricle of the heart. They are four in number, two for each lung, and are destitute of valves. They commence in a capillary network upon the walls of the air-cells, where they are continuous with the capillary ramifications of the pulmonary artery, and uniting, form one vessel for each lobule. These vessels, uniting successively form a single trunk for each lobe, three for the right and two for the left lung. The vein from the middle lobe of the right lung generally unites with that from the upper lobe. Thus, two trunks are formed on each side, which open separately into the left auricle. Occasionally the three veins on the right side remain separate. Not infrequently the two left pulmonary veins terminate by a common opening.

Within the lung, the branches of the pulmonary artery are *in front*, the veins *behind*, and the bronchi *between* the two.

At the root of the lung, the upper pulmonary vein lies in front of and a little below the pulmonary artery; the lower is situated below the other structures in the lung root, and on a plane posterior to the upper vein; behind the pulmonary artery is the bronchus.

Within the pericardium, their anterior surfaces are invested by the serous layer of this membrane. The right pulmonary veins pass behind the right auricle and ascending aorta and superior vena cava; the left pass in front of the thoracic aorta.

Applied Anatomy.—*Thrombosis* of larger or smaller tributaries of the pulmonary veins is common in inflamed areas of the lung; or as a consequence of pressure from tumors, but it does not give rise to any special symptoms.

FIG. 493.—Pulmonary veins, seen in a dorsal view of the heart and lungs. The left lung is pulled to the left, and the right lung has been partly cut away to show the ramifications of the air tubes and bloodvessels. (Testut.)

THE SYSTEMIC VEINS.

The **systemic veins** may be arranged into three groups: (1) The **cardiac veins**, which open directly into the right auricle of the heart. (2) Those of the **head and neck, upper extremity, and thorax**, which terminate in the superior vena cava. (3) Those of the **lower extremity, abdomen, and pelvis**, which terminate in the inferior vena cava.

THE CARDIAC VEINS.

The **coronary sinus** (*sinus coronarius*) is a wide venous channel about an inch in length which receives the majority of the veins draining the blood from the substance of the heart. It is situated in the posterior part of the auriculo-ventricular groove, and is covered by muscle fibres from the left auricle. It terminates in the right auricle between the opening of the inferior vena cava and the auriculoventricular aperture, its orifice being guarded by a semilunar valve, the **coronary valve, or valve of Thebesius**.

Tributaries.—

Great cardiac or left coronary.

Middle cardiac.

Small cardiac or right coronary.

Posterior vein of the left ventricle.

Oblique vein of Marshall.

1. The **great cardiac or left coronary vein** (*v. cordis magna*) begins at the apex of the heart and ascends along the anterior interventricular groove to the base of the ventricles. It then curves to the left in the auriculoventricular groove to the back of the heart, and opens into the left extremity of the coronary sinus. It receives tributaries from the left auricle, and from both ventricles; one of these, the **left marginal vein**, is of considerable size, and ascends along the left margin of the heart.

2. The **small cardiac or right coronary vein** (*v. cordis parva*) runs in the groove between the right auricle and ventricle, and opens into the right extremity of the coronary sinus. It receives blood from the back of the right auricle and ventricle; its largest tributary, the **right marginal vein**, ascends along the right margin of the heart and joins it in the auriculoventricular groove.

3. The **middle cardiac vein** (*v. cordis media*) commences at the apex of the heart, ascends in the posterior interventricular groove, and ends in the coronary sinus near its right extremity.

FIG. 494.—Cardiac veins, dorsal view. (Testut.)

4. The **posterior vein of the left ventricle** (*v. posterior ventriculi sinistri*) ascends on the back of the left ventricle to the coronary sinus, but may end in the great cardiac vein.

5. The **oblique vein of Marshall** (*v. obliqua atrii sinistri*) is a small vessel which descends obliquely on the back of the left auricle and ends in the coronary sinus near its right extremity; it is continuous above with the *vestigial fold of Marshall*, and the two structures form the remnant of the left Cuvierian duct.

The following cardiac veins do not terminate in the coronary sinus: (1) The **anterior cardiac veins** (*vv. cordis anteriores*), comprising three or four small vessels which collect blood from the front of the right ventricle and open into the right auricle. The right marginal vein frequently opens into the right auricle, and is therefore sometimes regarded as belonging to this group. (2) The **veins of Thebesius** (*vv. cordis minimae*), consisting of a number of minute veins which arise in the muscular wall of the heart; the majority open into the auricles, but a few empty their blood into the ventricles.

VEINS OF THE HEAD AND NECK.

The veins of the head and neck may be subdivided into three groups: (1) The veins of the exterior of the head and face. (2) The veins of the neck. (3) The veins of the diploë and the interior of the cranium.

Veins of the Exterior of the Head and Face (Fig. 495).

The veins of the exterior of the head and face are:

Frontal.
Supraorbital.
Angular.
Facial.

Superficial temporal.
Internal maxillary.
Temporomaxillary.
Posterior auricular.

Occipital.

The **frontal vein** (*v. frontalis*) commences on the anterior part of the skull in a venous plexus which communicates with the anterior tributaries of the superficial temporal vein. The veins converge to form a single trunk, which runs downward near the middle line of the forehead parallel with the vein of the opposite side. The two veins are joined, at the root of the nose, by a transverse branch called the **nasal arch** (*v. nasofrontalis*), which receives some small veins from the dorsum of the nose. Occasionally the frontal veins join to form a single trunk, which bifurcates at the root of the nose into the two angular veins. At the root of the nose the veins diverge and join the supraorbital vein, at the inner angle of the orbit, to form the angular vein.

The **supraorbital vein** (*v. supraorbitalis*) commences on the forehead, communicating with the anterior temporal vein, and runs downward and inward, superficial to the Occipitofrontalis muscle, receiving tributaries from the neighboring structures, and from the frontal vein of the diploë, and joins the frontal vein at the inner angle of the orbit to form the angular vein. Previous to its junction with the frontal vein, it sends through the supraorbital notch into the orbit a branch which communicates with the ophthalmic vein. As this vessel passes through the notch, it receives a diploic vein from the diploë of the frontal bone, through a foramen at the bottom of the notch.

The **angular vein** (*v. angularis*), formed by the junction of the frontal and supraorbital veins, runs obliquely downward and outward on the side of the root of the nose to the level of the lower margin of the orbit, where it becomes the facial vein. It receives the veins of the ala nasi on its inner side and the superior palpebral veins on its outer side; it, moreover, communicates with the ophthalmic vein, thus establishing an important anastomosis between the facial vein and the cavernous sinus.

The **facial vein** (*v. facialis anterior*) commences at the side of the root of the nose, being a direct continuation of the angular vein. It lies behind and follows a less tortuous course than the facial artery. It passes obliquely downward and outward, beneath the Zygomaticus major and minor muscles, descends along the anterior border of the Masseter, crosses over the body of the mandible with the facial artery to beneath the angle, and unites with the anterior division of the temporomaxillary vein (*v. facialis posterior*) to form the common facial vein.

The **common facial vein** (*v. facialis communis*) is formed by the union of the facial and the anterior division of the temporomaxillary vein, just beneath the angle of the mandible. The vein is covered by the Platysma, runs downward and

backward beneath the Sternomastoid muscle, crosses the external carotid artery, and empties into the internal jugular vein at the level of the hyoid line. It receives a large communicating branch at the anterior border of the Sternomastoid muscle, which comes from the anterior jugular vein in the suprasternal fossa.

Tributaries of Facial Veins.—The facial vein receives, near the angle of the mouth, communicating tributaries of considerable size, the deep facial (or anterior internal maxillary vein), from the pterygoid plexus. It is also joined by the inferior palpebral, the superior and inferior labial veins, the buccal veins from the cheek,

FIG. 495.—Veins of the head and neck.

and the masseteric veins. The common facial vein receives the submental; the inferior palatine, which returns the blood from the plexus around the tonsil and soft palate; the submaxillary vein, which commences in the submaxillary gland; and, generally, the ranine vein.

Applied Anatomy.—There are some points about the facial vein which render it of great importance in surgery. It is not so flaccid as are most superficial veins, and, in consequence of this, remains more patent when divided. It has, moreover, no valves. It communicates freely

with the intracranial circulation, not only at its commencement by its tributaries, the angular and supraorbital veins, communicating with the ophthalmic vein, a tributary of the cavernous sinus, but also by its deep tributaries, which communicates through the pterygoid plexus with the cavernous sinus by tributaries which pass through the foramen ovale and foramen lacerum medium. These facts have an important bearing upon the surgery of some diseases of the face, for on account of its patency the facial vein favors septic absorption, and therefore any phlegmonous inflammation of the face following a poisoned wound is liable to set up thrombosis in the facial vein, and detached portions of the clot may give rise to purulent foci in other parts of the body. On account of its communications with the cerebral sinuses these thrombi are apt to extend upward into them and so induce a fatal issue.

The **superficial temporal vein** (*vv. temporales superficiales*) commences by a minute plexus on the side and vertex of the skull, which communicates with the frontal and supraorbital veins in front, the corresponding vein of the opposite side, and the posterior auricular and occipital veins behind. From this network anterior and posterior branches are formed which unite above the zygoma, forming the trunk of the vein. The trunk is joined in this situation by a large vein, the **middle temporal** (*v. temporalis media*), which receives blood from the substance of the Temporal muscle and pierces the fascia at the upper border of the zygoma. The junction of the superficial temporal and the middle temporal vein forms the **common temporal vein** (*v. temporalis communis*), which descends between the external auditory meatus and the condyle of the mandible, enters the substance of the parotid gland, and unites with the internal maxillary vein to form the **temporomaxillary vein**.

Tributaries.—The common temporal vein receives in its course some parotid veins, an articular branch from the articulation of the mandible, anterior auricular veins from the external ear, and a vein of large size, the **transverse facial** (*v. transversa faciei*), from the side of the face. The middle temporal vein, previous to its junction with the temporal vein, receives a branch, the **orbital vein** (*v. orbitalis*), which is formed by some external palpebral branches, and passes backward between the layers of the temporal fascia.

The **pterygoid plexus** (*plexus pterygoideus*) is of considerable size, and is situated between the Temporal and External pterygoid, and partly between the two Pterygoid muscles. It receives tributaries corresponding with the branches of the internal maxillary artery. Thus, it receives the middle meningeal veins, the deep temporal, the pterygoid, masseteric, buccal, alveolar, some palatine veins, the inferior dental, and a branch which communicates with the ophthalmic vein through the sphenomaxillary fissure. This plexus communicates very freely with the facial vein and with the cavernous sinus by branches through the foramen Vesalii, foramen ovale, and foramen lacerum medium, at the base of the skull.

The **internal maxillary vein** (*v. maxillaris interna*) is a short trunk which accompanies the first part of the internal maxillary artery. It is formed by a confluence of the veins of the pterygoid plexus, and passes backward between the internal lateral ligament and the neck of the mandible, and unites with the superficial temporal vein to form the temporomaxillary vein.

The **temporomaxillary vein** (*v. facialis posterior*), formed by the union of the superficial temporal and internal maxillary veins, descends in the substance of the parotid gland, superficial to the external carotid artery, but beneath the facial nerve between the ramus of the mandible and the Sternomastoid muscle. It divides into two vessels, an *anterior*, sometimes called the **deep facial vein**, which passes inward to join the facial vein, and a *posterior*, which is joined by the posterior auricular vein and becomes the external jugular.

The **posterior auricular vein** (*v. auricularis posterior*) commences upon the side of the head by a plexus which communicates with the tributaries of the temporal and occipital veins. It descends behind the external ear, and joins the posterior division of the temporomaxillary vein, forming the external jugular.

It receives the stylomastoid vein and some tributaries from the back part of the external ear.

The **occipital vein** (*v. occipitalis*) commences in a plexus at the back part of the vertex of the skull. From the plexus the vein follows the course of the occipital artery, passing deeply beneath the muscles of the back part of the neck, and terminating in the suboccipital triangle by becoming continuous with the posterior vertebral vein (*v. cervicalis profunda*). Sometimes it is more superficial, and in this case is a tributary of the external jugular vein. As it passes across the mastoid portion of the temporal bone, it receives the mastoid vein, which thus establishes a communication with the lateral sinus.

The Veins of the Neck (Fig. 495).

The veins of the neck, which return the blood from the head and face, are:

External jugular.

Anterior jugular.

Posterior external jugular.

Internal jugular.

Vertebral.

The **external jugular vein** (*v. jugularis externa*) receives the greater part of the blood from the exterior of the cranium and deep parts of the face, and is formed by the junction of the posterior division of the temporomaxillary and the posterior auricular veins. It commences in the substance of the parotid gland, on a level with the angle of the mandible, and runs perpendicularly down the neck in the direction of a line drawn from the angle of the mandible to the middle of the clavicle. In its course it crosses the Sternomastoid muscle, and runs parallel with its posterior border as far as its attachment to the clavicle, where it perforates the deep fascia, and terminates in the subclavian vein, on the outer side of, or in front of, the Scalenus anticus muscle. It is separated from the Sternomastoid by the investing layer of the deep cervical fascia, and is covered by the Platysma, the superficial fascia, and the integument. This vein crosses about its middle the superficial cervical nerve, and throughout the upper half of its course is accompanied by the great auricular nerve. The external jugular vein varies in size, bearing an inverse proportion to that of the other veins of the neck; it is occasionally double. It is provided with two pairs of valves, the lower pair being placed at its entrance into the subclavian vein, the upper pair in most cases about an inch and a half above the clavicle. The portion of vein between the two sets of valves is often dilated, and is termed the **sinus**. These valves do not prevent the regurgitation of the blood or the passage of injection masses from below upward.

Tributaries.—This vein receives the occipital occasionally, the posterior external jugular, and, near its termination, the suprascapular, transverse cervical, and anterior jugular veins; in the substance of the parotid gland a large branch of communication from the internal jugular joins it.

The **posterior external jugular vein** (*v. jugularis posterior*) commences in the occipital region, and returns the blood from the integument and superficial muscles in the upper and back part of the neck, lying between the Splenius and Trapezius muscles. It runs down the back part of the neck, and opens into the external jugular just below the middle of its course.

The **anterior jugular vein** (*v. jugularis anterior*) commences near the hyoid bone from the convergence of the inferior labial coronary, the submental and the mental veins, and communicating branches. It passes down between the median line and the anterior border of the Sternomastoid, and at the lower part of the

neck passes beneath that muscle to open into the termination of the external jugular, or, in some instances, into the subclavian vein (Fig. 515). It varies considerably in size, bearing almost always an inverse proportion to the external jugular. Most frequently there are two anterior jugulars, a right and left, but occasionally only one. Its tributaries are some laryngeal veins, and occasionally a small thyroid vein. Just above the sternum the two anterior jugular veins communicate by a transverse trunk, which receives tributaries from the inferior thyroid veins; each also communicates with the internal jugular. There are no valves in this vein.

The **internal jugular vein** (*v. jugularis interna*) collects the blood from the interior of the cranium, from the superficial parts of the face, and from the neck. It is directly continuous with the lateral sinus, and *commences* in the posterior compartment of the jugular foramen, at the base of the skull (Fig. 507). At its origin it is somewhat dilated, and this dilatation is called the **sinus** or **bulb** of the **internal jugular vein** (*bulbus v. jugularis superior*). The vein runs down the side of the neck in a vertical direction, lying at first on the outer side of the internal carotid artery, and then on the outer side of the common carotid artery, and at

FIG. 496.—Veins of the tongue. (Testut, modified from Hirschfeld.)

the root of the neck unites with the subclavian vein to form the innominate vein. Just before its termination it is again distinctly dilated (*bulbus v. jugularis inferior*). The internal jugular vein, at its *commencement*, lies upon the Rectus capitis lateralis, and behind the internal carotid artery and the nerves passing through the jugular foramen; lower down, the vein and artery lie upon the same plane, the glossopharyngeal and hypoglossal nerves passing forward between them; the vagus descends between and behind them in the same sheath, and the spinal accessory passes obliquely outward, behind or in front of the vein. At the root of the neck the vein of the right side is placed at a little distance from the artery; on the left side it usually lies over the artery at its lower part. The right internal jugular vein crosses the first part of the subclavian artery. The internal jugular vein is of considerable size, but varies in different individuals, the left one being usually the smaller. It is provided with a pair of valves, which are placed about an inch above its termination.

Tributaries.—This vein receives in its course the inferior petrosal sinus, the common facial, lingual, pharyngeal, superior, and middle thyroid veins, and sometimes the occipital. A tributary from the cochlea opens into the bulb of the internal jugular vein. A venous plexus from the lateral sinus (*plexus venosus*

caroticus internus) surrounds the internal carotid artery in the carotid canal and empties into the internal jugular vein. At its point of junction with the common facial vein it becomes increased in size. (See Facial Veins, p. 712.)

The **inferior petrosal sinus** leaves the skull through the anterior compartment of the jugular foramen, and joins the vein near its commencement. Sometimes the inferior petrosal sinus is not a direct tributary of the internal jugular vein, the blood being conveyed to it by a venous plexus in the hypoglossal canal.

FIG. 497.—The veins of the neck, viewed from in front. (Spalteholz.)

The **lingual veins** (*vv. linguales*) (Fig. 496) *commence* on the dorsum, sides, and under surface of the tongue, and, passing backward along the course of the lingual artery and its branches, terminate in the internal jugular. The **ranine vein**, a tributary of considerable size *commencing* below the tip of the tongue, may join the lingual; generally, however, it passes backward on the Hyoglossus muscle in company with the hypoglossal nerve, and joins the facial. The lingual veins receive the sublingual and the dorsal lingual veins.

The **pharyngeal veins** (*vv. pharyngeae*) *commence* in the **pharyngeal plexus** on the wall of the pharynx, and, after receiving meningeal tributaries, the dural or meningeal veins, the Vidian veins, and the sphenopalatine veins, terminate in the internal jugular. They occasionally open into the facial, lingual, or superior thyroid vein.

The **superior thyroid vein** (*v. thyroidea superioris*) (Fig. 497) *commences* in the substance and on the surface of the thyroid gland by tributaries corresponding

FIG. 498.—Diagram showing common arrangement of thyroid veins. (Kocher.)

FIG. 499.—The fascia and middle thyroid veins. The veins here designated the inferior thyroid are called by Kocher the *thyroidea ima*. (Poirier and Charpy.)

with the branches of the superior thyroid artery, and terminates in the upper part of the internal jugular vein. It receives the superior laryngeal and crico-thyroid veins.

The **middle thyroid vein** (Fig. 483) collects the blood from the lower part of the lateral lobe of the thyroid gland, and after being joined by some veins from the larynx and trachea, terminates in the lower part of the internal jugular vein. Often in place of the middle thyroid vein there are two veins, the **superior and inferior accessory thyroid**. These veins pass into the internal jugular.

The **facial and occipital veins** have been described on pages 712 and 715.

Applied Anatomy.—The internal jugular vein occasionally requires ligation in cases of *septic thrombosis of the lateral sinus* from suppuration of the middle ear. This is done in order to prevent septic emboli being carried into the general circulation. This operation has been performed in a number of cases, with satisfactory results. The cases are generally those of chronic disease of the middle ear, with discharge of pus which perhaps has existed for many years. The patient is seized with acute septic inflammation, spreading to the mastoid cells, and, consequent on this, septic thrombosis of the lateral sinus extending to the internal jugular vein. Such cases are always extremely grave, for there is danger that a portion of the septic clot will be detached and cause septic embolism in the thoracic viscera. If thrombophlebitis of the sinus is suspected the mastoid should be opened and cleansed and the sinus should be at once exposed and explored. If the sinus is found to be thrombosed the surgeon should at once proceed to ligate the internal jugular vein, by an incision along the anterior border of the sternomastoid, the centre of which is on a level with the greater cornu of the hyoid bone. The vein should be ligated in two places or opened between. After the vessel has been secured and divided the lateral sinus is to be thoroughly cleared out, and, by removing the ligature from the upper end of the divided vein, all septic clots may be removed by syringing from the sinus through the vein. If hemorrhage occurs from the distal end of the sinus, it can be arrested by careful plugging with gauze.

The internal jugular vein is also surgically important, because it is surrounded by a large number of the deep chain of cervical lymph nodes; and when these are enlarged in tuberculous or malignant disease, they are liable to become adherent to the vessel, rendering their removal difficult and often dangerous. The proper course to pursue in these cases is to ligate the vessel above and below the glandular mass, and resect the included portion together with the nodes.

Cardiac pulsation is often demonstrable in the internal jugular vein at the root of the neck. There are no valves in the innominate veins or superior vena cava; in consequence, the systole of the right auricle causes a wave to pass up these vessels, and when the conditions are favorable this wave appears as a somewhat feeble flicker over the internal jugular vein at the root of the neck, quite distinct from, and just preceding, the more forcible impulse transmitted from the underlying common carotid artery and due to the ventricular systole.¹ This auricular systolic venous impulse is much increased in conditions in which the right auricle is abnormally distended with blood or is hypertrophied, as is often the case in disease of the mitral valves. In Stokes-Adams' disease (p. 568) it is this pulsation which gives evidence of the fact that the auricles are beating faster—often two or three times faster—than the ventricles.

The **vertebral vein** (*v. vertebralis*) (Fig. 500) is formed in the suboccipital triangle, from numerous small tributaries which spring from the intraspinal venous plexuses (*plexus venosi vertebrales*) and issue from the vertebral canal above the posterior arch of the atlas. They unite with small veins from the deep muscles at the upper and back part of the neck, and form a vessel which passes outward and enters the foramen in the transverse process of the atlas, and descends, forming a dense plexus around the vertebral artery, in the canal formed by the foramina in the transverse processes of the cervical vertebræ. This plexus unites at the lower part of the neck into a single trunk, which emerges from the foramen in the transverse process of the sixth cervical vertebra, and terminates at the root of the neck in the back part of the innominate vein near its origin, its mouth being guarded by a pair of valves. On the right side, it crosses the first part of the subclavian artery.

Tributaries.—In its course the vertebral vein communicates with a vein transmitted from the lateral sinus of the skull through the posterior condylar foramen. It anastomoses with the occipital vein and receives muscular veins from the muscles in the prevertebral region; intraspinal veins, from the back part of the cervical portion of the vertebral column; meningeoarachnoid veins, from the interior of

¹ The Interpretation of the Venous Pulse, by G. Bachmann, Amer. Jour. Med. Sci., November, 1908.

the vertebral canal; the anterior and posterior vertebral veins; and close to its termination it is sometimes joined by the first intercostal vein.

The **anterior vertebral vein** *commences* in a plexus around the transverse processes of the upper cervical vertebræ, descends in company with the ascending cervical artery between the Scalenus anticus and Rectus capitis anticus major muscles, and opens into the vertebral vein just before its termination.

FIG. 500. — The vertebral vein. (Poirier and Charpy.)

The **posterior vertebral** or **posterior deep cervical vein** (*v. cervicalis profunda*) (Fig. 500) accompanies the deep cervical artery, lying between the Complexus and Semispinalis colli. It *commences* in the suboccipital region by communicating branches from the occipital vein and tributaries from the deep muscles at the back of the neck. It receives tributaries from the plexuses around the spinous processes of the cervical vertebræ; and terminates in the lower end of the vertebral vein.

The Veins of the Diploë (Venæ Diploicae) (Fig. 501).

The diploic spaces of the cranial bones in the adult contain a number of tortuous canals, the **diploic canals** (*canales diploici* [*Brescheti*]), which are bounded by a more or less complete layer of compact osseous tissue. The veins they contain are large and capacious, their walls being thin, and formed only of endothelium resting upon a layer of elastic tissue; they present at irregular intervals pouch-like dilatations, or *culs-de-sac*, which serve as reservoirs for the blood.

In adult life, so long as the cranial bones are distinct and separable, these veins are confined to the particular bones; but in old age, when the sutures are united, they communicate with one another and increase in size. They communicate, in the interior of the cranium, with the veins and the sinuses of the dura, and on the exterior of the skull with the veins of the pericranium. They consist

of (1) the **frontal diploic vein** (*v. diploica frontalis*), which opens into the supra-orbital vein by an aperture in the supraorbital notch; (2) the **anterior temporal diploic vein** (*v. diploica temporalis anterior*), which is confined chiefly to the frontal bone, and opens into one of the deep temporal veins through an aperture in the greater wing of the sphenoid; (3) the **posterior temporal vein** (*v. diploica temporalis posterior*), which is situated in the parietal bone, and terminates in the lateral sinus through an aperture at the postero-inferior angle of the parietal bone or through the mastoid foramen; and (4) the **occipital diploic vein** (*v. diploica occipitalis*), the largest of the four, which is confined to the occipital bone, and opens into the lateral sinus or the torcular Herophili.

The **emissary veins** are considered on page 730.

FIG. 501.—Veins of the diploë as displayed by the removal of the outer table of the skull.

The **meningeal or dural veins** (*vv. meningeae*) chiefly correspond with the middle meningeal artery and its branches, as its two *venae comites*. The veins accompany the middle meningeal artery, are united to the sphenoparietal sinus, pass through the foramen spinosum, and join the pterygoid plexus. The other dural veins correspond somewhat to the anterior and posterior meningeal distribution and empty into the neighboring sinuses.

The Cerebral Veins (*Venae Cerebri*).

The **cerebral veins** possess no valves, and their walls, owing to the absence of muscle tissue, are extremely thin. They pierce the arachnoid membrane and the inner or meningeal layer of the dura and open into the cranial venous sinuses. They may be divided into two sets, cerebral and cerebellar.

The cerebral veins consist of (a) the **superficial veins**, which are placed on the surface of the brain, and (b) the **deep veins**, which lie in its interior.

The **superficial cerebral veins** (*venae cerebri externae*) ramify upon the surface of the brain, being lodged in the fissures between the convolutions, a few running across the convolutions. They receive tributaries from the substance of the brain and terminate in the sinuses. They are divisible into two sets, superior and inferior.

The **superior cerebral veins** (*vv. supercerebrales*, *vv. cerebri superiores*), eight to twelve in number on each side, return the blood from the convolutions on the superior surface of the hemisphere; they pass forward and inward toward the intercerebral fissure, where they receive the veins from the mesal surface of the hemisphere; near their terminations they become invested with tubular sheaths of the arachnoid, and open into the longitudinal sinus in the opposite direction to the course of the current of the blood in the sinus.

The **inferior cerebral veins** (*vv. subcerebrales*, *vv. cerebri inferiores*) ramify on the lower part of the outer and on the under surfaces of the cerebral hemisphere. Some, collecting tributaries from the under surface of the frontal lobes of the brain, terminate in the cavernous sinus. One vein of large size, the **middle cerebral or superficial sylvian vein** (*v. cerebri media*), commences on the under surface of the temporal lobe, and, running along the sylvian fissure, opens into the cavernous sinus. Another large vein, the **great anastomotic vein of Trolard**, connects the superior sagittal sinus with the cavernous sinus by becoming continuous above with one of the superior cerebral veins and below by joining the middle cerebral vein. A third, the **posterior anastomotic vein** connects the middle cerebral vein with the lateral sinus by coursing over the temporal lobe. A fourth, the **basilar vein** (*v. basilis* [*Rosenthalii*]), is formed at the anterior perforated spot by the union of (a) a small **anterior cerebral vein**, which accompanies the anterior cerebral artery (b) the **deep sylvian vein**, which receives tributaries from the island of Reil (or insula) and neighboring convolutions, and runs in the lower part of the sylvian fissure; and (c) the **inferior striate veins**, which leave the corpus striatum through the anterior perforated substance. The basilar vein passes backward around the crus cerebri, and ends in the vein of Galen; it receives tributaries from the interpeduncular space, the descending horn of the lateral ventricle, the uncinate gyre, and the mid-brain. Small inferior cerebral veins from the under surface of the frontal lobe end in the cavernous sinus; others from the temporal lobe terminate in the superior petrosal and lateral sinuses.

The **deep cerebral veins, or veins of Galen** (*venae Galeni*, *vv. cerebri internae*) (Fig. 723), are two in number. Each is formed by the union of two veins, the **vena corporis striati**, and the **choroid vein**, on either side. They run backward, parallel with each other, between the layers of the velum interpositum, and beneath the splenium, and in the region of the pineal body unite to form a short trunk, the **vena magna Galeni** (*v. cerebri magna*), which passes out of the brain at the great transverse fissure, and ends in the anterior extremity of the straight sinus. The two velar veins receive tributaries from the callosal region, from a portion of the occipital lobe, and just before their union each vein receives the corresponding basilar vein. Each vena magna Galeni also receives the superior cerebellar veins.

The **vena corporis striati** on each side *commences* in the groove between the corpus striatum and thalamus, receives numerous veins from both of these parts, and unites behind the anterior pillars of the fornix, with the choroid vein to form one of the *venae Galeni*.

The **choroid vein** (*v. choroidea*) originates in the extreme end of the middle horn of the lateral ventricle and runs along the whole length of the outer border of the choroid plexus, receiving veins from the hippocampus, the fornix, and corpus callosum, and unites, at the anterior extremity of the choroid plexus, with the vein of the corpus striatum to form the vena Galeni of that side.

The **superficial cerebellar veins** (Fig. 721) occupy the surface of the cerebellum, and are disposed in two sets, **superior** and **inferior**.

The **superior superficial cerebellar veins** (*vv. supercerebellares*, *vv. cerebelli superiores*) pass partly forward and inward, across the superior vermis (*prevermis*), to terminate in lateral branches which pass partly to the tentorial sinus and partly outward to the lateral and superpetrosal sinuses.

The **subcerebellar** or **inferior superficial cerebellar veins** (*vv. subcerebellares, vv. cerebelli inferiores*), of large size, terminate in the lateral, subpetrosal, and occipital sinuses.

The **deep cerebellar veins** bring blood from the interior of the cerebellum to the superficial veins.

Veins of the Pons.—Veins come from the interior of the pons, the **deep veins**, and empty into a plexus of **superficial veins**. From this superficial venous plexus a **superior vein** passes to the basilar vein, and an **inferior vein** either into a cerebellar vein or into the superpetrosal sinus.

Veins of the Medulla Oblongata.—Veins pass from the interior of the medulla oblongata and end in a plexus on the surface. From this plexus comes an **anterior median vein**, which is a prolongation of a like vein of the spinal cord—a **posterior median vein** corresponding to a like vein of the cord—and small branches which pass with the roots of the glossopharyngeal, vagus, spinal accessory, and hypoglossal nerves, and empty into the occipital and the subpetrosal sinuses.

The perivascular lymph spaces are especially found in connection with the vessels of the brain. These vessels are enclosed in a sheath, which acts as a lymphatic channel, through which the lymph is carried to the subarachnoid and subdural spaces, from which it is returned into the general circulation.

The Sinuses of the Dura (*Sinus Durae Matris*) (Figs. 502, 503). Ophthalmic Veins and Emissary Veins.

The **sinuses of the dura** are venous channels which drain the blood from the brain; they are situated between the two layers of the dura and are lined by endothelium continuous with that which lines the veins. They are sixteen in number, of which six are single and situated in the mesal plane; the other ten are paired, five being placed on either side of the mesal plane. They are divided into two sets: (1) Those situated at the upper and back part of the skull; (2) those at the base of the skull. The former are:

Superior sagittal sinus.

Inferior sagittal sinus.

Tentorial or straight sinus.

Lateral sinuses.

Occipital sinus.

The **superior sagittal sinus** (*sinus longitudinalis, sinus sagittalis superior* (Figs. 502 and 503) occupies the attached margin of the falx cerebri. Commencing at the foramen cecum, through which it usually communicates by a small branch with the veins of the nasal fossæ, it runs from before backward, grooving the inner surface of the frontal, the adjacent margins of the two parietals, and the superior division of the crucial ridge of the occipital; near the internal occipital protuberance it usually deviates toward the right, and is continued as the corresponding lateral sinus. The sinus is triangular on transverse section, is narrow in front, and gradually increases in size as it passes backward. Its inner surface presents the internal openings of the superior cerebral veins, which run, for the most part, from behind forward, and open chiefly at the back part of the sinus, their orifices being concealed by valve-like folds; numerous fibrous bands, **chordæ Willisi** (Fig. 504), are also seen extending transversely across the inferior angle of the sinus; and some small, white, projecting bodies, the **glandulae Pacchioni** (*granulationes arachnoidales*). This sinus communicates by numerous small apertures with spaces in the dura known as **lacunae laterales**, or **parasinoïdal spaces** (Fig. 504). The arachnoid villi project into these spaces. The superior sagittal sinus receives the superior cerebral veins, numerous veins from the diploë and

dura, the outlets of the parasinoidal spaces, and, at the posterior extremity of the sagittal suture, veins from the pericranium, which pass through the parietal foramina. Sometimes the sagittal sinus receives a twig from the nose which passes through the foramen cecum.

FIG. 502.—Coronal section of the skull to show the situations and shapes of the chief sinuses. (Poirier and Charpy.)

The **inferior sagittal sinus** (*sinus falcialis*, *sinus sagittalis inferior*) (Fig. 503) is contained in the posterior half or two-thirds of the free margin of the falx. It is of a cylindric form, increases in size as it passes backward, and terminates in the straight sinus. It receives several veins from the falx cerebri, and occasionally a few from the mesal surface of the hemispheres.

FIG. 503.—Sagittal section of the skull, showing the sinuses of the dura.

The **straight or tentorial sinus** (*sinus tentorii*, *sinus rectus*) (Figs. 502 and 503) is situated at the line of junction of the falx cerebri with the tentorium cerebelli. It is triangular on section, increases in size as it proceeds backward, and runs obliquely downward and backward from the termination of the inferior sigittal

sinus to the lateral sinus of the opposite side to that into which the sagittal sinus is prolonged. Its terminal part communicates by a cross-branch with the torcular Herophili (*confluence of the sinuses*). Besides the inferior sagittal sinus, it receives the vena magna Galeni and the superior cerebellar veins. A few transverse bands cross its lumen.

The **lateral sinuses** (Figs. 502 and 503) are of large size and *commence* at the internal occipital protuberance; one, generally the right, being the direct continuation of the superior sagittal sinus, the other of the straight sinus. Each lateral sinus (*sinus transversus*, BNA) passes outward and forward, describing a slight curve with its convexity upward, to the base of the petrous portion of the temporal bone, and is situated, in this part of its course, in the attached margin of the

FIG 504.—Sagittal sinus seen from above after removal of the skullcap. The chordae Willisii are clearly visible. The parasinoidal sinuses are also well shown. Probes passing from the latter to the longitudinal sinus show that they communicate. (Poirier and Charpy.)

tentorium cerebelli; it then leaves the tentorium, curves downward and inward to reach the jugular foramen, where it terminates in the internal jugular vein. In its course it rests upon the inner surface of the occipital, the postero-inferior angle of the parietal, the mastoid portion of the temporal bone, and on the occipital again, at the jugular process, just before its termination. The portion of the sinus which occupies the groove on the mastoid portion of the temporal bone is known as the **sigmoid sinus**. The lateral sinuses are frequently of unequal size, that formed by the sagittal sinus being the larger, and they increase in size as they proceed from behind forward. The horizontal portion is triangular on section, the curved portion semicylindric. Their inner surface is smooth, and not crossed by the fibrous bands found in the other sinuses. The lateral sinuses receive the blood from the superior petrosal sinuses at the base of the petrous portion of

the temporal bone, and they unite with the inferior petrosal sinus, just external to the jugular foramen, to form the internal jugular vein (Fig. 508). They communicate with the veins of the pericranium by means of the mastoid and posterior condylar veins, and they receive some of the inferior cerebral and inferior cerebellar veins, some veins from the diploë, and often veins from the internal ear (*vv. auditivæ internæ*), which come out of the internal auditory meatus. The **petrosquamous sinus**, when present, runs backward along the junction of the petrous and squamous portions of the temporal bone, and opens into the lateral sinus.

Applied Anatomy.—The lateral sinus may, as a result of middle-ear disease, be attacked by suppurative inflammation, which leads to blocking (*septic thrombophlebitis*). In such a case the surgeon will be obliged to open the sinus to remove the infected clot and tie the internal jugular vein to intercept thrombi. The line overlying the sinus is as follows: Draw a line horizontally outward from the occipital protuberance to a point one inch posterior to a vertical line drawn through the external auditory meatus, and from this point drop a second line to the mastoid process.

The **occipital sinus** (*sinus occipitalis*) (Fig. 503) is the smallest of the cranial sinuses. It is generally single, but occasionally there are two. It is situated in the attached margin of the falx cerebelli. It commences by several small veins around the margin of the foramen magnum, one of which joins the termination of the lateral sinus; it communicates with the posterior spinal veins and terminates in the torcular Herophili.

The **torcular Herophili**, or **confluence of the sinuses** (*confluens sinuum*), is the term applied to the dilated extremity of the superior sagittal sinus. It is of irregular form, and is lodged on one side (generally the right) of the internal occipital protuberance. From it the lateral sinus of the side to which it is deflected is derived. It also receives the blood from the occipital sinus, and is connected across the middle line with the commencement of the lateral sinus of the opposite side.

The sinuses at the base of the skull are:

Two cavernous sinuses.	Two superior petrosal sinuses.
Two sphenoparietal sinuses.	Two inferior petrosal sinuses.
Circular sinus.	Transverse sinus.

The **cavernous sinuses** (Figs. 507 and 508) are so named because they present a reticulated structure, due to their being traversed by numerous interlacing filaments (Fig. 505). They are of irregular form, larger behind than in front, and are placed one on each side of the sella turcica, extending from the sphenoidal fissure to the apex of the petrous portion of the temporal bone. Each cavernous sinus (*sinus cavernosus*) receives anteriorly the superior ophthalmic vein through the sphenoidal fissure, and opens behind into the petrosal sinuses. On the inner wall of each sinus is the internal carotid artery, accompanied by filaments of the carotid plexus and by the abducent nerve; and on its outer wall, the oculomotor, trochlear, ophthalmic, and superior maxillary divisions of the trigeminal nerve (Fig. 505). These parts are separated from the blood flowing along the sinus by the lining membrane, which is continuous with the inner coat of the veins. Each cavernous sinus receives some of the cerebral veins, and also the sphenoparietal sinus. It communicates with the lateral sinus by means of the superior petrosal sinus; with the internal jugular vein through the inferior petrosal sinus and through a plexus of veins on the internal carotid artery; with the pterygoid plexus through the foramen ovale, and with the angular vein through the ophthalmic vein. The two sinuses also communicate with each other by means of the circular sinus.

Applied Anatomy.—An arteriovenous communication may be established between the cavernous sinus and the carotid artery, as it lies in it, giving rise to a *pulsating tumor* in the orbit. Such a communication may be the result of injury, such as a bullet wound, a stab, or a blow or fall sufficiently severe to cause a fracture of the base of the skull in this situation, or it may occur from the rupture of an aneurism or a diseased condition of the internal carotid artery. The disease begins with sudden noise and pain in the head, followed by exophthalmos, swelling

FIG. 505.—Frontal section through the right cavernous sinus, enlarged. (Spalteholz.)

and congestion of the lids and conjunctivæ. A pulsating tumor develops at the margin of the orbit, with thrill and the characteristic bruit; accompanying these symptoms there may be impairment of the sight, paralysis of the iris and orbital muscles, and pain of varying intensity. In some cases the opposite orbit becomes affected by the passage of the arterial blood into the opposite sinus by means of the circular sinus. Or the arterial blood may find its way through the emissary veins into the pterygoid plexus, and thence into the veins of the face. Pulsating

FIG. 506.—Veins of the orbit. (Poirier and Charpy.)

tumors of the orbit may also be due to traumatic aneurism of one of the orbital arteries, and symptoms resembling those of pulsating tumor may be produced by pressure on the ophthalmic vein, as it enters the sinus, by an aneurism of the internal carotid artery. Ligation of the internal or the common carotid artery has been performed in these cases with some degree of success.

Of recent years more attention has been paid to thrombosis of the cavernous sinus than formerly, and it is now well established that carries in the upper parts of the nasal fossæ and sup-

puration in certain of the accessory sinuses of the nose, are frequently responsible for septic thrombosis of the cavernous sinuses, in exactly the same way as lateral sinus thrombosis is due to septic disease in the mastoid process. Many deaths from meningitis, hitherto unaccounted for, are in reality due to the spread of an infection from an ethmoidal or sphenoidal air cell to the cavernous sinus, and thence to the meninges. It is obvious, therefore, that no case of chronic nasal suppuration should be left untreated.

The **sphenoparietal sinuses** may be regarded, together with the ophthalmic veins, as the commencement of the corresponding cavernous sinuses. Each of these sinuses (*sinus sphenoparietalis*) is lodged in the dura on the under surface of the lesser wing of the sphenoid bone. It takes origin from one of the middle meningeal veins, usually receives blood from the diploë of the skull, passes inward, and ends in the anterior part of the cavernous sinus.

The **ophthalmic veins** are two in number, **superior** and **inferior**.

The **superior ophthalmic vein** (*v. ophthalmica superior*) (Fig. 506) begins as the **nasofrontal vein** (*v. nasofrontalis*), which communicates with the angular vein at the inner angle of the orbit. It joins the angular vein with the cavernous sinus;

it pursues the same course as the ophthalmic artery, and receives tributaries corresponding to the branches derived from that vessel. Forming a short single trunk, it passes through the inner extremity of the sphenoidal fissure, and terminates in the cavernous sinus. It anastomoses with the inferior ophthalmic vein and receives lacrimal, anterior and posterior ethmoidal, and muscular branches, and veins of the eyelids and of the eyeball (*vv. vorticosae*).

The **inferior ophthalmic vein** (*v. ophthalmica inferior*) (Fig. 506) arises in the veins of the eyelids and lacrimal sac, receives the veins from the floor of

FIG. 507.—The sinuses at the base of the skull.

the orbit, and either passes out of the orbit through the sphenoidal fissure to join the pterygoid plexus of veins, or else, passing backward through the sphenoidal fissure, it enters the cavernous sinus, either by a separate opening, or, more frequently, in common with the superior ophthalmic vein. It receives muscular tributaries and veins of the eyeball, and anastomoses with the superior ophthalmic and the deep facial vein.

The **circular sinus** (*sinus circularis*) (Figs. 505 and 507) is formed by two transverse vessels, the **anterior** and **posterior intracavernous sinuses** (*sinus intercavernosus anterior* and *sinus intercavernosus posterior*), which connect the two cavernous sinuses; one passes in front and the other behind the pituitary body, and thus they form with the cavernous sinuses a venous circle around that body. The anterior one is usually the larger of the two, and one or other is occasionally absent.

The **superior petrosal sinus** (*sinus superpetrosus, sinus petrosus superior*) (Figs. 503 and 507) is situated along the superior border of the petrous portion of the temporal bone, in the front part of the attached margin of the tentorium cerebelli. It is small and narrow, and connects the cavernous and lateral sinuses at each side. It receives some cerebellar and inferior cerebral veins, and veins from the tympanic cavity.

The **inferior petrosal sinus** (*sinus subpetrosus, sinus petrosus inferior*) (Figs. 503 and 508) is situated in the groove formed by the junction of the posterior border of the petrous portion of the temporal with the basilar process of the occipital bone. It commences in front at the termination of the cavernous sinus, and passing through the anterior compartment of the jugular foramen, ends in the commencement of the internal jugular vein. The inferior petrosal sinus receives a vein from the internal ear (*vv. auditivae internae*) and also veins from the medulla oblongata, pons, and under surface of the cerebellum.

FIG. 508.—Relation of nerves to sinuses in jugular foramen. (Henle.)

The exact relation of the parts to one another in the foramen is as follows: The inferior petrosal sinus is in front, with the meningeal branch of the ascending pharyngeal artery, and is directed obliquely downward and backward; the lateral sinus is situated at the back part of the foramen with a meningeal branch of the occipital artery, and between the two are the glossopharyngeal, vagus, and spinal accessory nerves (Fig. 508). These three sets of structures are divided from each other by two processes of fibrous tissue. The junction of the inferior petrosal sinus with the internal jugular vein takes place superficial to the nerves, so that these latter lie a little internal to the venous channels in the foramen (Fig. 508).

The **transverse or basilar sinus** (*plexus basilaris*) (Figs. 507 and 508) consists of several interlacing veins between the layers of the dura over the basilar process of the occipital bone, which serve to connect the two inferior petrosal sinuses. They communicate with the anterior spinal veins.

The **emissary veins** (*emissaria*) are vessels which pass through apertures in the cranial wall and establish communications between the sinuses inside the skull and the diploic veins in the diploë, and the veins external to the skull. Some of these are always present, others only occasionally so. They vary much in size in different individuals. The principal emissary veins are the following: (1) A vein (*emissarium mastoideum*) almost always present, runs through the mastoid foramen and connects the lateral sinus with the posterior auricular or with the occipital vein. (2) A vein (*emissarium parietale*) which passes through the parietal foramen and connects the superior sagittal sinus with the veins of the scalp. (3) A plexus of minute veins (*rete canalis hypoglossi*), which pass through the anterior condylar (hypoglossal) foramen and connect the occipital sinus with the vertebral vein and deep veins of the neck. (4) An inconstant vein (*emissarium condyloideum*) which passes through the posterior condylar foramen and connects the lateral sinus with the deep veins of the neck. (5) A plexus of veins (*rete foraminis ovalis*) connects the cavernous sinus with the pterygoid and pharyngeal plexuses through the foramen ovale. (6) Two or three small veins run through the foramen lacerum medium and connect the cavernous sinus with the pterygoid and pharyngeal plexuses. (7) There is sometimes a small vein connecting the same parts and passing through the inconstant foramen of Vesalius opposite the root of the pterygoid process of the sphenoid bone. (8) A plexus of veins (*plexus venosus caroticus internus*) traverses the carotid canal and connects the cavernous sinus with the internal jugular vein. (9) A small vein (*emissarium occipitale*) usually connects the occipital vein with the lateral sinus or the torcular Herophili and the occipital diploic vein. (10) A vein is usually transmitted through the foramen cecum and connects the superior sagittal sinus with the veins of the mucous membrane of the nose.

Applied Anatomy.—These emissary veins are of great importance in surgery. In addition to them there are, however, other communications between the intra- and extracranial circulation, as, for instance, the communication of the angular and supraorbital veins with the ophthalmic vein at the inner angle of the orbit, and the communication of the veins of the scalp with the diploic veins. Through these communications inflammatory processes commencing on the outside of the skull may travel inward, leading to osteophlebitis of the diploë and inflammation of the membranes of the brain. To this in former days was to be attributed one of the principal dangers of scalp wounds and other injuries of the scalp.

By means of these emissary veins blood may be abstracted almost directly from the intracranial circulation. For instance, leeches applied behind the ear abstract blood almost directly from the lateral sinus by means of the vein passing through the mastoid foramen. Again, epistaxis in children will frequently relieve severe headache, the blood which flows from the nose being derived from the superior sagittal sinus by means of the vein which passes through the foramen cecum.

VEINS OF THE UPPER EXTREMITY AND THORAX.

The **veins of the upper extremity** are divided into two sets, **superficial** and **deep**.

The **Superficial Veins** are placed immediately beneath the integument between the layers of the superficial fascia.

The **Deep Veins** accompany the arteries, and constitute the *venae comites* of those vessels.

Both sets of vessels are provided with valves, which are more numerous in the deep than in the superficial veins.

FIG. 509.—The veins on the dorsum of the hand. (Bourguery.)

The Superficial Veins of the Upper Extremity (Fig. 510).

The superficial veins of the upper extremity are:

Superficial veins of the hand.
Anterior ulnar.
Posterior ulnar.
Common ulnar.
Radial.

Median.
Median cephalic
Median basilic.
Basilic.
Cephalic.

The **superficial veins of the hand and fingers** (Figs. 509 and 510) are principally situated on the dorsal surface. These dorsal veins *begin* in each finger as a venous plexus, in which are distinct veins running in a longitudinal direction and called **dorsal digital veins** (*vv. digitales dorsales propriae*). The dorsal digital veins terminate over the first phalanges in the **venous arches of the fingers** (*arcus*

venosi digitales). From these arches take origin the four **dorsal interosseous** or the **interdigital veins** (*vv. metacarpeae dorsales*). These veins form the **dorsal**

venous plexus of the hand (*rete venosum dorsale manus*). This plexus lies in a line with the lower ends of the shafts of the metacarpal bones. It receives the dorsal interosseous veins, the radial digital vein of the index finger, and numerous superficial veins from the back of the hand. It gives origin to the superficial radial vein and the posterior ulnar vein. The superficial veins of the palmar surface are of less size and number than the dorsal veins. They arise from each of the phalanges by a plexus (*vv. digitales volares propriae*). Vessels at the borders of the fingers take most of the blood to the dorsal veins. There are also veins in the finger webs (*vv. intercapitulares*), which convey the blood from the palm to the dorsum. A superficial plexus, the **palmar plexus**, lies upon the palmar fascia, the fascia of the thenar eminence, and the fascia of the hypothenar eminence.

The **anterior ulnar vein** (*v. ulnaris anterior*) (Fig. 510) commences on the anterior surface of the ulnar side of the hand and wrist, and ascends along the anterior surface of the ulnar side of the forearm to the bend of the elbow, where it joins with the posterior ulnar vein to form the common ulnar. Occasionally it opens separately into the median basilic vein. It communicates with tributaries of the median vein in front and with the posterior ulnar behind.

The **posterior ulnar vein** (*v. ulnaris posterior*) (Fig. 509) commences on the posterior surface of the ulnar side of the wrist. It runs on the posterior surface of the ulnar side of the forearm, and just below the elbow unites with the anterior ulnar vein to form the common ulnar, or else joins the median basilic and helps to form the basilic. It communicates with the deep veins of the palm by a vein which emerges from beneath the Abductor minimi digiti muscle.

The **common ulnar vein** (*v. ulnaris communis*) (Fig. 510) is a short trunk which is not constant. When it exists

FIG. 510.—The superficial veins of the flexor aspect of the upper extremity.

it is *formed* by the junction of the two preceding veins, and, passing upward and outward, joins the median basilic to form the basilic vein. When it does not exist the anterior and posterior ulnar veins open separately into the median basilic vein.

The **radial vein** (*v. radialis*) (Figs. 510 and 511) *commences* upon the dorsal surface of the wrist, and communicates with the deep veins of the palm by a branch which passes through the first interosseous space. The radial vein soon forms a large vessel, which ascends along the radial side of the forearm and receives numerous veins from both its surfaces. At the bend of the elbow it unites with the median cephalic to form the cephalic vein.

The **median vein** (*v. mediana cubiti*) (Fig. 510) ascends on the front of the forearm, and communicates with the anterior ulnar and radial veins. At the bend of the elbow it receives a branch of communication from the deep veins, the **deep median vein**, and divides into two trunks, the **median cephalic** and **median basilic**, which diverge from each other as they ascend.

The **median cephalic** (*v. mediana cephalica*) (Fig. 510), usually the smaller of the two, passes outward in the groove between the Brachioradialis and Biceps muscles, and joins with the radial to form the cephalic vein. The branches of the external cutaneous nerve pass beneath this vessel.

The **median basilic vein** (*v. mediana basilica*) (Fig. 510) passes obliquely inward, in the groove between the Biceps and Pronator teres muscles, and joins the common ulnar to form the basilic. This vein passes in front of the brachial artery, from which it is separated by a fibrous expansion, the **bicipital fascia**, which is given off from the tendon of the Biceps to the fascia covering the Flexor muscles of the forearm. Filaments of the internal cutaneous nerve pass in front as well as behind this vessel.

Venesection is usually performed at the bend of the elbow, and as a matter of practice the largest vein in this situation is commonly selected. This is usually the median basilic, and there are anatomical advantages and disadvantages in selecting this vein. The advantages are, that, in addition to its being the largest, and therefore yielding a greater supply of blood, it is the least movable and can be easily steadied on the bicipital fascia on which it rests. The disadvantages are, that it is in close relationship with the brachial artery, separated only by the bicipital fascia; and formerly, when venesection was frequently practised, arteriovenous aneurism was no uncommon result of this practice. Another disadvantage is, that the median basilic is crossed by some of the branches of the internal cutaneous nerve, and these may be divided in the operation, giving rise to "traumatic neuralgia of extreme intensity" (Tillaux).

Intravenous infusion of normal saline solution is very frequently required in modern surgery for all conditions of severe shock and after profuse hemorrhages, the older method of transfusion of blood having sunk into oblivion. The patient's arm is surrounded by a tight bandage so as to impede the venous return, and a small incision is made over the largest vein visible in front of the elbow; a double ligature is now passed around the vein, and the lower one is tied; the vein is then opened and a cannula connected with a funnel by tubing and filled with hot saline solution is inserted. The bandage is next removed from the arm, and two, three, or more pints of fluid are allowed to flow into the vein; when a sufficient quantity has gone in, the upper ligature around the vein is tied and a stitch put in the skin wound.

The **basilic vein** (*v. basilica*) (Figs. 511 and 513) is of considerable size and is formed by the coalescence of the common ulnar vein with the median basilic. It passes upward along the inner side of the Biceps muscle and pierces the deep fascia a little below the middle of the arm. The opening in the fascia is known as the **semilunar hiatus** (*hiatus semilunaris*). The vein ascends in the course of the brachial artery to the lower border of the tendons of the Latissimus dorsi and Teres major muscles, and is continued onward as the axillary vein.

The **cephalic vein** (*v. cephalica*) (Figs. 510) is formed by the union of the median cephalic and the radial veins. It courses along the outer border of the Biceps muscle, lying in the same groove with the upper external cutaneous branch of the musculospiral nerve, to the upper third of the arm; it then passes in the interval

between the Pectoralis major and Deltoid muscles, lying in the same groove with the descending or humeral branch of the acromiothoracic artery. It pierces the costocoracoid membrane, and, crossing the axillary artery, terminates in the axillary vein just below the clavicle. This vein is occasionally connected with the external jugular or subclavian by a branch which passes from it upward in front of the clavicle.

The **accessory cephalic vein** (*v. cephalica accessoria*) arises either from a small tributary plexus on the back of the forearm or from the ulnar side of the dorsal venous arch; it joins the cephalic below the elbow. In some cases the accessory cephalic springs from the cephalic above the wrist and joins it again higher up. A large oblique branch frequently connects the basilic and cephalic veins on the back of the forearm.¹

The Deep Veins of the Upper Extremity.

The **deep veins of the upper extremity** (Fig. 511) follow the course of the arteries, forming their *venae comites*, or *companion veins*. Usually there is one vein lying on each side of the corresponding artery, and they are connected at intervals by short transverse branches.

Two **digital veins** accompany each artery along the sides of the fingers; these, uniting at their base, pass along the interosseous spaces in the palm, and terminate in the two *venae comites* which accompany the superficial palmar arch. Branches from these vessels on the radial side of the hand accompany the superficialis volae, and on the ulnar side terminate in the deep ulnar veins (Fig. 511). The deep ulnar veins, as they pass in front of the wrist, communicate with the interosseous and superficial veins, and at the elbow unite with the deep radial veins to form the *venae comites* of the brachial artery. The *venae comites* of the brachial communicate by numerous transverse branches, which cross over or under the artery.

The **interosseous veins** (Fig. 511) accompany the anterior and posterior interosseous arteries. The anterior interosseous veins *commence* in front of the wrist, where they communicate with the deep radial and ulnar veins; at the upper part of the forearm they receive the posterior interosseous veins, and terminate in the *venae comites* of the ulnar artery.

The **deep palmar veins** accompany the deep palmar arch, being formed by tributaries which accompany the ramifications of that vessel. At the wrist they receive a dorsal and a palmar tributary from the thumb. The deep palmar veins communicate with the deep ulnar veins at the inner side of the hand, and on the outer side terminate in the **deep radial veins** (Fig. 511), which are the *venae comites* of the radial artery. Accompanying the radial artery the deep radial veins terminate in the *venae comites* of the brachial artery.

The **brachial veins** (*vv. brachiales*) (Fig. 511) are placed one on each side of the brachial artery; receiving tributaries corresponding with the branches given off from that vessel; at the lower margin of the Subscapularis muscle they join the axillary vein.

These deep veins have numerous anastomoses, not only with each other, but also with the superficial veins. One of the brachial veins empties into the axillary, the other, usually the smaller, generally unites with the basilic.

The **axillary vein** (*v. axillaris*) (Fig. 512) is of large size, and is the continuation upward of the basilic vein. It *commences* at the lower border of the tendon of the Teres major muscle, increases in size as it ascends, by receiving tributaries corre-

¹ Concerning the variations in the arrangement and course of the veins of the upper extremity, consult the article by W. Krause in Henle's *Handbuch der Anatomie*.

sponding with the branches of the axillary artery, and terminates immediately beneath the clavicle at the outer border of the first rib, where it becomes the subclavian vein. This vessel is covered in front by the Pectoral muscles and costocoracoid membrane, and lies on the thoracic side of the axillary artery, which it partially overlaps. Near the lower margin of the Subscapularis it receives the venae comites of the brachial artery, and, near its termination, the cephalic vein. This vein is provided with a pair of valves opposite the lower border of the Subscapularis muscle; valves are also found at the termination of the cephalic and subscapular veins.

Other tributaries of the axillary vein are:

The **long thoracic vein** (*v. thoracalis lateralis*) (Fig. 513), which receives the **thoracoepigastric vein** (*v. thoracoepigastrica*), and which comes from the superficial epigastric or from the femoral vein; and the **costoaxillary veins** (*vv. costoaxillares*) (Fig. 513), which come from the first six intercostal spaces and convey the blood from the intercostal veins to the axillary.

FIG. 511.—The deep veins of the upper extremity. (Bourguery.)

Applied Anatomy.—There are several points of surgical interest in connection with the axillary vein.

Being more superficial, larger, and slightly overlapping the axillary artery, it is more liable to be wounded in the operation of extirpation of the axillary nodes, especially as these nodes, when diseased, are liable to become adherent to the vessel. When wounded there is always danger of air being drawn into its interior, in which case death is usually the result. This is due not only to the fact that it is near the thorax, and therefore liable to be influenced by the respiratory movements, but also because it is adherent by its anterior surface to the costocoracoid membrane, and therefore if wounded is likely to remain patulous and favor the chance of air being sucked in. This adhesion of the vein to the fascia prevents its collapsing, and therefore favors the furious bleeding which takes place in these cases.

To avoid wounding the axillary vein in the extirpation of nodes from the axilla no undue force should be used in isolating the nodes. If the vein is found to be so embedded in the malignant deposit that the latter cannot be removed without taking away a part of the vein, this must be done, the vessel having been first ligated above and below the diseased area.

The **subclavian vein** (*v. subclavia*) (Figs. 472 and 479), the continuation of the axillary, extends from the outer border of the first rib to the inner end of the clavicle, where it unites with the internal jugular to form the innominate vein. It is in relation, in *front*, with the clavicle and the Subclavius muscle; *behind* and *above*, with the subclavian artery, from which it is separated internally by the Scalenus anticus muscle and phrenic nerve. *Below*, it rests in a depression on the first rib and upon the pleura. *Above*, it is covered by the cervical fascia and integument.

An expansion of the aponeurosis of the Subclavius muscle lies upon the vein (Fig. 513).

The subclavian vein occasionally rises in the neck to a level with the third part of the subclavian artery, and in two instances has been seen passing with this vessel behind the Scalenus anticus. It is usually provided with a pair of valves about an inch from its termination.

FIG. 512.—The veins of the right axilla, viewed from in front. (Spalteholz.)

FIG. 513.—The aponeurotic expansion of the Subclavius muscle over the subclavian vein. (Poirier and Charpy.)

Tributaries.—It receives the external jugular vein, sometimes the anterior jugular vein, and occasionally a small branch from the cephalic. At the angle of junction with the internal jugular the left subclavian vein receives the thoracic duct (Fig. 514), while the right subclavian vein receives the right lymphatic duct.

The **innominate** or **brachio-cephalic veins** (*vv. anonymae*) (Fig. 515) are two large trunks, placed one on either side of the root of the neck, and formed by the union of the internal jugular and subclavian veins of the corresponding side.

The **right innominate vein** (*v. anonyma dextra*) is a short vessel, an inch in length, which commences at the inner end of the clavicle, and, passing almost vertically downward, joins with the left innominate vein just below the cartilage of the first rib, close to the right border of the sternum, to form the superior vena cava. It lies superficial and external to the innominate artery; on its right side is the phrenic nerve, and the pleura is here interposed between it and the apex of the lung. This vein, at the angle of junction of the internal jugular with the

subclavian, receives the right vertebral vein, and, lower down, the right internal mammary, right inferior thyroid, and sometimes the right thyroidea ima and the right superior intercostal veins.

The **left innominate vein** (*v. anonyma sinistra*), about two and a half inches in length, and larger than the right, passes from left to right across the upper and front part of the thorax, at the same time inclining downward, and unites with the right innominate vein to form the superior vena cava. It is in relation, in front, with the first piece of the sternum, from which it is separated by the Sternohyoid and Sternothyroid muscles, the thymus gland or its remains, and some loose areolar tissue. Behind it are the three large arteries arising from the arch of the aorta, together with the vagus and phrenic nerves. This vessel is joined by the left vertebral, left internal mammary, left inferior thyroid, left thyroidea ima, and the left superior intercostal veins, and occasionally some thymic and pericardiac veins. There are no valves in the innominate veins.

FIG. 514.—The bend of the thoracic duct at its termination in the subclavian vein. (Poirier and Charpy.)

Peculiarities.—Sometimes the innominate veins open *separately* into the right auricle; in such cases the right vein takes the ordinary course of the superior vena cava; but the left vein—the *left superior vena cava*, as it is termed—after communicating by a small branch with the right one, passes in front of the root of the left lung, and, turning to the back of the heart, receives the cardiac veins, and terminates in the back of the right auricle. This occasional condition in the adult is due to the persistence of the early fetal condition, and is the normal state of things in birds and some mammalia.

The **internal mammary veins** (*vv. mammae internae*), two to each internal mammary artery, follow the course of that vessel, and receive tributaries corresponding to the branches of the artery. The two veins unite into a single trunk which terminates in the corresponding innominate vein. It receives the twelve anterior intercostal veins from the upper six intercostal spaces of the corresponding side—six anterior perforating veins (*rami perforantes*)—veins from the surface of the sternum (*rami sternales*)—muscular veins, and vessels from the mediastinum and pleura. The internal mammary veins anastomose below with the venae comites of the musculophrenic and superior epigastric arteries. The **superior phrenic vein** (*i. e.*, the vein accompanying the *arteria comes nervi phrenici*) usually opens into the internal mammary vein.

The **vertebral vein** (see p. 719).

The **inferior thyroid veins** (*vv. thyroideae inferiores*) (Fig. 515), two, frequently three or four, in number, arise in the **venous plexus on the thyroid body** (*plexus thyroideus impar*), communicating with the middle and superior thyroid veins. They form a plexus in front of the trachea, behind the Sternothyroid muscles.

From this plexus a left vein descends and joins the left innominate trunk, and a right vein passes obliquely downward and outward across the innominate artery to open into the right innominate vein, just at its junction with the superior vena

cava. The **thyreoidea ima vein** (*v. thyreoidea ima*) passes downward in front of the trachea and terminates in the left innominate vein. These veins receive tributaries from the **tracheal veins** (*vv. tracheales*), from the **oesophageal veins** (*vv. oesophageae*), from the **inferior laryngeal veins** (*v. laryngea inferior*).

The **superior intercostal veins** (right and left) drain the blood from two or three of the intercostal spaces below the first. The **right superior intercostal vein** (*v. intercostalis suprema dextra*) passes downward and inward and opens into the vena azygos major; the **left superior intercostal vein** (*v. intercostalis suprema sinister*) runs across the arch of the aorta and opens into the left innominate vein. It usually receives the left bronchial and left superior phrenic vein, and communicates below with the vena azygos minor superior. The vein from the first intercostal space opens directly into the corresponding vertebral or innominate vein.

The **superior vena cava** (*precava; v. cava superior*) (Fig. 515) receives the blood which is conveyed to the heart from the whole of the upper half of the body. It is a short trunk, varying from two inches and a half to three inches in length, formed by the junction of the two innominate veins. It *commences* at the level of the

FIG. 515.—The vena cava and azygos veins, with their formative tributaries.

lower border of the cartilage of the first rib close to the sternum on the right side, and, descending vertically, enters the pericardium about an inch and a half above the heart, and terminates in the upper part of the right auricle opposite the upper border of the third right costal cartilage. In its course it describes a slight curve, the convexity of which is to the right side.

Relations.—*In front*, with the pericardium and process of cervical fascia which is continuous with it; these separate it from the thymus gland, the sternum, and the second and third right costal cartilages; *behind*, with the root of the right lung. On its *right side*, it is in relation with the phrenic nerve and right pleura; on its *left side*, with the commencement of the innominate artery and ascending part of the aorta, the latter somewhat overlapping it. The portion contained within the pericardium is covered in front and laterally by the serous layer of that membrane. It receives the vena azygos major just before it enters the pericardium, and several small veins from the pericardium and parts in the mediastinum. The superior vena cava has no valves.

The **azygos veins** are three in number; they collect the blood from the majority of the intercostal spaces, and connect the superior and inferior venæ cavæ.

The **vena azygos major** (*v. azygos*) (Fig. 515) *commences* opposite the first or second lumbar vertebra by a branch from the right lumbar veins, called the **right ascending lumbar vein** (*v. lumbalis ascendens dextra*); sometimes by a branch from the right renal vein or from the inferior vena cava. It enters the thorax through the aortic opening in the Diaphragm, and passes along the right side of the vertebral column to the fourth thoracic vertebra, where it arches forward over the root of the right lung, and terminates in the superior vena cava just before that vessel enters the pericardium. While passing through the aortic opening of the Diaphragm it lies with the thoracic duct on the right side of the aorta, and in the thorax it lies upon the intercostal arteries on the right side of the aorta and thoracic duct, and is partly covered by pleura.

Tributaries.—It receives the lower ten posterior intercostal veins of the right side, the upper two or three of these opening, first of all, into the right superior intercostal vein. It receives the azygos minor veins, several œsophageal, mediastinal and pericardial veins; near its termination, the right bronchial vein; and generally the right superior intercostal vein. A few imperfect valves are found in this vein; but its tributaries are provided with complete valves.

The **intercostal veins** (*vv. intercostales*) are divided into anterior and posterior intercostals.

The **anterior intercostal veins** are tributaries of the internal mammary or the musculophrenic veins (p. 737).

The **posterior intercostal veins** (Fig. 515) number eleven on each side, there being one vein in each intercostal space. Each vein lies in the groove at the lower margin of the rib above the corresponding intercostal artery. On the right side the first posterior intercostal vein crosses the neck of the first rib anteriorly and opens into the vertebral vein or the innominate vein. The first posterior intercostal of the left side follows a like course, and empties into the vertebral or innominate vein. The posterior intercostals of the right side, from the fifth to the eleventh, inclusive, open individually into the vena azygos major. The left upper azygos vein is formed by the fifth, sixth, seventh, and eighth posterior intercostals of the left side. The left lower azygos vein receives the ninth, tenth, and eleventh left posterior intercostals.

The **vena azygos minor inferior** (*v. hemiazygos*) (Fig. 515) *commences* in the lumbar region by a branch from one of the lumbar veins, **ascending lumbar** (*v. lumbalis ascendens*), or from the left renal. It enters the thorax through the left crus of the Diaphragm, and, ascending on the left side of the vertebral column as high as the ninth thoracic vertebra, passes across the vertebral column, behind the aorta, œsophagus, and thoracic duct, to terminate in the major azygos vein.

It receives the four or five lower intercostal veins of the left side, and some œsophageal and mediastinal veins.

The **vena azygos minor superior** (*v. hemiazygos accessoria*) varies inversely in size with the left superior intercostal. It receives veins from the intercostal spaces between the left superior intercostal vein and highest tributary of the vena azygos minor inferior. They are usually three or four in number, usually the fourth, fifth, sixth, and seventh left posterior intercostal veins. They join to form a trunk which ends in the major azygos vein or in the vena azygos minor inferior. When this vein is small or altogether wanting, the left superior intercostal vein will extend as low as the fifth or sixth intercostal space. It sometimes receives the left bronchial vein.

Applied Anatomy.—In obstruction of the inferior vena cava, the azygos veins are one of the principal means by which the venous circulation is carried on, connecting as they do the superior and inferior venae cavae, and communicating with the common iliac veins by the ascending lumbar veins and with many of the tributaries of the inferior vena cava.

Thrombosis of the superior vena cava is oftenest due to pressure exerted on the vessel by an aneurism or a tumor; it may also occur by propagation of clotting from a tributary peripheral vein. If occlusion of the vessel take place slowly, a collateral venous circulation may be established; the patient will have some œdema with dilatation and congestion of the veins about the head and neck, and may also suffer from attacks of dyspnea and recurrent pleural effusion. In most cases, however, the blockage of the superior vena cava takes place rapidly, and is rapidly fatal.

The **bronchial veins** (*vv. bronchiales*) return the blood from the larger bronchi and from the structures at the roots of the lungs; that of the right side opens into the vena azygos major, near its termination; that of the left side opens into the left superior intercostal vein or the vena azygos minor superior. A considerable quantity of the blood which is carried to the lungs through the bronchial arteries is returned to the left side of the heart by the pulmonary veins.

The Spinal Veins.

The spinal veins may be arranged into four groups—viz.:

1. The extraspinal veins.
2. The intraspinal veins.
3. The veins of the bodies of the vertebræ.
4. The veins of the spinal cord.

1. The **extraspinal veins** (*plexus venosi vertebrales externi*) commence by small branches which receive their blood from the integument of the back of the vertebral column and from the muscles in the vertebral grooves. They form two plexuses, an **anterior plexus** (*plexus venosi vertebrales anteriores*) upon the vertebral bodies and a **posterior plexus** (*plexus venosi vertebrales posteriores*), which surrounds the spinous processes, the laminæ, and the transverse and articular processes of all the vertebræ. At the bases of the transverse processes they communicate, by means of ascending and descending branches, with the veins surrounding the contiguous vertebræ, and they join with the veins in the vertebral canal by branches which perforate the ligamenta subflava. Other branches pass obliquely forward, between the transverse processes, and communicate with the intraspinal veins through the intervertebral foramina (*vv. intervertebrales*). The extraspinal veins terminate by joining the vertebral veins in the neck, the intercostal veins in the thorax, and the lumbar and lateral sacral veins in the loins and pelvis.

2. The **intraspinal veins** (*plexus venosi vertebrales interni*) are situated between the spinal dura and the vertebræ. They consist of two longitudinal plexuses, one

of which runs along the posterior surface of the bodies of the vertebræ, **anterior longitudinal spinal veins**. The other plexus, **posterior longitudinal spinal veins**, is placed on the inner or anterior surface of the laminæ of the vertebræ.

The **anterior longitudinal spinal veins** (*sinus vertebrales longitudinales*) consist of two large, tortuous veins which extend along the whole length of the vertebral column, from the foramen magnum, where they communicate with each other by a venous ring around that opening and with the basilar and occipital sinuses through the foramen, to the base of the coccyx, being placed one on each side of the posterior surface of the bodies of the vertebræ along the margin of the posterior common ligament. These veins communicate opposite each vertebra by transverse trunks which pass beneath the ligament. Each transverse trunk receives the large **vena basis vertebræ** (*v. basivertebralis*) from the interior of the body of the vertebra. The anterior longitudinal spinal veins are least developed in the cervical and sacral regions. They are not of uniform size throughout, being alternately enlarged and constricted. At the intervertebral foramina they

FIG. 516.—Transverse section of a thoracic vertebra, showing the spinal veins.

FIG. 517.—Vertical section of two thoracic vertebrae, showing the spinal veins.

communicate with the extraspinal veins, and with the vertebral veins in the neck, with the intercostal veins in the thoracic region, and with the lumbar and sacral veins in the corresponding regions.

The **posterior longitudinal spinal veins**, smaller than the anterior, are situated one on either side, between the inner surface of the laminæ and the theca vertebralis. They communicate (like the anterior) opposite each vertebra by transverse trunks, and with the anterior longitudinal veins by lateral transverse branches which pass from behind forward. The posterior longitudinal veins, by branches which perforate the ligamenta subflava, join with the extraspinal veins. From them branches are given off which pass through the intervertebral foramina and join the vertebral, intercostal, lumbar, and sacral veins.

The **intervertebral veins** (*vv. intervertebrales*) accompany the spinal nerves in the intervertebral foramina, receive veins from the spinal cord, and join the intra- and extraspinal veins.

3. The **veins of the bodies of the vertebræ** (*vv. basivertebrales*) emerge from the foramen on the posterior surface of each vertebra and join the transverse trunk connecting the anterior longitudinal spinal veins. They are contained

in large, tortuous channels in the substance of the bones, similar in every respect to those found in the diploë of the cranial bones. These canals lie parallel to the upper and lower surfaces of the bones. They commence by small openings on the front and sides of the bodies of the vertebræ, through which communicating branches from the veins external to the bone pass into its substance, and converge to the principal canal, which is sometimes double toward its posterior part. They open into the corresponding transverse branch uniting the anterior longitudinal veins. They become greatly enlarged in advanced age.

4. The **veins of the spinal cord** (*vv. spinales*) emerge from the cord substance and form a minute, tortuous, venous plexus which covers the entire surface of the cord, being situated between the pia and arachnoid. In this plexus there are (1) two median longitudinal veins, one in front of the ventral fissure, and the other behind the dorsal groove of the cord; and (2) four lateral longitudinal veins which run behind the nerve roots. These vessels are largest in the lumbar region. Near the base of the skull they unite, and form two or three small trunks, which communicate with the vertebral veins, and terminate in the inferior cerebellar veins or in the inferior petrosal sinuses. Each of the spinal nerves is accompanied by a radicular efferent vessel as far as the intervertebral foramina, where it joins the other veins from the vertebral canal.

There are no valves in the spinal veins.

VEINS OF THE LOWER EXTREMITY, ABDOMEN, AND PELVIS

(Figs. 518, 519).

The **veins of the lower extremity** are subdivided, like those of the upper, into two sets, **superficial** and **deep**; the superficial veins are situated beneath the integument, between the two layers of superficial fascia, the deep veins accompanying the arteries, and forming the *venae comites* of those vessels. Both sets of veins are provided with valves, which are more numerous in the deep than in the superficial set. These valves are also more numerous in the lower than in the upper limb.

The Superficial Veins of the Lower Extremity.

The Superficial Veins of the Foot.—In the sole of the foot there is a **subcutaneous venous plexus** (*rete venosum plantare cutaneum*), from which some branches go to the deep veins, but most of the branches pass around the margins to the dorsum of the foot. There is a transverse venous arch at the root of the toes which receives plantar vessels from the toes and sends branches between the toes (*vv. intercapitulares*) to the venous arch of the dorsum. On the dorsum of each toe the veins gather into two vessels, known as the **dorsal digital veins** (*vv. digitales pedis dorsalis*). The dorsal digital veins from the opposed margins of two toes unite to form a dorsal interdigital vein. There are four **dorsal interdigital veins** (*vv. digitales communes pedis*), and they pass into the venous arch of the dorsum. The dorsal digital vein, from the inner surface of the great toe, passes directly into the internal saphenous vein, and the dorsal digital vein, from the outer surface of the little toe, passes directly into the external saphenous vein.

The **venous arch of the dorsum** of the foot (*arcus venosus dorsalis pedis [cutaneus]*), is situated in the superficial structures over the anterior extremities of the metatarsal bones. It has its convexity directed forward, and receives digital tributaries from the upper surface of the toes; at its concavity it is joined by numerous small veins which form a **plexus** on the dorsum of the foot (*rete venosum dorsale pedis cutaneum*). The arch terminates internally in the long saphenous, externally in the short saphenous vein.

The chief superficial veins of the lower extremity are the **internal or long saphenous** and the **external or short saphenous**.

The **internal or long saphenous vein** (*v. saphena magna*) (Figs. 518 and 521) *commences* at the inner side of the arch on the dorsum of the foot; it ascends in

FIG. 518.—The internal or long saphenous vein and its tributaries.

FIG. 519.—External or short saphenous vein.

front of the inner malleolus and along the inner side of the leg, behind the inner margin of the tibia, accompanied by the internal saphenous nerve. At the knee it passes backward behind the inner condyle of the femur, ascends along the inside of the thigh, and, passing through the saphenous opening in the fascia lata, terminates in the femoral vein about an inch and a half below Poupart's ligament. This vein receives in its course cutaneous tributaries from the leg and thigh, and at the saphenous opening receives the superficial epigastric, superficial circumflex iliac, and external pudic veins. The veins from the inner and back part of the thigh frequently unite to form a large vessel, which enters the main trunk near the saphenous opening; and sometimes those on the outer

side of the thigh join to form another large vessel; so that occasionally three large veins are seen converging from different parts of the thigh toward the saphenous opening. The internal saphenous vein communicates in the foot with the internal plantar vein; in the leg, with the posterior tibial veins by branches which perforate the tibial origin of the Soleus muscle, and also with the anterior tibial veins; at the knee, with the articular veins; in the thigh, with the femoral vein by one or more branches. The valves in this vein vary from two to six in number; they are more numerous in the thigh than in the leg.

The **external or short saphenous vein** (*v. saphena parva*) (Fig. 519) *commences* at the outer side of the arch on the dorsum of the foot; it ascends behind the outer malleolus, and along the outer border of the tendo Achillis, across which it passes at an acute angle to reach the middle line of the posterior aspect of the leg. Passing directly upward, it perforates the deep fascia in the lower part of the popliteal space, and terminates in the popliteal vein, between the heads of the Gastrocnemius muscle. It receives numerous large tributaries from the back part of the leg, and communicates with the deep veins on the dorsum of the foot and behind the outer malleolus. Before it perforates the deep fascia it gives off a communicating branch, which passes upward and inward to join the internal saphenous vein. This vein contains from nine to twelve valves, one of which is always found near its termination in the popliteal vein. The external saphenous nerve lies close beside this vein.

Applied Anatomy.—A *varicose* condition of the saphenous veins is more frequently met with than in the other veins of the body, except perhaps the spermatic and hemorrhoidal veins. The course of the internal saphenous is in front of the tip of the inner malleolus, over the subcutaneous surface of the lower end of the tibia, and then along the internal border of this bone to the back part of the internal condyle of the femur, whence it follows the course of the Sartorius muscle, and is represented on the surface by a line drawn from the posterior border of the Sartorius on a level with the internal condyle to the saphenous opening. The external saphenous lies behind the external malleolus, and from this follows the middle line of the calf to just below the ham. It is not generally so apparent beneath the skin as the internal saphenous. Both these veins in the leg are accompanied by nerves, the internal saphenous being joined by its companion nerve just below the level of the knee-joint. No doubt much of the pain of varicose veins in the leg is due to this fact.

Operations for the relief of varicose veins are frequently required, portions of the veins being removed after having been ligated above and below. It is important to note whether the main varicose area drains into the internal or the external saphenous vein—the former condition being much the more common—and to control the venous return by removing a small portion of the main trunk just before it opens into the deep vein by passing through the deep fascia; thus in most cases a piece should be removed from the internal saphenous just before it passes through the saphenous opening, and in addition the affected veins should be excised just above and just below the level of the knee-joint. In other cases the external saphenous will have to be dealt with immediately below the point where it pierces the fascial roof of the popliteal space.

The Deep Veins of the Lower Extremity.

The **deep veins of the lower extremity** accompany the arteries and their branches and are called the **venae comites** of those vessels. The venae comites in the lower extremity pass into one trunk, the **popliteal vein**, whereas in the upper extremity the venae comites continue with the artery to the axilla.

The Deep Veins of the Foot.—The **plantar digital veins** (*vv. digitales plantares*) form the **plantar metatarsal veins** (*vv. metatarsae plantares*), which communicate with the veins of the dorsum of the foot by perforating veins and also communicate with the deep venous arch of the sole of the foot (*arcus venosus plantaris profundus*). The plantar arch gives off **lateral or external plantar veins**, which unite with **median or internal plantar veins** to form the posterior tibial veins. On the dorsum of the foot the deep veins begin as the **dorsal metatarsal veins** (*vv. metatarsae dorsales pedis*), which form the venae comites of the dorsalis pedis artery.

The **posterior tibial veins** (*vv. tibiales posteriores*) accompany the posterior tibial artery and are joined by the peroneal veins.

The **anterior tibial veins** (*vv. tibialis anteriores*) are formed by a continuation upward of the venae comites of the dorsalis pedis artery. They pass between the tibia and fibula, through the large oval aperture above the interosseous membrane, and form, by their junction with the posterior tibial, the popliteal vein.

The valves in the deep veins are very numerous.

The **popliteal vein** (*v. poplitea*) (Fig. 520) is formed by the junction of the anterior and posterior tibial veins; it ascends through the popliteal space to the aperture in the Adductor magnus tendon, where it becomes the femoral vein. In the lower part of its course it is placed internal to the artery; between the heads of the Gastrocnemius it is superficial to that vessel; but above the knee-joint it is close to the outer side of the artery. It receives the **sural veins** from the Gastrocnemius muscle, the articular veins, and the external saphenous veins. The valves in this vein are usually four in number.

The **femoral vein** (*v. femoralis*) (Figs. 521 and 522) accompanies the femoral artery through the upper two-thirds of the thigh. In the lower part of its course it lies external to the artery; higher up it is behind it; and at Poupart's ligament it lies to its inner side and on the same plane. It receives numerous muscular tributaries, and about an inch and a half below Poupart's ligament it is joined by the deep femoral; near its termination it is joined by the internal saphenous vein. The valves in the femoral vein are four or five in number.

The **deep femoral vein** (*v. profunda femoris*) receives tributaries corresponding to the perforating branches of the profunda artery, and through these establishes communications with the popliteal vein below and the sciatic vein above. It also receives the internal and external circumflex veins.

The **external iliac vein** (*v. iliaca externa*) (Figs. 522 and 524) *commences* at the termination of the femoral, beneath the crural arch, and, passing upward along the brim of the pelvis, terminates opposite the sacroiliac synchondrosis by uniting with the internal iliac to form the common iliac vein. On the right side it lies at first along the inner side of the external iliac artery, but as it passes upward gradually inclines behind it. On the left side it lies altogether on the inner side of the artery. It receives, immediately above Poupart's ligament, the deep epigastric and deep circumflex iliac veins and a small pubic vein, corresponding to the pubic branch of the obturator artery. It frequently contains one and sometimes two valves.

Tributaries.—The external iliac vein receives the deep epigastric, deep circumflex iliac, and pubic veins.

The **deep epigastric vein** (*v. epigastrica inferior*) (Fig. 522) is formed by the union of the venae comites of the deep epigastric artery, which communicates above with the superior epigastric vein; it joins the external iliac about half an inch above Poupart's ligament.

The **deep circumflex iliac vein** (*v. circumflexa ilium profunda*) (Fig. 522) is formed by the union of the venae comites of the deep circumflex iliac artery,

FIG. 520.—The popliteal vein.
(Poirier and Charpy.)

and joins the external iliac vein about three-quarters of an inch above Poupart's ligament.

The **pubic vein** communicates with the obturator vein in the obturator foramen, and ascends on the back of the pubis to terminate in the external iliac vein.

The **internal iliac vein** (*v. iliaca interna*, *v. hypogastrica*) commences near the upper part of the great sacrosciatic foramen, passes upward behind and slightly to the inner side of the internal iliac artery, and at the brim of the pelvis joins with the external iliac to form the common iliac.

FIG. 521.—The femoral vein and its tributaries. (Poirier and Charpy.)

Tributaries.—With the exception of the fetal umbilical vein, which passes upward and backward from the umbilicus to the liver, and the iliolumbar vein which usually joins the common iliac vein, the tributaries of the internal iliac vein correspond with the branches of the internal iliac artery. It receives (a) the gluteal, sciatic, internal pudic, and obturator veins, which have their origins outside the pelvis; (b) the lateral sacral veins, which lie in front of the sacrum; and (c) the middle hemorrhoidal, vesical, uterine, and vaginal veins, which originate in venous plexuses connected with the pelvic viscera.

1. The **gluteal veins** (*vv. gluteae superiores*) or *venae comites* of the gluteal artery, receive tributaries from the buttock corresponding with the branches of

the artery; they enter the pelvis through the great sacrosciatic foramen, above the Piriformis, and frequently unite before ending in the internal iliac vein.

2. The **sciatic veins** (*vv. gluteae inferiores*), or *venae comites* of the sciatic artery, begin on the upper part of the back of the thigh, where they anastomose with the internal circumflex and first perforating veins. They enter the pelvis through the lower part of the sacrosciatic foramen and join to form a single stem which opens into the lower part of the internal iliac vein.

3. The **internal pudic veins** (*vv. pudendae internae*) are the *venae comites* of the internal pudic artery. They commence in the veins which issue from the corpus cavernosum, accompany the internal pudic artery, and unite to form a single vessel, which ends in the internal iliac vein. They receive the veins from the bulb of the urethra, the superficial perineal, and the inferior hemorrhoidal veins (*vv. hemorrhoidales inferiores*). The deep dorsal vein of the penis communicates with the internal pudic veins, but ends mainly in the vesicoprostatic venous plexus.

FIG. 522.—The iliac veins. (Poirier and Charpy.)

4. The **obturator vein** (*v. obturatoria*) begins in the upper portion of the adductor region of the thigh and enters the pelvis through the anterior part of the obturator foramen. It runs backward and upward on the lateral wall of the pelvis below the obturator artery, and then passes between the ureter and the internal iliac artery, to end in the internal iliac vein.

5. The **lateral sacral veins** (*vv. sacrales laterales*) accompany the lateral sacral arteries on the anterior surface of the sacrum and terminate in the internal iliac vein.

6. The **middle hemorrhoidal vein** (*v. hemorrhoidalis media*) takes origin in the hemorrhoidal plexus and receives tributaries from the bladder, prostate gland, and seminal vesicle; it runs outward on the pelvic surface of the Levator ani to end in the internal iliac vein.

The **hemorrhoidal plexus** surrounds the rectum, and communicates in front with the vesicoprostatic plexus in the male, and the uterovaginal plexus in the female. It consists of two parts, an *internal* in the submucosa, and an *external* outside the muscular coat. Below, the internal plexus presents a series of dilated pouches which are arranged in a circle around the tube immediately above the anal orifice and are connected by transverse branches.

The lower part of the external plexus is drained by the inferior hemorrhoidal veins into the internal pudic; its middle part by the middle hemorrhoidal vein, which joins the internal iliac; and its upper part by the superior hemorrhoidal vein, which forms the commencement of the inferior mesenteric vein, a tributary of the portal vein. A free communication between the portal and systemic venous systems is established through the hemorrhoidal plexus.

FIG. 523.—Scheme of the anastomosis of the veins of the rectum. (Poirier and Charpy.)

The **vesicoprostatic plexus** surrounds the prostate gland and the neck of the bladder, and lies partly in the fascial sheath of the prostate and partly between the sheath and the capsule of the gland. In front it receives the deep dorsal vein of the penis; behind, it communicates with the hemorrhoidal and vesical plexuses, and derives tributaries from the vasa deferentia and seminal vesicles. It is drained into the internal iliac veins by one or more vessels on either side. The corresponding plexus in the female is named the **vesicovaginal**.

The **vesical plexus** lies on the muscular coat of the bladder, and is best marked toward the base and sides of this viscus; it drains into the vesicoprostatic plexus.

Applied Anatomy.—The veins of the hemorrhoidal plexus are liable to become dilated and varicose, and form piles. This is due to several anatomical reasons: the vessels are contained in very loose, lax connective tissue, so that they get less support from surrounding structures than most other veins, and are less capable of resisting increased blood pressure; the condition is favored by gravitation, being influenced by the erect posture, either sitting or standing, and by the fact that the superior hemorrhoidal and portal veins have no valves; the veins pass

through muscle tissue and are liable to be compressed by its contraction, especially during the act of defecation; they are affected by every form of portal obstruction.

The prostatic plexus of veins is liable to become congested in many inflammatory conditions in the neighborhood, such as acute gonorrheal prostatitis. It is owing to the free communication which exists between this and the middle hemorrhoidal plexus that great relief can be given by free saline purgation.

Hemorrhage may be very free from the prostatic plexus after operations on that gland, but can usually be checked by hot fluid irrigation. Septic thrombosis sometimes occurs after operations, and infected emboli may find their way into the general circulation.

FIG. 524.—The veins of the male pelvis, right half, viewed from the left. The Psoas muscle has been removed and the rectum drawn down somewhat to the side. (Spalteholz.)

The **dorsal veins of the penis** are two in number, a superficial and a deep. The *superficial* vein drains the prepuce and skin of the penis, and, running backward in the subcutaneous tissue, inclines to the right or left, and opens into the corresponding superficial external pudic vein, a tributary of the internal or long saphenous vein. The *deep* vein receives the blood from the glans penis and corpora cavernosa; it courses backward in the middle line between the dorsal arteries, beneath the deep fascia, and near the root of the penis passes between

the two parts of the suspensory ligament and then through an aperture between the subpubic ligament and the apex of the triangular ligament, and divides into two branches, which enter the vesicoprostatic plexus. The dorsal vein of the clitoris corresponds in woman to the dorsal vein of the penis in man, and empties into the inferior vesical plexus.

FIG. 525.—The penis in transverse section, showing the bloodvessels. (Testut.)

hind, and are drained by the **vaginal veins**, one on either side, into the internal iliac veins.

The **uterine plexuses** (Fig. 526) are situated along the sides and superior angles of the uterus, between the two layers of the broad ligament, and communicate with the ovarian and vaginal plexuses. They are drained by the **uterine veins**

The Vaginal Plexuses and Veins

(Fig. 526).—The vaginal plexuses are placed at the sides of the vagina, being especially developed at the orifice of the canal. They receive vessels from the vaginal walls. The plexuses communicate with the uterine plexus above, with the bulbar veins below, with the inferior vesical plexus in front, and with the hemorrhoidal plexus be-

FIG. 526.—Vessels of the uterus and its appendages, rear view. (Testut.)

(*vv. uterinae*) (Fig. 526) which arise from the lower part of the plexus. There are usually two veins on each side, and they are not provided with valves. These veins for the first portion of their course are placed in the base and inner portion of the broad ligament; they then pass back with the uterine artery and terminate in the internal iliac vein.

During pregnancy the uterine veins become greatly enlarged.

The **common iliac veins** (Figs. 522 and 524) are formed by the union of the external and internal iliac veins in front of the sacroiliac articulation; passing obliquely upward toward the right side, each vein terminates upon the intervertebral substance between the fourth and fifth lumbar vertebræ, where the veins of

the two sides unite at an acute angle to form the inferior vena cava. The **right common iliac** (*v. iliaca communis dextra*) is shorter than the left, nearly vertical in its direction, and ascends behind and then to the outer side of its corresponding artery. The **left common iliac** (*v. iliaca communis sinistra*), longer than the right, and more oblique in its course, is at first situated on the inner side of the corresponding artery, and then behind the right common iliac. Each common iliac receives the ilio-lumbar, and sometimes the lateral sacral veins. The left receives, in addition, the middle sacral vein. No valves are found in these veins.

The **middle sacral veins** (Figs. 522 and 523) accompany the corresponding artery along the front of the sacrum, and join to form a single vein (*v. sacralis media*), which terminates in the left common iliac vein; occasionally in the angle of junction of the two iliac veins. The middle sacral veins communicate with the inferior hemorrhoidal.

The **ilio-lumbar veins** (*vv. ilio-lumbales*) receive branches from the iliac fossæ, spinal muscles, and vertebral canal. One vein on each side runs with the artery, passes posterior to the Psoas muscle, and joins the common iliac vein.

Peculiarities.—The left common iliac vein, instead of joining with the right in its usual position, occasionally ascends on the left side of the aorta as high as the kidney, where, after receiving the left renal vein, it crosses over the aorta, and then joins with the right vein to form a short inferior vena cava. In these cases the two common iliacs are connected by a small communicating branch at the spot where they are usually united.

The **inferior vena cava** (*postcava, v. cava inferior*) (Figs. 515 and 522) returns to the heart the blood from all the parts below the Diaphragm. It is formed by the junction of the two common iliac veins on the right side of the intervertebral substance between the fourth and fifth lumbar vertebræ. It passes upward along the front of the vertebral column on the right side of the aorta, and, having reached the liver, is contained in a groove on its posterior surface. It then perforates the Diaphragm between the mesal and right portions of the central tendon; it subsequently inclines forward and inward for about an inch, and, piercing the fibrous pericardium, passes behind the serous pericardium to open into the lower and back part of the right auricle. In front of its auricular orifice is a semilunar valve, the **Eustachian valve** (*valvula v. cavæ inferioris [Eustachii]*); this is rudimentary in the adult, but is of large size and exercises an important function in the fetus.

Relations.—*In front*, from below upward, with the mesentery, right spermatic artery, transverse portion of the duodenum, the pancreas, portal vein, and the posterior surface of the liver, which, in most cases, partly and occasionally completely surrounds it; *behind*, with the vertebral column, the right crus of the Diaphragm, the right renal and lumbar arteries, the right semilunar ganglion, and the inner part of the right suprarenal gland; on the *right side*, with the right kidney and ureter; on the *left side*, with the aorta. The thoracic portion is short and covered anterolaterally by the serous layer of the pericardium.

Peculiarities.—*In Position.*—This vessel is sometimes placed on the left side of the aorta, as high as the left renal veins, after receiving which it crosses over to its usual position on the right side; or it may be placed altogether on the left side of the aorta, as far upward as its termination in the heart; in such cases the abdominal and thoracic viscera, together with the great vessels, are all transposed. The vessel may be double, due to the bilateral persistence of the cardinal veins.

Point of Termination.—Occasionally the inferior vena cava joins the vena azygos major, which is then of large size. In such cases the superior vena cava receives the whole of the blood from the body before transmitting it to the right auricle, except the blood from the hepatic veins, which passes directly into the right auricle.

Applied Anatomy.—Thrombosis of the inferior vena cava is due to much the same causes as that of the superior (see page 740). It usually causes edema of the legs and back, without ascites; if the renal veins are involved, blood and albumin will often appear in the urine. An extensive collateral venous circulation is soon established by enlargement either of the superficial or of the deep veins, or of both. In the first case the epigastric, the circumflex iliac, the

long thoracic, the internal mammary, the intercostals, the external pudic, and the lumbar vertebral anastomotic veins of Braune effect the communication with the superior cava; in the second, the deep anastomosis is made by the azygos major and minor and the lumbar veins.

Tributaries.—It receives in its course the following veins:

Lumbar.
Right spermatic, or ovarian.
Renal.

Suprarenal.
Inferior phrenic.
Hepatic.

The **lumbar veins** (*vv. lumbales*), four in number on each side, collect the blood by dorsal tributaries from the muscles and integument of the loins and by abdominal tributaries from the walls of the abdomen, where they communicate with the epigastric veins. At the vertebral column they receive veins from the spinal plexuses, and then pass forward, around the sides of the bodies of the

FIG. 527.—Spermatic veins. (Testut.)

vertebræ beneath the Psoas magnus muscle, and terminate at the back part of the inferior vena cava. The left lumbar veins are longer than the right, and pass behind the aorta. The lumbar veins of either side are connected by a longitudinal vein which passes in front of the transverse processes of the lumbar vertebræ, and is called the **ascending lumbar vein** (*v. lumbalis ascendens*) (Fig. 515). It forms the most frequent origin of the corresponding azygos vein, and

serves to connect the common iliac, ilio-lumbar, lumbar, and azygos veins of the corresponding side of the body.

The **spermatic veins** (*vv. spermaticae*) (Fig. 527) emerge from the back of the testis, and receive tributaries from the epididymis; they unite and form a convoluted plexus called the **spermatic plexus** (*plexus pampiniformis*), which constitutes the greater mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal abdominal ring, coalesce to form two veins, which ascend on the Psoas muscle behind the peritoneum, lying one on either side of the spermatic artery. These unite to form a single vein, which opens on the *right* side into the inferior vena cava at an acute angle; on the left side into the *left* renal vein at a right angle (Fig. 528). The spermatic

FIG. 528.—Terminations of the right and left spermatic veins. (Poirier and Charpy.)

veins are provided with valves, particularly at the termination. The left spermatic vein passes behind the sigmoid flexure of the colon, and is thus exposed to pressure from the contents of that bowel.

Applied Anatomy.—The spermatic veins are very frequently *varicose*, constituting the disease known as *varicocele*. Though it is quite possible that the originating cause of this affection may be a congenital abnormality either in the size or number of the veins of the spermatic plexus, still it must be admitted that there are many anatomical reasons why these veins should become varicose—viz., the imperfect support afforded to them by the loose tissue of the scrotum; their great length; their vertical course; their dependent position; their plexiform arrangement in the scrotum, with their termination in one small vein in the abdomen; their few and imperfect valves; and the fact that they may be subjected to pressure in their passage through the abdominal wall. The left veins more often become varicose than the right veins, probably, as Brinton suggests, because the right spermatic vein practically always has a valve and opens into the inferior vena cava at an acute angle, whereas the left spermatic vein is not unusually destitute of a valve at its opening and passes into the left renal vein at a right angle.

The operation for the removal of a varicocele consists in making a small incision just over the external abdominal ring and passing an aneurism needle around the mass of veins, taking care that the vas deferens is not included. The veins are isolated from the vas and ligated above and below, as high and as low as possible, and the intermediate portion cut away; the divided ends are fixed together with a suture, and the skin wound closed.

The **ovarian veins** (*vv. ovaricae*) (Fig. 526) correspond with the spermatic in the male; they form a plexus in the broad ligament near the ovary and about the Fallopian tube, and communicate with the uterine plexus. They terminate in the same way as the spermatic veins in the male. Valves are occasionally found in these veins. Like the uterine veins, these vessels become greatly enlarged during pregnancy.

The **renal veins** (*vv. renales*) (Fig. 516) are of large size, and are placed in front of the renal arteries. The left is longer than the right, and passes in front of the aorta, just below the origin of the superior mesenteric artery. It receives the left spermatic, the left inferior phrenic, and, generally, the left suprarenal veins. It opens into the inferior vena cava a little higher than the right.

The **suprarenal veins** (*vv. suprarenales*) (Fig. 515) are two in number; that on the right side terminates in the inferior vena cava; that on the left side, in the left renal or in the left phrenic vein.

The **inferior phrenic veins** (*vv. phrenicae inferiores*) follow the course of the phrenic arteries; the right ends in the inferior vena cava, the left in the left renal vein.

The **hepatic veins** (*vv. hepaticae*) commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery, **intra-lobular veins**; these tributaries, gradually uniting into **sublobular veins**, usually form three large hepatic veins, which converge toward the posterior surface of the liver and open into the inferior vena cava, where that vessel is situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the inferior vena cava, that from the middle of the organ and lobulus Spigelii having a straight course. The hepatic veins run singly, and are in direct contact with the hepatic tissue. They are destitute of valves.

THE PORTAL SYSTEM OF VEINS (Fig. 529).

The **portal system** includes all the veins which drain the blood from the abdominal part of the alimentary canal (with the exception of the lower part of the rectum) and from the spleen, pancreas, and gall-bladder. From these viscera the blood is conveyed to the liver by the *portal vein*. In the substance of the liver the portal vein ramifies like an artery and terminates in the *portal capillaries* (*sinusoids*), from which the blood is conveyed to the inferior vena cava by the hepatic veins. From this it will be seen that the blood of the portal system passes through two sets of capillary vessels—viz., (a) the capillaries of the alimentary canal, spleen, pancreas, and gall-bladder; and (b) the portal capillaries in the substance of the liver. The portal vein and its tributaries are destitute of valves.

The **portal vein** (*vena portae*) is about three inches in length, and is formed at the level of the second lumbar vertebra by the junction of the superior mesenteric and splenic veins, the union of these veins taking place in front of the inferior vena cava and behind the neck of the pancreas. It passes upward behind the first part of the duodenum and then ascends near the right border of the lesser omentum to the right extremity of the transverse fissure of the liver, where it divides into right and left branches, which accompany the corresponding branches of the hepatic artery into the substance of the liver. In the lesser omentum it is placed behind and between the common bile duct and the hepatic artery, the former lying to the right of the latter. It is surrounded by the hepatic plexus of nerves, and is accompanied by numerous lymphatic vessels and some lymph nodes. The *right branch* of the portal vein enters the right lobe of the liver, but before doing so generally receives the cystic vein. The *left branch*, longer but of smaller caliber than the right, crosses the longitudinal fissure, gives branches

to the caudate and Spigelian lobes, and then enters the left lobe of the liver. As it crosses the longitudinal fissure it is joined in front by a fibrous cord, the *ligamentum teres* of the liver or impervious *umbilical vein*, and is united to the inferior vena cava by a second fibrous cord, the *ligamentum venosum* or *impervious ductus venosus*.

The tributaries of the portal vein are:

Splenic.
Superior mesenteric.
Gastric.

Pyloric.
Cystic.
Parumbilical.

FIG. 529.—Portal vein and its branches.

NOTE.—In this diagram the right gastroepiploic vein opens into the splenic vein; generally it empties itself into the superior mesenteric, close to its termination.

The **splenic vein** (*v. lienalis*) (Fig. 529) *commences* by five or six large branches which *return* the blood from the substance of the spleen. These, uniting, form a

single vessel, which passes from left to right, grooving the upper and back part of the pancreas below the artery, and terminates at its greater end by uniting at a right angle with the superior mesenteric to form the portal vein. The splenic vein is of large size, and not tortuous like the artery.

Tributaries.—The splenic vein receives the vasa brevia from the left extremity of the stomach, the left gastroepiploic vein, the pancreatic veins, and the inferior mesenteric vein.

(a) The **short gastric veins** (*vv. gastricae breves*), some four or five in number, drain the fundus and left part of the greater curvature of the stomach, and pass between the two layers of the gastrosplenic omentum to terminate in the splenic vein or in one of its large tributaries.

(b) The **left gastroepiploic vein** (*v. gastroepiploica sinistra*) receives tributaries from the anterior and posterior surfaces of the stomach and from the great omentum; it runs from right to left along the greater curvature of the stomach and ends in the commencement of the splenic vein.

(c) The **pancreatic veins** (*vv. pancreaticae*) consist of several small vessels which drain the body and tail of the pancreas, and open into the trunk of the splenic vein.

(d) The **inferior mesenteric vein** (*v. mesenterica inferior*) returns blood from the rectum, and the pelvic, iliac, and descending parts of the colon. It begins in the rectum as the **superior hemorrhoidal vein** (*v. haemorrhoidalis superior*), which has its origin in the hemorrhoidal plexus, and through this plexus communicates with the middle and inferior hemorrhoidal veins. The superior hemorrhoidal vein leaves the pelvis and crosses the iliac vessels in company with the superior hemorrhoidal artery, and is continued upward as the inferior mesenteric vein. This vein lies to the left of the inferior mesenteric artery, and ascends behind the peritoneum and in front of the left Psoas; it then passes behind the body of the pancreas and opens into the splenic vein; sometimes it terminates in the angle of union of the splenic and superior mesenteric veins.

Tributaries.—The inferior mesenteric vein receives the **sigmoid veins** (*vv. sigmoideae*) from the sigmoid flexure and the **left colic vein** (*v. colica sinistra*) from the descending colon and splenic flexure.

The **superior mesenteric vein** (*v. mesenterica superior*) returns the blood from the small intestine, and from the cecum and ascending and transverse portions of the colon. It begins in the right iliac fossa by the union of the veins which drain the terminal part of the ileum, the cecum, and vermiform appendix, and ascends between the two layers of the mesentery on the right side of the superior mesenteric artery. In its upward course it passes in front of the right ureter, the inferior vena cava, the third part of the duodenum, and the uncinate process of the head of the pancreas. Behind the neck of the pancreas it unites with the splenic vein to form the portal vein.

Tributaries.—Besides the tributaries which correspond with the branches of the superior mesenteric artery—viz., the **veins of the small intestine** (*vv. intestinales*), the **ileocolic** (*v. ileocolica*), the **right colic** (*vv. colica dextrae*), and the **middle colic** (*v. colica media*), the superior mesenteric vein is joined by the right gastroepiploic and pancreaticoduodenal veins.

The **right gastroepiploic vein** (*v. gastroepiploica dextra*) receives tributaries from the great omentum and from the lower parts of the anterior and posterior surfaces of the stomach; it runs from left to right along the greater curvature of the stomach; between the two layers of the great omentum.

The **pancreaticoduodenal veins** (*vv. pancreaticoduodenales*) accompany their corresponding arteries; the lower of the two frequently joins the right gastroepiploic vein.

The **gastric vein** (*v. coronaria ventriculi*) derives tributaries from both surfaces

of the stomach; it runs from right to left along the lesser curvature of the stomach, between the two layers of the gastrohepatic omentum, to the œsophageal end of the stomach, where it receives some œsophageal veins. It then turns backward and passes from left to right behind the lesser sac of the peritoneum and ends in the portal vein.

The **pyloric vein** (*v. pylorica*) is of small size, and runs from left to right along the pyloric portion of the lesser curvature of the stomach, between the two layers of the gastrohepatic omentum, to terminate in the portal vein.

The **cystic vein** (*v. cystica*) (Fig. 529) drains the blood from the gall-bladder, and, ascending along the cystic duct, usually terminates in the right branch of the portal vein.

Parumbilical Veins (*vv. parumbilicales*).—In the course of the ligamentum teres of the liver and of the urachus small veins (*parumbilical*) are found, which establish an anastomosis between the veins of the anterior abdominal wall and the portal and iliac veins. The best marked of these small veins is one which commences at the umbilicus and runs backward and upward in, or on the surface of, the ligamentum teres between the layers of the falciform ligament to terminate in the left branch of the portal vein.

Anastomoses between the Portal and Systemic Veins.—Some tributaries of the portal vein communicate with certain neighboring systemic veins. The more important communications are between (a) the gastric veins and the œsophageal veins which empty into the vena azygos minor; (b) the parumbilical veins, which anastomose with the deep epigastric and internal mammary veins; (c) the superior and middle hemorrhoidal veins, the latter opening into the internal iliacs.

Applied Anatomy.—Obstruction to the portal vein may produce *ascites*, and this may arise from many causes, as (1) the pressure of a tumor on the portal vein, such as cancer or hydatid cyst, in the liver, enlarged lymph nodes in the lesser omentum, or cancer of the head of the pancreas; (2) from cirrhosis of the liver, when the radicles of the portal vein are pressed upon by the contracting fibrous tissue in the portal canals; (3) from valvular disease of the heart, and back pressure on the hepatic veins, and so on the whole of the circulation through the liver. In this condition the prognosis as regards life and freedom from ascites may be much improved by the establishment of a good collateral venous circulation to relieve the portal obstruction in the liver. This is effected by communications between (a) the gastric veins, and the œsophageal veins emptying themselves into the vena azygos minor inferior, which often project as a varicose bunch into the stomach; (b) the veins of the colon and duodenum, and the left renal vein; (c) the accessory portal system of Sappey, branches of which pass in the round and falciform ligaments (particularly the latter), to unite with the epigastric and internal mammary veins, and through the diaphragmatic veins with the azygos; a single large vein shown to be a parumbilical vein, may pass from the hilus of the liver by the round ligament to the umbilicus, producing there a bunch of prominent varicose veins known as the *Caput Medusae*; (d) the veins of Retzius, which connect the intestinal veins with the inferior vena cava and its retroperitoneal branches; (e) the inferior mesenteric veins, and the hemorrhoidal veins that open into the internal iliacs; (f) very rarely the ductus venosus remains patent, affording a direct connection between the portal vein and the inferior vena cava.

An operation for the relief of portal obstruction on these lines has been advocated by Rutherford Morison and by Talma. It consists in curetting the opposed surfaces of the liver and diaphragm and stitching them together, so as to secure vascular inflammatory adhesions between the two. The great omentum may with advantage be interposed between them, so as to increase the amount of the adhesions, and the spleen has been similarly scraped and sutured to or into the abdominal wall. The operation should not be deferred until the patient is moribund.

Thrombosis of the portal vein, or pylethrombosis, is a very serious event, and is oftenest due to pathological processes causing compression of the vessel or injury to its wall, such as tumors or inflammation about the pylorus, head of the pancreas, or appendix, or to gallstones or cirrhosis of the liver. If the thrombus is infected with bacteria, as is often the case when it is due to appendicitis, septic or suppurative pylephlebitis results; this condition is known also as *portal pyemia*. Fragments of the infected clot break off and are carried away to lodge in the smaller veins in the liver, with the development of multiple abscesses in its substance and a rapidly fatal result. When the thrombus is sterile, the chief signs produced are enlargement of the spleen, recurrent ascites, and the establishment of a collateral venous circulation, the case clinically resembling one of atrophic cirrhosis of the liver.

DEVELOPMENT OF THE BLOOD-VASCULAR SYSTEM.

There are three distinct stages in the development of the circulatory system, each in accordance with the manner in which nourishment is provided for at different periods of the existence of the individual. In the first stage there is the *vitelline circulation*, during which nutriment is extracted from the *vitellus* or contents of the yolk sac. In the second stage there is the *placental circulation*, during which nutriment is obtained by means of the placenta from the blood of the mother. In the third stage, commencing after birth, there is the *complete circulation of the adult*, during which nutrition is provided for by the organs of the individual.¹

FIG. 530.—Section through vascular area to show commencing development of bloodvessel. (Semidiagrammatic.)

Bloodvessels first make their appearance in the mesodermal wall of the yolk sac, *i. e.*, outside the body of the embryo. Here the cells become arranged into solid strands or cords which join to form a close-meshed network. The peripheral cells of these strands become flattened and joined to each other by their edges to form the walls of the primitive bloodvessels. Fluid collects within the strands and converts them into tubes, and the more centrally situated cells of the cell cords are thus pushed to the sides of the vessels and appear as masses of loosely arranged cells which project toward the lumen of the tube. These masses are termed *blood islands* (Fig. 530); their cells acquire coloring matter (hemoglobin), and are then detached to form the blood-corpuscles or erythroblasts (Fig. 531).² The earliest blood corpuscles are all nucleated; they

FIG. 531.—Later stage.

are also capable of subdivision and of executing ameboid movements, and in these respects resemble colorless blood corpuscles. Soon, however, true colorless blood corpuscles make their appearance, and, according to Beard,³ are first derived from the rudiments of the thymus.

Coincidentally with the development of the bloodvessels in the vascular area, the first rudiment of the *heart* appears as a pair of tubular vessels which are developed in the splanchnopleure of the pericardial area. These are named the *primitive aortæ*, and a direct continuity is soon established between them and the vessels of the vascular area. Each receives anteriorly a vein—the vitelline vein—from the yolk sac, and is prolonged backward on the lateral aspect of the notochord under the name of the dorsal aorta. The dorsal aortæ end at first on the yolk sac; but with the development of the allantois, they are continued onward through the body stalk as the umbilical arteries to the villi of the chorion.

By the forward growth and flexure of the head the pericardial area and the anterior portions of the primitive aortæ are folded caudad on the ventral aspect of the fore-gut, and the original

¹ That the umbilical circulation precedes the vitelline in the human embryo seems to be shown by Eternod's and Dandy's independent observations. Consult the latter's article, *A Human Embryo with Seven Pairs of Somites*, *American Journal of Anatomy*, January, 1910.

² According to Dandy (*loc. cit.*) there is at first no apparent connection between this blood-forming area and the vascular system of the very young human embryo, and that the presence of blood corpuscles in the latter is probably explained by endothelial proliferation from the capillaries in the chorionic membrane.

³ *Anatomischer Anzeiger*, December, 1900.

relation of the layers of the pericardial area is reversed. Each primitive aorta now consists of a ventral and a dorsal part connected cephalad by an arched vessel traversing the first or mandibular visceral arch. In each succeeding visceral arch a similar vessel develops, so that in all *six pairs* of aortic arches are formed, of which the fifth atrophies early.

FIG. 532.—Human embryo of about fourteen days old with yolk sac. (After His, from Kollmann's *Entwicklungsgeschichte*.)

In the pericardial region the two primitive aortæ grow together and fuse to form the *single-chambered* primitive heart tube (Fig. 533), the caudal end of which receives the two vitelline veins, while from its cephalic end the two ventral aortæ emerge. By the rhythmic contraction of the tubular heart the blood is forced through the aortæ and bloodvessels of the vascular area,

FIG. 533.—Diagram to illustrate the simple tubular condition of the heart. (Drawn from Ecker-Ziegler model.)

FIG. 534.—Heart further advanced than in Fig. 180. (Drawn from Ecker-Ziegler model.)

from which it is returned to the heart by the vitelline veins; by this vitelline circulation the nutriment is absorbed from the vitellus.

Umbilical or Placental Circulation.—With the atrophy of the yolk sac the vitelline circulation diminishes and ultimately ceases, while an increasing amount of blood is carried through

the umbilical arteries to the villi of the chorion. Subsequently, as the nonplacental chorionic villi atrophy, their vessels disappear, and then the umbilical arteries convey the whole of the blood to the placenta, whence it is returned to the heart by the umbilical veins. In this manner the placental circulation is established, and by means of it nutritive materials are absorbed from, and waste products given up to, the maternal blood.

FIG. 535.—Head of chick embryo of about thirty-eight hours' incubation, viewed from the ventral surface. $\times 26$. (From Duval's Atlas d'Embryologie.)

The umbilical veins, like the vitelline, become interrupted by the liver, and the blood returned by them passes through this organ before reaching the heart. Ultimately the right umbilical vein disappears.

During the occurrence of these changes great alterations take place in the primitive heart and bloodvessels, and now require description.

Further Development of the Heart.—The simple tubular heart, already described, becomes elongated and bent on itself so as to form an S-shaped loop, the cephalic part bending to the right and the caudal part to the left. The intermediate portion arches transversely from right to left, and then turns sharply forward into the cephalic part of the loop. Slight con-

FIG. 536.—Heart of human embryo of about fifteen days. (Reconstruction by His.)

strictions make their appearance in the tube and divide it from behind forward into four parts, viz.: (1) The *sinus venosus*; (2) the *primitive auricle*; (3) the *primitive ventricle*; (4) the *aortic bulb*, which consists of two portions, a proximal muscular portion known as the *bulbus cordis*, and a distal portion, the *primitive aortic stem* (Figs. 533 to 535). The constriction between the auricle and ventricle constitutes the *auricular canal*, and indicates the site of the future auriculo-ventricular valves.

The *sinus venosus* is at first situated in the septum transversum behind the common auricle, and is formed by the union of the vitelline veins. The veins or ducts of Cuvier from the body of

the embryo and the umbilical veins from the placenta subsequently open into it (Fig. 545). The sinus is at first placed transversely, and opens by a median aperture into the common auricle.

Soon, however, it assumes an oblique position, and becomes crescentic in form; its right half or horn increases more rapidly than the left, while the opening into the auricle now communicates with the right portion of the auricular cavity. The right horn ultimately becomes incorporated with and forms a part of the right auricle, the line of union between it and the auricle proper being indicated in the interior of the adult auricle by a vertical crest (*crista terminalis* of His). The left horn, which ultimately receives only the left duct of Cuvier, persists as the

FIG. 537.—Heart showing expansion of auricles. (Drawn from Ecker-Zeigler model.)

coronary sinus (Fig. 494). The vitelline and umbilical veins are soon replaced by a single vessel, the inferior vena cava, and the three veins (inferior vena cava and right and left Cuvierian ducts) open into the dorsal aspect of the auricle by a common slit-like aperture (Fig. 542). The upper part of this aperture represents the opening of the permanent superior vena cava, the lower that of the inferior vena cava, and the intermediate part the orifice of the coronary sinus. The slit-like aperture lies obliquely, and is guarded by two valves, the **right and left venous valves**, which unite with each other above the opening and are continuous with a fold named the **septum spurium**. The left venous valve practically disappears, while the right is subsequently divided to form the Eustachian and Thebesian valves. At the lower extremity

FIG. 538.—Heart of human embryo, 4.2 mm. long, seen from behind. (His.)

of the slit is a triangular thickening, the *spina vestibuli* of His, which partly closes the aperture between the two auricles, and, according to His, takes a part in the formation of both the inter-auricular and interventricular septa.

The auricular canal is at first a short straight tube connecting the auricular with the ventricular portion of the heart, but its growth is relatively slow, and it becomes overlapped by the auricles and ventricles so that its position on the surface of the heart is indicated only by an annular constriction (Fig. 537). Its lumen is reduced to a transverse slit, and two thickenings appear, one on its dorsal and another on its ventral wall. These thickenings, or *endocardial cushions* (Fig. 542), as they are termed, project into the canal, and, meeting in the middle line,

unite to form the *septum intermedium* which divides the canal into two channels, the future right and left auriculoventricular orifices.

The primitive auricular cavity becomes subdivided into right and left auricles by an incomplete septum, the *septum primum* (Fig. 542), which grows downward into the auricular cavity. For a time the two auricles communicate with each other by an opening, the *ostium primum* of Born, below the free margin of the septum. This opening is, however, closed by the union of the septum primum with the septum intermedium, and the communication between the auricles is reestablished through an opening which is developed in the upper part of the septum primum;

FIG. 539.—Diagrams to show the development of the septum of the aortic bulb and of the ventricles. (Born.)

this opening is known as the **foramen ovale** (*ostium secundum* of Born), and persists until birth. A second septum, the **septum secundum**, semilunar in shape, grows downward from the upper wall of the auricle to the right of the primary septum and foramen ovale. Shortly after birth it fuses with the primary septum, and by this means the foramen ovale is closed, but sometimes the fusion is incomplete and the upper part of the foramen remains patent. The annulus ovalis denotes the free margin of the septum secundum.

The primitive ventricle becomes divided by a septum, the **septum inferius** or **ventricular septum** (Figs. 539 and 542), which grows upward from the lower part of the ventricle, its position being indicated on the surface of the heart by a furrow. Its dorsal part grows more rapidly

FIG. 540.—Diagrams to illustrate the transformation of the bulbus cordis. Ao. Primitive aortic stem. Au. Auricle. B. Bulbus cordis. RV. Right ventricle. LV. Left ventricle. P. Pulmonary artery. (Keith.)

than its ventral portion, and fuses with the dorsal part of the septum intermedium. For a time an interventricular foramen exists above its ventral portion, but this foramen is ultimately closed by the fusion of the *aortic septum* with the ventricular septum.

As already stated, the *aortic bulb* consists of a proximal muscular portion, the *bulbus cordis*, and a distal portion, the *primitive aortic stem*. When the heart assumes its S-shaped form the bulbus cordis lies ventral to and in front of the primitive ventricle. The adjacent walls of the bulbus cordis and ventricle approximate, fuse, and finally disappear, and the bulbus cordis now communicates freely with the right ventricle, while the junction of the bulbus with the primitive

aortic stem is brought directly ventral to and applied to the auricular canal. By the upgrowth of the ventricular septum the bulbus cordis is in great measure separated from the left ventricle, but remains an integral part of the right ventricle, of which it forms the *infundibulum*.

The *primitive aortic stem* is divided by the *aortic septum* (Fig. 541). This makes its appearance as two ridge-like thickenings which project into the lumen of the tube; these increase in size, and ultimately meet and fuse to form the septum, and thus the primitive aortic stem is divided into the pulmonary artery and the aorta. The aortic septum takes a spiral course

FIG. 541.—Transverse sections through the aortic bulb to show the growth of the aortic septum. The lowest section is on the left, the highest on the right of the figure. (After His.)

toward the proximal end of the stem, so that the two vessels lie side by side above, but near the heart the pulmonary artery is in front of the aorta (Fig. 418). The septum grows down into the ventricle as an oblique partition, which ultimately blends with the ventricular septum in such a way as to bring the bulbus cordis into communication with the pulmonary artery, and through the latter with the sixth pair of aortic arches; while the left ventricle is brought into continuity with the aorta which communicates with the remaining aortic arches.

FIG. 542.—Interior of dorsal half of heart from a human embryo 10 mm. long. (His.)

The Valves of the Heart.—The auriculoventricular valves are developed in relation to the auricular canal. By the upward expansion of the bases of the ventricles the canal becomes invaginated into the ventricular cavities. The invaginated margin forms the rudiments of the lateral cusps of the auriculoventricular valves; the mesal or septal cusps of the valves are developed as downward prolongations of the septum intermedium. The aortic and pulmonary valves are formed from four endocardial thickenings—an anterior, a posterior, and two lateral—which appear at the proximal end of the primitive aortic stem. As the aortic septum grows downward it divides each of the lateral thickenings into two, thus giving rise to six thickenings—the rudiments of the semilunar valves—three at the aortic and three at the pulmonary orifice.

Further Development of the Arteries.—It has been seen (p. 759) that each primitive aorta consists of a ventral and a dorsal stem which are continuous through the first aortic arch. The dorsal aortæ at first run backward separately on either side of the notochord, but about the third week they fuse from about the level of the fourth thoracic to that of the fourth lumbar segment to form a single trunk, the descending aorta. The first aortic arches pass through the mandibular arches, and caudad of them five additional pairs are developed within the visceral arches; so that, in all, six pairs of aortic arches are formed (Fig. 544). The first and second arches pass between the ventral and dorsal aortæ, while the others arise at first by a common trunk from the aortic bulb, but terminate separately in the dorsal aortæ. As the neck elongates, the ventral aortæ are lengthened, and the third and fourth arches arise directly from these vessels.

FIG. 543.—Profile view of a human embryo estimated at twenty or twenty-one days old. (After His.)

In fishes these arches persist and give off branches to the gills, in which the blood is oxygenated. In mammals some of them remain as permanent structures, while others disappear or become impervious (Fig. 544).

The Ventral Aortæ.—These persist on both sides. The right forms (a) the innominate artery, (b) the right common and external carotid arteries. The left gives rise to (a) the short portion of the aortic arch, which reaches from the origin of the innominate artery to that of the left common carotid artery; (b) the left common and external carotid trunks.

The Aortic Arches.—The first and second disappear; the third (*carotid arch*) constitutes the commencement of the internal carotid artery. The fourth right arch forms the right sub-clavian as far as the origin of its internal mammary branch; while the fourth left arch constitutes the arch of the aorta between the origin of the left carotid artery and the termination of the ductus arteriosus. The fifth arch disappears on both sides. The sixth right arch disappears;

the sixth left arch gives off the pulmonary arteries and forms the ductus arteriosus; this duct remains pervious throughout fetal life, but becomes impervious a few days after birth.¹

The Dorsal Aortæ.—Cephalad of the third aortic arches the dorsal aortæ persist and form the headward continuation of the internal carotid arteries. Caudad of the third arch the right dorsal aorta disappears as far as the point where the two dorsal aortæ fuse to form the descending aorta. The part of the left dorsal aorta which intervenes between the third and fourth arches disappears, while the remainder persists to form the descending part of the arch of the aorta. A constriction, the *aortic isthmus*, is sometimes seen in the aorta between the origin of the left subclavian and the attachment of the ductus arteriosus. Below this isthmus the aorta expands slightly to form the *aortic spindle*.

Sometimes the right subclavian artery arises from the aortic arch beyond the origin of the left subclavian and passes upward and to the right behind the trachea and œsophagus. This condition may be explained by the persistence of the right dorsal aorta and the obliteration of the fourth right arch.

In birds the fourth right arch forms the arch of the aorta; in reptiles the fourth arch on both sides persists and gives rise to the double aortic arch in these animals.

The heart originally lies on the ventral aspect of the pharynx, immediately behind the stomatodeum. With the elongation of the neck and development of the lungs it recedes within the thorax, and, as a consequence, the anterior ventral aortæ are drawn out and the original position of the fourth and fifth arches is greatly modified. Thus, on the right side the fourth recedes to

FIG. 544.—Scheme of the aortic arches and their derivatives. (Modified from Kollmann.)

the root of the neck, while on the left side it is withdrawn within the thorax. The recurrent laryngeal nerves originally pass to their distribution under the sixth pair of arches, and are therefore pulled backward with the descent of these structures, so that in the adult the left hooks around the ductus arteriosus; owing to the disappearance of the fifth and the sixth right arches the right nerve hooks around that immediately above them, *i. e.*, the commencement of the subclavian artery. A series of segmental arteries arises from the primitive dorsal aortæ, those in the neck alternating with the cervical segments of the vertebral column. The seventh segmental artery, which lies between the sixth and seventh cervical segments, is of special interest, since it forms the lower part of the vertebral artery and, when the forelimb bud appears, sends a branch to it (*i. e.*, the subclavian artery); the upper part of the vertebral artery is formed by an inter-segmental anastomosis between the higher segmental arteries. From the seventh segmental arteries the entire left subclavian and the greater part of the right subclavian are formed.

The subclavian artery is prolonged into the limb under the names of the axillary and brachial arteries, and these together constitute the arterial stem for the upper arm. The direct continuation of this stem into the forearm forms the anterior interosseous artery; while the radial and ulnar vessels, which ultimately exceed this artery in size, are in reality lateral branches of the main stem.

The formation of the primary caudal branches has already been referred to (p. 758), and the fusion of the dorsal aortæ to form the greater part of the systemic aorta has been pointed out

¹ His found that in the young embryo the right and left sixth arches each give off a branch to the lungs, but that later both pulmonary arteries take origin from the left arch.

(page 764). The middle sacral artery of the adult was formerly regarded as the direct continuation of the adult aorta, but Young and Robinson¹ maintain that it is a secondary branch, probably representing fused segmental arteries. The caudal continuations of the aortæ in the adult are the common iliac, internal iliac, and the partially impervious hypogastric arteries.

The *hypogastric arteries* are continued into the umbilical cord as the umbilical arteries. After birth they become impervious cords from the umbilicus as far as the origin of the superior vesical arteries.

The primary arterial stem for the lower limb is formed by the sciatic artery, which accompanies the great sciatic nerve along the posterior aspect of the thigh to the back of the knee, where it is continued as the peroneal artery. The femoral artery arises later as a branch of the common iliac, and, passing down the front and inner side of the thigh to the bend of the knee, joins the sciatic artery. The femoral quickly enlarges, and coincidentally with this the part of the sciatic immediately above the knee undergoes atrophy. The anterior and posterior tibial arteries are branches of the main arterial stem.

FIG. 545.—Human embryo with heart and anterior body wall removed to show the sinus venosus and its tributaries. (After His, from Kollmann's *Entwicklungsgeschichte*.)

Further Development of the Veins.—The formation of the great veins of the embryo may be best considered by dividing them into two groups, visceral and parietal.

The *visceral veins* are the two vitelline or omphalomesenteric veins bringing the blood from the yolk sac, and the two umbilical or allantoic veins returning the blood from the placenta; these four veins open close together into the sinus venosus (Fig. 547).

The *vitelline veins* run cephalad at first in front, and subsequently on either side of the intestinal canal. They unite on the ventral aspect of the canal, and beyond this are connected to one another by two cross branches, the first on the dorsal, the second on the ventral aspect of the duodenal portion of the intestine, which is thus encircled by two venous rings (Fig. 546). The portions of the veins above the upper ring become invaded by the developing liver and broken up by it into a plexus of small capillary-like vessels termed *sinusoids* (Minot). The branches conveying the blood to this plexus are named the *venae advehentes*, and become the branches of the

¹ Journal of Anatomy and Physiology, vol. xxxii.

portal vein; while the vessels draining the plexus into the sinus venosus are termed the *venae revehentes*, and form the future hepatic veins (Figs. 545 and 546). Ultimately the left vena revehens no longer communicates directly with the sinus venosus, but opens into the right vena revehens. The lower part of the *portal vein* is formed from the fused vitelline veins which receive the veins from the alimentary canal; its upper part is derived from the venous rings by the persistence of the left half of the lower and the right half of the upper ring, so that the vessel forms a spiral turn round the duodenum (Fig. 546).

The two *umbilical veins* fuse early to form a single trunk in the body stalk, but remain separate within the embryo and pass forward to the sinus venosus in the side walls of the body. Like the vitelline veins, their direct connection with the sinus venosus becomes interrupted by the invasion of the liver, and thus at this stage the whole of the blood from the yolk sac and placenta passes through the substance of the liver before it reaches the heart. The right umbilical vein shrivels and disappears; the left, on the other hand, becomes enlarged and opens into the upper venous ring of the vitelline veins. Finally, a direct channel is established between this ring and the right hepatic vein; this channel is called the *ductus venosus*, and, enlarging rapidly, it forms a wide channel through which most of the blood, returned from the placenta, is carried directly to the heart without being obliged to pass through the liver. The left umbilical vein and ductus venosus become impervious after birth, and form, respectively, the *ligamentum teres* and *ligamentum venosum* of the liver (Fig. 1052).

FIG. 546.—The liver, and the veins in connection with it, of a human embryo, twenty-four or twenty-five days old, as seen from the visceral surface. (After His.) (Copied from Milnes Marshall's Embryology.)

The Parietal Veins.—The first indication of a parietal system consists in the appearance of two short transverse veins (the *ducts of Ovier*), which open, one on either side, into the sinus venosus. Each of these ducts receives an ascending and descending vein. The ascending veins return the blood from the parietes of the trunk and from the mesonephroi, and are called **postcardinal veins**. The descending veins return the blood from the head and upper limbs, and are called the **precordial** or **primitive jugular veins** (Fig. 547). The blood from the lower limbs is collected by the right and left iliac veins, which, in the earlier stages of development, open into the corresponding right and left postcardinals (Fig. 548); later on, a transverse channel (the *left common iliac vein*) is developed between the caudal parts of the two postcardinal veins (Fig. 549), and through this the blood is carried to the right postcardinal vein. The portion of the left postcardinal vein below the level of the left renal vein atrophies and disappears up to the point of entrance of the left spermatic vein; above this level the left postcardinal persists as the superior and inferior azygos minor veins. The right postcardinal vein, which now receives the blood from both lower limbs, forms a large venous trunk along the posterior abdominal wall. Above the level of the renal veins the right postcardinal vein persists as the vena azygos major, and receives the right intercostal veins, while the azygos minor veins are brought into communication with it by the development of transverse anastomotic channels in front of the vertebral column (Fig. 515).

Inferior Vena Cava.—The development of the inferior vena cava is associated with the formation of two pairs of veins, the *subcardinal* and *supracardinal veins* (Figs. 548 and 549), and with the *ductus venosus*. The *subcardinal veins* lie parallel to, and ventrad of, the *postcardinal veins* and originate as longitudinal anastomosing channels which communicate with the post-

FIG. 547.—Scheme of arrangement of parietal veins.

FIG. 548.—Scheme showing early stages of development of the inferior vena cava.

cardinals above and below and also by a series of transverse channels. Of the transverse channels, only one persists to join each renal vein. The left subcardinal vein practically disappears, while the right subcardinal enlarges and joins the ductus venosus cephalad and the right postcardinal caudad. At this stage the blood draining the lower extremities passes along a right-sided channel which courses ventrad of the ureter.

FIG. 549.—Diagram illustrating the development of the inferior vena cava in the cat. The cardinal and subcardinal veins and ductus venosus are blue and the supracardinal black. (Adopted from McClure and Huntingdon.)

The **supracardinal veins** develop as bilaterally symmetrical channels dorsomesad of the postcardinals, by longitudinal anastomoses between parietal postcardinal tributaries (Huntington and McClure). Each vein extends from where the posterior limb veins open into the post-

cardinals to the junction of the primitive renal vein with the transverse subcardinal segment, and is situated *dorsad* of the corresponding ureter. The two supracardinals fuse into a single channel and wholly replace the postrenal segment of the primitive postcardinal system. To review, it is seen that the inferior vena cava is a composite vessel made up of the following parts, enumerated in order from the heart: (1) The part of the ductus venosus between the hepatic veins and the heart; (2) the cephalic part (renal level) of the right subcardinal; (3) the fused supracardinals; (4) the conjunction of the right and left postcardinal veins draining the pelvis and lower extremities (Fig. 549).

In consequence of the atrophy of the Wolffian bodies the postcardinal veins diminish in size; the precardinal veins, on the other hand, become enlarged, owing to the rapid development of the head and brain. They are further augmented by receiving the veins (*subclavian*) from the upper extremities, and so come to form the chief veins of the Cuvierian ducts; these ducts gradually assume an almost vertical position in consequence of the descent of the heart into the thorax. The right and left Cuvierian ducts are originally of the same diameter, and are frequently termed the *right and left superior venae cavae*. By the development of a transverse channel (the *left brachiocephalic vein*) between the two precardinal veins, the blood is carried across from the left to the right precardinal (Fig. 547). The portion of the right primitive jugular vein between the left brachiocephalic and the vena azygos major forms the upper part of the superior vena cava of the adult; the lower part of this vessel (*i. e.*, below the entrance of the vena azygos major) is formed by the right Cuvierian duct. Below the origin of the transverse channel the left primitive jugular vein and left Cuvierian duct atrophy, the former constituting the upper part of the left superior intercostal vein, while the latter is represented by the *vestigial fold* and *oblique vein of Marshall*. Both right and left superior venae cavae are present in some animals, and are occasionally found in the adult human being. The oblique vein of Marshall passes downward across the back of the left auricle to open into the coronary sinus, which, as already indicated, represents the persistent left horn of the sinus venosus.

The primitive jugular or precardinal veins are situated on the ventral surface of the brain, on the mesal side of the cranial nerve roots. A considerable portion of each of these veins disappears and is replaced by a vein which is developed on the lateral aspect of the cranial nerves from the fifth to the twelfth, inclusive. This new vein (*vena capitis lateralis*) leaves the skull in company with the facial nerve. The blood from the hind-brain is collected into a vein (*the future lateral sinus*) which passes through the foramen jugulare on the lateral aspect of the vagus nerve; here the two vessels join to form the internal jugular vein. On the dorsal aspect of the ear capsule an anastomotic channel is opened up between the vena capitis lateralis and the lateral sinus; and, coincident with this, the portion of the former vein which extends from the fifth to the tenth cranial nerve becomes obliterated, and thus the whole of the blood from the brain is ultimately drained away by the lateral sinuses. The primitive jugular vein is therefore represented in the adult by the internal jugular, and not by the external jugular, as is usually stated.¹ The external jugular vein is a vessel of later formation, which at first drains the region behind the ear (posterior auricular) and enters the primitive jugular as a lateral tributary. A group of veins from the face and lingual region converge to form a common vein, the *linguofacial*,² which also terminates in the primitive jugular. Later, cross communications develop between the external jugular and the linguofacial, with the result that the posterior group of facial veins are transferred to the external jugular.

The development of the lymphatics will be described at the beginning of the section on the lymph-vascular system.

¹ Consult *Die Entwicklung des Blutgefäß-systems*, by Hochstetter, in Hertwig's *Entwicklungslehre*; and also an article by Mall in the *American Journal of Anatomy*, December, 1904, vol. iv.

² Heuer, *American Journal of Anatomy*, February, 1909, vol. ix, No. 1.

THE LYMPHATIC SYSTEM.

THE lymphatic system¹ includes the lymphatic vessels and lymph nodes or lymphatic glands. The lymphatic vessels of the small intestine receive the special designation of *lacteals* or *chyliferous vessels*; they differ in no respect from the lymphatic vessels, except that during digestion they contain a milk-white fluid, the *chyle*.

It is now generally held that the lymphatic system is a closed system peripherally, and that the tissue spaces are not in direct communication with lymphatics, although Mall has shown that granules injected into the portal vein are returned by both lymphatics and veins. Elsewhere, apparently, the absorption of the lymph is carried on by transudation through the endothelial lining of the lymph vessels and not by permanent openings (the so-called *stomata*) between the endothelial cells.

The *tissue spaces* (*lymph spaces*) are found in practically all tissues and organs, and may be classified as *pericellular* or *intercellular*, *perivascular* and *perineural spaces*, which are not lined by endothelium. The lymph exudes into these spaces out of the blood capillaries and transudes into the lymphatic capillaries wherever such exist. Spaces like the subdural and subarachnoid, and the serous cavities of the body (pleural, pericardial, peritoneal, synovial bursæ) are lined by endothelium, through which the lymph transudes by osmosis, while the lymphocytes may actually traverse the membrane. The ventricles of the brain and the central canal of the spinal cord, lined by the ependyma, contain a similar fluid derived from the plasma of the blood in the choroid plexuses, and they communicate with the subarachnoid space through the foramen of Magendie and those of Key and Retzius.

Lymph is a transparent, colorless or slightly yellow fluid of a specific gravity of 1.015, more dilute than the blood plasma from which it is derived, containing only about 5 per cent. of proteins and 1 per cent. of salts and extractives. It contains formed elements of the lymphocyte class, and is slightly coagulable.

Chyle is the intestinal lymph which is of a milky appearance during digestion on account of the emulsified fats absorbed by the lacteals.

The **lymphatic vessels** are arranged into a superficial and a deep set. On the surface of the body the **superficial lymphatic vessels** are placed immediately beneath the integument, accompanying the superficial veins; they join the deep lymphatics in certain situations by perforating the deep fascia. In the interior of the body the lymphatics lie in the submucous areolar tissue throughout the whole length of the gastropulmonary and genitourinary tracts, and in the subserous tissue of the thoracic and abdominal cavities. In the cranial cavity the perivascular sheaths are lymph spaces. A plexiform network of minute, closed, capillary lymphatics may be found interspersed among the proper elements and bloodvessels of the several tissues, the vessels composing which, as well as the meshes between them, are much larger than those of the capillary bloodvessel plexus. From these networks small collecting vessels emerge, pass to a neighboring node, and divide

¹ In the revision of the section on the lymphatic system, the editor has consulted the work by Poirier and Cunéo, translated by Cecil H. Leaf, 1904; the articles by Sabin, Lewis, and Heuer in the *American Journal of Anatomy*, February 1, 1909; and the articles by Huntington, McClure, and others (symposium) in the *Anatomical Record*, May, 1908. Consult also G. S. Huntington and C. F. W. McClure, on the Anatomy and Development of the Jugular Lymph Sacs in the Domestic Cat (*Felis domestica*), *American Journal of Anatomy*, April, 1910, vol. x, No. 2.

into a capillary network in the node. Numerous small vessels emerge from the node, which unite into one lymphatic vessel, which joins a larger lymphatic trunk, which empties into a tributary of the superior vena cava. The **deep lymphatics**, fewer in number and larger than the superficial, accompany the deep bloodvessels. Their mode of origin is probably similar to that of the superficial vessels. The lymphatics of any part or organ exceed the veins in number and in capacity, but in size they are much smaller. Their anastomoses also, especially those of the large trunks, are more frequent, and are effected by vessels equal in calibre to those which they connect, the continuous trunks retaining the same diameter throughout.

The **lymph nodes**, or **lymphatic glands** (*lymphoglandulae*), are small, solid, glandular bodies situated in the course of the lymphatic and lacteal vessels. They vary from microscopic dimensions to the size of an olive, and their color, on section, is of a pinkish-gray tint, excepting the bronchial nodes, which in the adult are mottled with black, the hepatic nodes, which are yellow, and the splenic nodes, which are brown. Each node has a layer or capsule of cellular tissue investing it, from which prolongations dip into its substance, forming partitions. The lymphatic and lacteal vessels traverse these nodes in their passage to the lymphatic ducts. Before entering a node a lymphatic or lacteal vessel divides into several small branches, which are named **afferent vessels** (*vasa afferentia*). As they enter, the external coat becomes continuous with the capsule of the node, and the vessels becoming much thinned, and consisting only of their internal or endothelial coat, pass into the node, and branch out upon and in the tissue of the capsule, these branches opening into the **lymph sinuses** of the node. There is an extensive sinus beneath the capsule; from this **subcapsular sinus** numerous channels run inward to a **central sinus**. From both sinuses fine branches proceed to form a plexus, the vessels of which unite to form a single **efferent vessel** (*vas efferens*), which, on emerging from the node, is again invested with an external coat from the gland capsule. The lymph nodes are filters or traps through which lymph and chyle flow, and also have a cytogenic function. In the nodes are masses of newly formed lymphocytes which attack any bacteria in the lymph or chyle.

FIG. 550.—A lymph node with its afferent and efferent vessels. (Testut.)

Like the lymphatics, the lymph nodes are arranged in **superficial** and **deep** sets; they are usually embedded in fat and are distinctly movable. Occasionally a node exists alone, but, as a rule, from eight to twelve, or even more, are assembled in communities or chains, and are usually arranged around bloodvessels. The nodes have a plentiful blood supply, and contain not only vasomotor nerves, but definite nerve plexuses. Besides the nodes, the body contains numerous lymphoid areas, which, in structure and function, are allied to lymph nodes (tonsils, Peyer's patches, etc.).

Hemolymph nodes exist in various regions, but are most common in the abdomen in front of the vertebræ. They are like ordinary lymph nodes in form and also in size, but differ from them in being deep red instead of light pink. Their function is to destroy red blood cells and to form lymphocytes, phagocytes, and eosinophiles. Hemolymph nodes develop like the ordinary lymphatic nodes except that the sinuses are blood channels.

Structure of Lymphatics.—The lymphatic vessels, including in this term the lacteal vessels, which are identical in structure with them, are composed of three coats. The *internal* is an endothelial and elastic coat. It is thin, transparent, slightly elastic, and ruptures more easily than the other coats. It is composed of a layer of elongated endothelial cells with serrated margins, by which the adjacent cells are dovetailed into one another. These are supported on an elastic membrane. The *middle* coat is composed of smooth muscle and fine elastic fibres, disposed in a transverse direction. The *external* coat consists of connective tissue, intermixed with smooth muscle fibres, longitudinally or obliquely disposed. It forms a protective covering to the other coats, and serves to connect the vessel with the neighboring structures. The above description applies only to the larger lymphatics; in the smaller vessels there is no muscular or elastic coat, and the wall consists only of a connective-tissue coat, lined by endothelium. The thoracic duct has a more complex structure than the other lymphatics; it presents a distinct subendothelial layer of branched cells, similar to that found in the arteries, and in the middle coat is a layer of connective tissue with its fibres arranged longitudinally. The lymphatics are supplied by nutrient vessels, which are distributed to their outer and middle coats; and here also have been traced many amyelinic nerve fibres in the form of several fine plexuses of fibrils.

The lymphatics are very generally provided with valves, which assist materially in effecting the circulation of the fluid they contain. These valves are formed of thin layers of fibrous tissue, covered on both surfaces by endothelium, which presents the same arrangement upon the two surfaces as was described in connection with the valves of veins. In form they are semilunar; they are attached by their convex edges to the sides of the vessel, the concave edges being free and directed along the course of the contained current. Usually two such valves, of equal size, are found opposite each other; but occasionally exceptions occur, especially at or near the anastomoses of lymphatic vessels. Thus, one valve may be of very rudimentary size and the other increased in proportion.

The valves in the lymphatic vessels are placed at much shorter intervals than in the veins. They are most numerous near the lymphatic nodes, and are found more frequently in the lymphatics of the neck and upper extremity than in those of the lower extremity. The wall of a lymphatic immediately above the point of attachment of each segment of a valve is expanded into a pouch or sinus, which gives to these vessels, when distended, the knotted or beaded appearance which they present. Valves are wanting in the vessels composing the plexiform network in which the lymphatics usually originate on the surface of the body.

Lymphatic vessels have been found in nearly every tissue and organ of the body which contains bloodvessels; nonvascular structures, such as cartilage, the nails, cuticle, and hair, have none. Lymphatic vessels have not been demonstrated in the brain, spinal cord, eyeball, and internal ear; the pathway of the lymph is apparently along the intercellular and perivascular tissue spaces.

Origin of Lymphatics.—The finest lymphatic vessels (lymphatic capillaries) form a plexiform network in the tissues and organs, and their walls consist of a single layer of endothelial plates, with more or less sinuous margins; the vessels of the lymphatic system, therefore, form a series of closed tubes similar to those of the blood-vascular system. The lymphatic vessels, for the most part, accompany the arteries or veins throughout the body; sometimes a minute artery may be seen to be ensheathed for a certain distance by a lymphatic capillary vessel, which is often many times wider than a blood capillary. These are known as perivascular lymphatics.

Terminations of Lymphatics.—The lymphatics, including the lacteals, discharge their contents into the veins at two points, namely, at the angles of junction of the subclavian and internal jugular veins—on the left side by means of the thoracic duct, and on the right side by the right lymphatic duct.

Development of the Lymphatic Vessels.—The lymphatic system begins as a series of sacs¹ at the points of junction of certain of the embryonic veins. These lymph sacs are developed by the confluence of numerous venous radicles, which at first lose their connections with the venous system, but subsequently, on the formation of the sacs, regain them. The lymphatic system is therefore developmentally an offshoot of the venous system, and the lining walls of its vessels are always endothelial. It forms a closed system, and has not, as was formerly supposed, any direct communication with tissue clefts or spaces.

In the human embryo the lymph sacs from which the lymphatic vessels are derived are six

¹ Consult the articles by Lewis, Sabin, and Heuer in the *American Journal of Anatomy*, February, 1909, vol. ix, No. 1.

in number—two paired, the jugular and the posterior lymph sacs; and two unpaired, the retroperitoneal and the cisterna chyli. In lower mammals an additional pair, subclavian, is present, but in the human embryo these are merely extensions of the jugular sacs.

The position of the sacs is as follows: (1) *jugular sac*, at the junction of the subclavian vein with the primitive jugular; (2) *posterior sac*, at the junction of the iliac vein with the post-cardinal; (3) *retroperitoneal*, in the position of the cross branch between the renal veins; (4) *cisterna chyli*, at the site of the cross-branch between the two iliac veins (Fig. 551). From the lymph sacs the lymphatic vessels bud out along fixed lines corresponding more or less closely to the course of the embryonic bloodvessels. They all arise as endothelial outgrowths, which later become canalized. Both in the body wall and in the wall of the intestine the deeper plexuses are the first to be developed; by continued growth of these the vessels in the superficial layers are gradually formed. It is as yet undetermined whether the thoracic duct is formed from anastomosing outgrowths from the jugular sac and cisterna chyli or whether it is developed by the transformation of some of the radicles of the azygos veins. At its connection with the cisterna chyli it is at first double, but the right vessel soon joins with the left.

All the lymph sacs except the cisterna chyli are, at a later stage, divided up by slender connective-tissue bridges and transformed into groups of lymph nodes. The lower portion of the cisterna chyli is similarly converted, but its upper portion remains as the receptaculum chyli.

FIG. 551.—Scheme showing relative positions of primary lymphatic sacs based on the description given by Florence Sabin.

Applied Anatomy.—The lymphatic channels and nodes draining any infected area of the body are very liable to become infected, and do so with the production of acute or chronic *lymphangitis* and *lymphadenitis*. In acute cases the paths of the superficial lymphatics are often marked out on the skin by the appearance over them of the four cardinal signs of inflammation—pain, redness, heat, and swelling—while the nodes swell and may suppurate. Chronic inflammation leads to growth and fibrosis of the lymphatics and the connective tissue around them; obstruction to the passage of the lymph results, as the fibrous tissue contracts and causes stenosis or obliteration of the lymphatic channels, and hard edema of the involved skin and subcutaneous tissue follows (*pachydermia lymphangiectatica*). Chronic lymphangitis, together with the blocking of numerous lymphatic vessels by the escaped ova of the minute parasitic worm *Microfilaria nocturna*, is the cause of elephantiasis, a condition common in the tropics and subtropics, and characterized by enormous enlargement and thickening of the integument of some part of the body, most frequently the leg. Tubercular and syphilitic enlargements of the lymphatics and nodes are both very commonly met with. Primary tumors of the lymphatics are lymphangioma and endothelioma; the so-called “congenital cystic hygroma” of the neck, arm, trunk, or thigh is a cystic lymphangioma. Primary tumors of the lymph nodes may be benign (lymphadenoma, myxoma, chondroma) or malignant (lymphosarcoma); cancer is an extremely common secondary affection.

In an operation for cancer it is not sufficient to cut wide of the growth and remove it; it is imperatively necessary to remove the lymph nodes which receive lymph from the diseased area, and also, when possible, the lymphatic vessels between the cancer and the nodes. Nodes are diseased very early in cancer, long before they are palpably enlarged, and are usually infected by emboli of cancer cells. The rule is in any cancer, however recent, to regard the associated nodes as diseased, whether enlarged or not, and to remove them thoroughly, if possible, in one piece, with the intervening lymph vessels and the area of primary malignant growth.

FIG. 552.—The thoracic and right lymphatic ducts.

THE THORACIC DUCT.

The thoracic duct (*ductus thoracicus*) (Fig. 552) conveys the great mass of lymph and chyle into the blood. It is the common trunk of all the lymphatic vessels of the body, excepting those of the right side of the head and neck, the right upper extremity, the right lung, right side of the heart, and part of the convex surface of the liver. In the adult it varies in length from fifteen to eighteen inches, and extends from the second lumbar vertebra to the root of the neck. It commences in the abdomen by a triangular or fusiform dilatation, the *receptaculum chyli*, which is situated upon the front of the bodies of the first and of the second lumbar vertebræ, to the right side and behind the aorta, overlapped by the right crus of the Diaphragm. It enters the thorax through the aortic opening in the Diaphragm, lying to the right of the aorta, and is then placed in the posterior mediastinum between the aorta and vena azygos major. Here it lies in front of the vertebral column, from which it is separated by the right intercostal arteries, and by the azygos minor veins as they cross the middle line to open into the vena azygos major. Opposite the fifth thoracic vertebra it inclines toward the left side, enters the superior mediastinum, and ascends behind the arch of the aorta

on the left side of the oesophagus, and behind the first portion of the left subclavian artery, to the upper opening of the thorax. Opposite the seventh cervical vertebra it turns outward in front of the vertebral artery and vein, behind the left common carotid artery and vagus nerve, and then curves downward over the

subclavian artery and in front of the *Scalenus anticus* muscle and the phrenic nerve, so as to form an arch; it terminates in the angle of junction of the left subclavian vein with the left internal jugular vein. It usually opens at the apex of the angle in the superior and outer surface, but may open on the posterior surface. Sometimes it terminates by two or more branches. Figs. 552 and 554 show the termination of the thoracic duct. The thoracic duct, at its commencement, is about 2 to 3 mm. in diameter, diminishes considerably in its caliber in the middle of the thorax, and is again dilated just before its termination, the **ampulla**. It is generally flexuous in its course, the older the person the greater the flexuosity, and it is constricted at intervals so as to present a varicose appearance. The thoracic duct not infrequently divides in the middle of its course into two branches of unequal size, which soon reunite, or divides into several branches, which form a plexiform interlacement. It occasionally divides, at its upper part, into two vessels, of which the one on the left side terminates in the usual manner, while that on the right opens into the right subclavian vein, in connection with the right lymphatic duct. The thoracic duct has several valves throughout its whole course, but they are more numerous in the upper than in the lower part, and the lower valves are not competent; at its termination it is provided with a pair of competent valves, the free borders of which are turned toward the vein, so as to prevent the passage of venous blood into the duct.

FIG. 553.—Modes of origin of the thoracic duct: *a*, Thoracic duct. *a'*, Receptaculum chyli. *b, c*, Efferent trunks from lateral aortic nodes. *d*, An efferent passing through the left crus of the diaphragm. *e, f*, Lateral aortic nodes. *g*, Preaortic node. *h*, Retroaortic node. *i*, Common intestinal trunk. *j*, Descending tributary from intercostal lymphatics. (Poirier and Charpy.)

The **receptaculum chyli** (*cisterna chyli*) (Figs. 552 and 553) receives the two lumbar lymphatic trunks, right and left, and the intestinal lymphatic trunk. The **lumbar lymphatic trunks** (*trunci lumbales*) are formed by the union of the efferent vessels from the lateral aortic lymph nodes. They receive the lymph from the lower limbs, from the walls and viscera of the pelvis, from the kidneys and suprarenal bodies, and the deep lymphatics of the greater part of the abdominal wall. The **intestinal lymphatic trunk** (*truncus intestinalis*) receives the lymph from the stomach and small intestine, from the pancreas and spleen, and from the lower and front part of the liver.

Tributaries.—Opening into the commencement of the thoracic duct, on either side, is a descending trunk from the posterior intercostal nodes of the lower six or seven intercostal spaces. In the thorax the duct is joined, on either side, by a trunk which drains the upper lumbar nodes and pierces the crus of the Diaphragm. It also receives the efferents from the posterior mediastinal nodes and from the posterior intercostal nodes of the upper six left spaces. In the neck it is joined by the *left jugular* and *left subclavian* trunks, and sometimes by the left

bronchomediastinal trunk; the last named, however, usually opens independently into the junction of the left subclavian and internal jugular veins.

Structure.—The thoracic duct is composed of three coats, which differ in some respects from those of the lymphatic vessels. The **internal coat** consists of a single layer of flattened endothelial cells; of a subendothelial layer, similar to that found in the arteries; and an elastic fibrous layer, the fibres of which run in a longitudinal direction. Each endothelial cell is shaped like a lance-head and has serrated borders. The **middle coat** consists of a longitudinal layer

FIG. 554.—The bend of the thoracic duct at its termination in the subclavian vein. (Poirier and Charpy.)

of white connective tissue with elastic fibres, external to which are several laminae of muscle tissue, the fibres of which are for the most part disposed transversely, but some are oblique or longitudinal. The muscle fibres are intermixed with elastic fibres. The **external coat** is composed of areolar tissue, with elastic fibres and isolated fasciculi of nonstriated muscle fibres.

The Right Lymphatic Duct (Ductus Lymphaticus Dexter) (Figs. 552, 555).

The **right lymphatic duct**, about half an inch in length, courses along the inner border of the *Scalenus anticus* at the root of the neck and terminates in the right

FIG. 555.—Terminal collecting trunks of the right side: *a*. Jugular trunk *b*. Subclavian trunk. *c*. Broncho-mediastinal trunk. *d*. Right lymphatic trunk. *e*. Node of the internal mammary chain. *f*. Node of the deep cervical chain. (Poirier and Charpy.)

subclavian vein at its angle of junction with the right internal jugular vein. The orifice of the right lymphatic duct is guarded by two semilunar valves, which prevent the passage of venous blood into the duct.

Tributaries.—It receives the lymph from the right side of the head and neck through the *right jugular trunk*; from the right upper extremity through the *right*

subclavian trunk; from the right side of the thorax, the right lung, and right side of the heart, and from part of the convex surface of the liver, through the *right bronchomediastinal trunk*. These three collecting trunks frequently open separately in the angle of union of the two veins.

Applied Anatomy.—Blockage of the thoracic duct by mature specimens of the minute parasitic worm *Microfilaria nocturna* gives rise to stasis of the chyle, and to its passage in various abnormal directions on its course past the obstruction. The neighboring abdominal, renal, and pelvic lymphatics become enlarged, varicose, and tortuous, and chyle may make its way into the urine (*chyluria*), the tunica vaginalis (*chylocele*), the abdominal cavity (*chylous ascites*), or the pleural cavity (*chylous pleural effusion*), in consequence of rupture of some of these distended lymphatic vessels.

The thoracic duct may be secondarily infected in intestinal or pulmonary tuberculosis, and may contain either miliary tubercles, caseating tuberculous masses, or even tuberculous ulcers. It is often the seat of secondary carcinomatous deposits in cases of cancer of some abdominal viscus, becoming infiltrated throughout until it becomes a stiff moniliform rod as thick as a pencil, with multiple stenoses and dilatations of its lumen; in such cases the left supraclavicular nodes often become infected and enlarged, while the lungs remain entirely free from secondary growths.

LYMPHATICS OF THE HEAD, FACE, AND NECK.

Intracranial lymphatics have not been demonstrated. It is probable, but not yet conclusively demonstrated, that the perivascular spaces around the cerebral arteries are the beginning of a cerebral lymph system, and that these perivascular lymph channels pass out of the cranium with the arteries and the internal jugular veins and terminate in the superior deep cervical nodes. It is also probable that lymph spaces surround the dural bloodvessels and terminate in the superior deep cervical and the internal maxillary nodes. The lymphatics of the nasal fossæ can be injected from the subdural and subarachnoid spaces.

The **extracranial lymphatics** are divided into **superficial** and **deep**, and the two systems freely communicate. All of these vessels run into nodes about the head and neck. The superficial lymphatics take origin in the subcutaneous tissue and superficial muscles. The deep vessels arise in the orbit, mouth, nose, pharynx, œsophagus, tongue, larynx, and the muscular, ligamentous, and osseous structures.

The Lymph Nodes of the Head and Face.

The lymphatic nodes of the head and face are as follows:

1. The Occipital.
2. The Posterior Auricular.
3. The Parotid and Subparotid.
4. The Facial.
5. The Internal Maxillary.
6. The Lingual.
7. The Retropharyngeal.

The **occipital nodes** (*lymphoglandulae occipitales*) (Fig. 556), one to three in number, are situated upon the occipital insertion of the Complexus muscle, at the lateral border of the Trapezius, and beneath the deep fascia. Their afferents drain the occipital region of the scalp, while their efferents pass to the upper deep cervical nodes.

The **posterior auricular or mastoid nodes** (*lymphoglandulae auriculares posteriores*) (Fig. 556), usually two in number, are situated upon the mastoid insertion of the Sternomastoid muscle. Their afferents drain the posterior part of the temporoparietal region, the upper part of the internal surface of the pinna,

and the posterior surface of the external auditory meatus; their efferents pass to the upper deep cervical nodes.

FIG. 556.—General arrangement of the lymph nodes of the head and neck. (Poirier and Charpy.)

FIG. 557.—The lymphatics of the neck. (Küttner.)

The **parotid lymph nodes** (*lymphoglandulae parotideae*) (Figs. 556 and 557) are divided into three groups, superficial, deep, and the subparotid.

The **superficial parotid** or **preauricular lymph nodes** (*lymphoglandulae auriculares anteriores*) are situated between the parotid fascia and the parotid salivary gland. The **deep parotid lymph nodes**, from fifteen to twenty in number, are embedded in the substance of the parotid gland. The afferents of the superficial and deep parotid nodes drain the eyelids, eyebrows, the root of the nose, upper portion of the cheek, frontotemporal portion of the scalp, from the outer surface of the pinna, from the external auditory meatus, and from the tympanum. Their efferents pass to the upper deep cervical nodes.

The **subparotid nodes** lie beneath the parotid gland, on the lateral wall of the pharynx, and they are close to the internal carotid artery and the internal jugular vein. Their afferents drain the posterior part of the nasal fossa, nasopharynx, and Eustachian tube; their efferents pass to the upper deep cervical nodes.

The **facial nodes** comprise three groups in the course of the afferents of the submaxillary nodes. (1) A **maxillary**, over the infraorbital region; (2) a **buccal**, upon the outer surface of the Buccinator where that muscle is pierced by the parotid duct; (3) a **mandibular** group, upon the outer surface of the mandible, at the anterior margin of the Masseter muscle, beneath the Platysma and in contact with the facial vessels. Their afferent vessels drain the eyelids, the conjunctiva, integument, and mucous membrane of the nose and cheek.

FIG. 558.—The retropharyngeal nodes. (Poirier and Charpy.)

The **internal maxillary nodes** (*lymphoglandulae faciales profundae*) are deeply placed beneath the ramus of the mandible on the outer surface of the External pterygoid, in relation to the internal maxillary artery. Their afferent vessels drain the temporal and zygomatic fossæ and the nasopharynx; their efferents pass to the upper nodes of the deep cervical group.

The **lingual nodes** (*lymphoglandulae linguales*) are two or three small nodules lying on the Hyoglossus and under the Geniohyoglossus. They form merely nodal substations in the course of the lymphatic vessels of the tongue.

The **retropharyngeal nodes** (Fig. 558) lie in the buccopharyngeal fascia, behind the upper part of the pharynx and in front of the arch of the atlas, being separated, however, from the latter by the Rectus capitis anticus major. Their afferents drain an extensive area, comprising the nasal fossæ, the nasopharynx, and the Eustachian tube as far as the tympanum; their efferents pass to the upper nodes of the deep cervical group.

The **lymphatic vessels of the scalp** are divisible into (a) those of the frontal region, which terminate in the parotid nodes; (b) those of the temporoparietal region, which end in the parotid and posterior auricular nodes; and (c) those of the occipital region, which terminate partly in the occipital glands and partly in a trunk which runs down along the posterior border of the Sternomastoid to end in the lower group of deep cervical nodes.

The **lymphatic vessels of the pinna and external auditory meatus** are also divisible into three groups: (a) an *anterior*, from the outer surface of the pinna and anterior wall of the meatus to the parotid nodes; (b) a *posterior*, from the margin of the pinna, the upper part of its inner surface, the internal surface and posterior wall of the meatus to the posterior auricular and upper deep cervical nodes; (c) an *inferior*, from the floor of the meatus and from the lobule to the external jugular and upper deep cervical nodes.

The **lymphatic vessels of the face** are more numerous than those of the scalp. Those from the eyelids and conjunctivæ terminate partly in the submaxillary, but mainly in the parotid nodes. The vessels from the posterior part of the cheek also pass to the parotid nodes, while those of the anterior portion of the cheek, the side of the nose, the upper lip, and the lateral portions of the lower lip terminate in the submaxillary nodes. The deeper vessels from the temporal and zygomatic fossæ pass to the internal maxillary and upper deep cervical nodes. The deeper vessels of the cheek and lips terminate, like the superficial, in the submaxillary nodes. Both superficial and deep vessels of the central part of the lower lip run to the suprahyoid nodes.

The **lymphatic vessels of the nasal fossæ** can be injected from the subdural and subarachnoid spaces. Those from the anterior parts of the fossæ terminate in the submaxillary nodes; those from the posterior two-thirds of the fossæ and from the communicating air sinuses pass partly to the retropharyngeal nodes and partly to the upper deep cervical nodes.

The **lymphatic vessels of the mouth** terminate as follows: (a) Those of the gums terminate in the submaxillary nodes; (b) those of the hard palate terminate in the upper deep cervical and subparotid nodes; (c) those of the soft palate, in the retropharyngeal and upper deep cervical nodes; (d) those of the anterior part of the floor of the mouth pass through the submental and suprahyoid nodes to the upper deep cervical group; (e) those from the rest of the floor of the mouth terminate in the submaxillary and upper deep cervical nodes.

The **lymphatic vessels of the tongue** (Fig. 559) are drained chiefly into the deep cervical nodes lying between the posterior belly of the Digastric and the posterior belly of the Omohyoid; one node situated at the bifurcation of the common carotid artery is so intimately associated with these vessels that it is known as the **principal node of the tongue**. The apical vessels of the tongue pass to the suprahyoid nodes and principal gland of the tongue; the marginal vessels pass partly to the submaxillary and partly to the upper deep cervical nodes. The base of the tongue in the region of the circumvallate papillæ is drained by vessels which terminate in the upper deep cervical nodes.

The **lymph nodes of the neck** include the following groups.

1. The Superficial Cervical, including the external jugular and the anterior cervical.
2. The Submaxillary.
3. The Submental.
4. The Retropharyngeal.
5. The Deep Cervical.

The **superficial cervical nodes** (*lymphoglandulæ cervicales superficiales*) (Fig. 557) are composed of two groups, the **external jugular** and the **anterior cervical nodes**.

The **external jugular nodes** (Figs. 557 and 560) are superficial to the Sternomastoid muscle. They are four to six in number and lie along the external jugular vein upon the outer surface of the deep cervical fascia, each node occupying a depression in the fascia. They are usually gathered in a group a little below the parotid gland, but sometimes extend to the middle of the vein. Their afferents drain the lower part of the pinna and parotid region, while their efferents pass around the anterior margin of the Sternomastoid and terminate in the upper deep cervical nodes.

FIG. 559.—The lymphatics of the tongue, lateral view. (Poirier and Charpy.)

The **submaxillary nodes** (*lymphoglandulae submaxillares*) (Figs. 556 and 557), three to six in number, are placed in the submaxillary triangle beneath the body of the mandible in the submaxillary triangle and rest on the superficial surface of the sheath of the submaxillary gland. One node (the **middle gland of Stahr**), which lies on the facial artery as it turns over the mandible, is the most constant of the series. Small lymph nodes are sometimes found on the deep surface of the submaxillary gland. Their afferents drain the inner canthus of the eye, the cheek, the side of the nose, the upper lip, the outer part of the lower lip, the gums, and the anterior part of the margin of the tongue; efferent vessels from the facial and suprahyoid nodes also enter the submaxillary nodes. Their efferent vessels pass to the upper nodes of the deep cervical group.

The **submental** or **suprahyoid nodes** (Figs. 556 and 559) are usually two nodes situated between the anterior bellies of the two Digastric muscles and upon the Mylohyoid muscle. They receive lymph from the cutaneous surface of the chin, from the cutaneous and mucous surfaces of the central portion of the lower lip, from the central portion of the gums, from the floor of the mouth, and from the tip of the tongue. They send some vessels to the submaxillary lymph nodes, and frequently a node is interposed on the anterior belly of the Digastric muscle. They send other vessels to the upper deep cervical nodes.

The **anterior cervical nodes** form an irregular and inconstant group on the front of the larynx and trachea. They may be divided into (a) a **superficial set**, placed on the anterior jugular vein; (b) a **deeper set**, which is further subdivided into **prelaryngeal**, on the cricothyroid membrane, and **pretracheal**, on the front of the trachea. This deeper set drains the lower part of the larynx, the thyroid body, and the upper part of the trachea; their efferents pass to the lower nodes of the upper deep cervical group.

The **retropharyngeal nodes** have been described on page 779.

FIG. 560.—Deep cervical chain. (Poirier and Charpy.)

The **deep cervical nodes** (*lymphoglandulae cervicales profundae*) (Figs. 556 and 560) are numerous and of large size; they form a chain along the carotid sheath lying by the side of the pharynx, oesophagus, and trachea, and extending from the base of the skull to the root of the neck. They are usually described in two groups: (1) an **upper** or **substernomastoid** group (*lymphoglandulae cervicales profundae superiores*) lying under the Sternomastoid in close relation with the spinal accessory nerve and the internal jugular vein, some of the nodes lying in front of and others behind the vessel; (2) a **lower** or **supraclavicular** group (*lymphoglandulae cervicales profundae inferiores*) extending beyond the posterior margin of the Sternomastoid into the supraclavicular triangle, where they are closely related to the brachial plexus and subclavian vein. A few minute nodes are situated alongside the recurrent laryngeal nerves on the lateral aspects of the trachea and oesophagus. The **upper** deep cervical nodes drain the occipital portion of the scalp, the pinna, and the back of the neck, the tongue, larynx, thyroid body, trachea, nasopharynx, nasal fossæ, palate, and oesophagus. They receive also the efferent vessels from all the other nodes of the head and neck,

except those from the lower deep cervical group. The **lower** deep cervical nodes drain the back of the scalp and neck, the superficial pectoral region, part of the arm (see page 786), and occasionally part of the upper surface of the liver. In addition, they receive vessels from the upper group. The efferents of the upper deep cervical nodes pass partly to the lower group and partly to a trunk which unites with the efferent trunk of the lower deep cervical nodes and forms the **jugular trunk** (*truncus jugularis*). This trunk, on the right side, ends in the junction of the internal jugular and subclavian veins, while on the left side it joins the thoracic duct.

The **lymphatic vessels of the skin and muscles of the neck** pass to the deep cervical nodes. From the upper part of the **pharynx** the lymphatic vessels pass to the retropharyngeal, from the lower part to the deep cervical nodes. From the **larynx** two sets of vessels arise, an upper and a lower. The vessels of the upper set pierce the thyrohyoid membrane and join the upper deep cervical nodes. Of the lower set, some pierce the cricothyroid membrane and join the pretracheal and prelaryngeal nodes; others run between the cricoid and first tracheal ring and enter the lower deep cervical nodes. The lymphatic vessels of the **thyroid body** consist of two sets, an upper, which accompanies the superior thyroid artery and enters the upper deep cervical nodes, and a lower, which runs partly to the pretracheal and partly to the small nodes which accompany the recurrent laryngeal nerve. These latter nodes receive also the lymphatic vessels from the cervical portion of the trachea.

Applied Anatomy.—The cervical nodes are very frequently the seat of tuberculous disease. This condition is most usually set up by some lesion in those parts from which they receive their lymph. It is very desirable, therefore, for the surgeon, in dealing with these cases, to possess a knowledge of the relation of the respective groups of glands to the periphery, while in order to eradicate them by operation a long and difficult dissection may be required. Sir Frederick Treves prepared a table to show to what group lymph from each region is sent. The table is practically as follows:

Scalp—Posterior part = suboccipital and mastoid nodes. Frontal and parietal portions = parotid nodes.

Lymphatic vessels from the scalp also enter the superficial cervical set of nodes.

Skin of face and neck = submaxillary, parotid, and superficial cervical nodes.

External ear = superficial cervical nodes.

Lower lip = submaxillary and suprahyoid nodes.

Buccal cavity = submaxillary and upper set of deep cervical nodes.

Gums of lower jaw = submaxillary nodes.

Tongue—Anterior portion = suprahyoid and submaxillary nodes. Posterior portion = upper set of deep cervical nodes.

Tonsils and palate = upper set of deep cervical nodes.

Pharynx.—Upper part = parotid and retropharyngeal nodes. Lower part = upper set of deep cervical nodes.

Larynx, orbit, and roof of mouth = upper set of deep cervical nodes.

Nasal fossæ = retropharyngeal nodes, upper set of deep cervical nodes. Some lymphatic vessels from posterior part of the fossæ enter the parotid nodes.

Treves' table indicates the nodes usually involved, but the seat of primary disease cannot invariably be affirmed from a knowledge of the seat of glandular involvement, because the course of the lymphatic vessels is sometimes varied from that which usually maintains; for instance, in some cases lymphatics from the right side of the tongue pass to nodes in the left side of the neck.

A **retropharyngeal abscess** begins laterad of the pharynx. It enlarges toward the centre rather than from it, because the constrictors of the pharynx limit the outward progress of the pus.

The nodes within the parotid salivary glands not unusually become tuberculous, and the surgeon may be led to believe that the salivary gland is the seat of primary disease.

Sometimes, though seldom, after the extensive removal of lymph nodes the region drained by their tributaries becomes the seat of persistent hard edema (*lymph edema*). It used to be thought that wounds of the thoracic duct were of necessity fatal, but it is now known that, unless close to the vein, they are seldom even very dangerous. It may be possible to suture a partly divided duct. In an unsutured wound of the duct recovery follows if a collateral lymphatic circulation is established.

THE LYMPHATICS OF THE UPPER EXTREMITY.**The Lymph Nodes of the Upper Extremity.**

The lymph nodes of the upper extremity are divided into two sets, **superficial** and **deep**.

FIG. 561.—The superficial lymphatics and nodes of the upper extremity.

The **superficial lymph nodes** (Fig. 561) of the upper extremity are few in number and small in size. They lie in the subcutaneous tissue. They are not receiving depots of great areas, but interrupt lymphatic vessels here and there. The nodes in the axilla receive all of the lymphatic vessels, superficial and deep. There may be three sets of superficial nodes.

One set, the **antecubital nodes**, lie in front of the elbow. These nodes are often absent. When these nodes are present they receive vessels from the

anterior portion of the forearm and the middle of the palm. The vessels from them pass upward along the front and inner aspect of the arm.

One or two superficial nodes lie above the internal condyle. This is the **supratrochlear or epitrochlear group of nodes**. There is usually but one node, but there may be two or more. It receives vessels from the three inner fingers, the inner portion of the hand, and the inner portion of the forearm, but, because of free anastomoses, also may receive lymph from any portion of the hand and forearm. Lymph vessels from the supratrochlear node pass up along the basilic vein to the axillary nodes.

There are sometimes several small nodes along the cephalic vein in the groove between the Deltoid and the great Pectoral muscle. These are called **infraclavicular nodes**, the efferents of which drain into the subclavian nodes.

FIG. 562.—Axillary nodes and lymphatics of the breast. (Poirier and Charpy.)

The Deep Lymph Nodes of the Upper Extremity or the Axillary Nodes (*lymphoglandulae axillares*) (Figs. 562 and 563).—The chief deep nodes are situated adjacent to the axillary vessels. There are also a few small nodes along the radial, ulnar, and brachial arteries which receive deep lymphatics from bones, muscles, and ligaments, and send lymphatics to the axillary nodes. The axillary nodes number from fifteen to thirty-five in each axilla. They are embedded in the axillary fat and receive the lymphatic vessels from the upper extremity, from the skin of the upper portion of the thorax, from the Pectoral muscles, and from the mammary gland. They may be arranged in the following groups:

(1) An **external group**, the **humeral chain**, lying on the inner surface of the vessels and nerves, particularly the axillary vein, to the sheath of which they are adherent. Occasionally one or several of these nodes are found beneath the vein. Some of the vessels from these nodes pass into the central group of lymph nodes; others enter the subclavian nodes; others pass above the clavicle and terminate in nodes situated in that region. (2) An **anterior or pectoral group** (*lymphoglandulae pectorales*), situated along the lower border of the Pectoralis minor and in relation

with the long thoracic artery. The afferents of this group drain the skin and muscles of the pectoral and subaxillary regions of the thorax and part of the mammary gland; their efferents pass to the central and subclavicular nodes. (3) A **posterior group**, the **subscapular chain**, lying along the subscapular artery. Their afferents drain the skin and muscles of the lower part of the neck and of the posterior thoracic wall; their efferents pass to the central axillary group of nodes. (4) A **central or intermediate group** of three or four large nodes situated in the adipose tissue near the base of the axilla, their afferents draining all the preceding groups of axillary nodes; their efferent vessels end in the subclavicular nodes. The nodes of the central group in many individuals protrude through the opening in the axillary fascia known as the **foramen of Langer**. (5) A **subclavicular group**, situated behind the upper margin of the Pectoralis minor. From the axillary nodes come many vessels which, by anastomosing, form the **infraclavicular plexus**; they then unite into a trunk, the **subclavian trunk** (*truncus subclavius*), which courses between the subclavian vein and Subclavius muscle. On the right side it empties into the junction of the internal jugular and subclavian vein or unites with the jugular trunk to form the right lymphatic duct. On the left side it may empty into the venous junction or into the thoracic duct.

FIG. 563.—Scheme of the axillary nodes. The dotted line indicates the position of the clavicle. (Poirier and Charpy.)

The Lymphatic Vessels of the Upper Extremity (Figs. 561, 564).

The lymphatic vessels of the upper extremity are divided into the **superficial** and the **deep**.

The **superficial lymphatic vessels of the upper extremity** begin as plexuses in the skin and form vessels which ascend in the subcutaneous tissue. These plexuses are particularly plentiful in the palm and palmar surface of the digits (Fig. 564). On each side of each finger two lymph vessels are formed; they ascend toward the hand, cross the dorsum, and anastomose frequently with each other. The vessels from the dorsum of the hand join the lymph vessels of the forearm, which ascend chiefly along the superficial veins. The lymph vessels which ascend with the superficial ulnar vein pass into the supratrochlear node. The vessels which accompany the median veins pass into the antecubital or supratrochlear nodes. Some of the lymph vessels on the radial side of the forearm run up along the cephalic vein and terminate in the infraclavicular nodes. All the other lymph vessels of the upper extremity pass direct to the axillary

nodes. In the forearm there are about thirty vessels, in the middle of the arm there are from fifteen to eighteen (Sappey).

The **deep lymphatic vessels of the upper extremity** convey the lymph from bone, periosteum, muscle, ligament, etc. They pass up the limb with the chief vessels, there usually being two trunks to each artery. In the arm there are two or three vessels. Some few vessels terminate in the small nodes along the radial, ulnar, and brachial arteries, but most of them pass directly to the axillary nodes.

Applied Anatomy.—In *malignant diseases*, or other affections implicating the upper part of the back and shoulder, the front of the thorax and mammae, the upper part of the front and side of the abdomen, or the hand, forearm, or arm, the axillary nodes are liable to be found enlarged.

In *secondary syphilis* the supratrochlear node is found to be enlarged. This node is subcutaneous and readily palpable against the subjacent bone when enlarged. Normal axillary nodes cannot be palpated. The axilla is a passageway for structures between the neck or thorax and the upper extremity, and purulent collections or tumors may extend from the neck or thorax into the axilla or from the axilla into the neck or thorax.

The axillary nodes are involved early in cases of cancer of the mammary gland, and later the lower deep cervical nodes are involved, and, as Snow has pointed out, regurgitation of lymph containing cancer cells leads to retrosternal involvement and to secondary cancer of the head of the humerus. In operating for cancer of the breast, follow the principle of Halsted and remove the breast, the skin over it, the muscles and fascia, the lymph vessels, and the axillary nodes in one piece. By this plan thorough removal is possible, and as lymph vessels containing carcinoma cells are not cut across, the wound is not grafted with malignant epithelial cells. Diseased axillary nodes are apt to adhere to the sheath of the vein. In removing cancerous nodes, always excise the sheath of the vein.

FIG. 564.—Lymphatic vessels of the dorsal surface of the hand. (Sappey.)

THE LYMPHATICS OF THE LOWER EXTREMITY.

The Lymph Nodes of the Lower Extremity.

The **lymph nodes of the lower extremity** consist of the anterior tibial node and the popliteal and inguinal nodes.

The **anterior tibial node** (*lymphoglandula tibialis anterior*) is small and inconstant. It lies on the interosseous membrane in relation to the upper part of the anterior tibial vessels, and constitutes a substation in the course of the anterior tibial lymphatic trunks.

The **popliteal nodes** (*lymphoglandulae popliteae*), small in size and some six or seven in number, are embedded in the fat contained in the popliteal space. One lies immediately beneath the popliteal fascia, near the terminal part of the

external saphenous vein, and drains the region from which this vein derives its tributaries. Another is placed between the popliteal artery and the posterior ligament of the knee; it receives the lymphatic vessels from the knee-joint together with those which accompany the articular arteries. The others lie at the sides of the popliteal vessels, and receive as afferents the trunks which accompany the anterior and posterior tibial vessels. The efferents of the popliteal nodes pass almost entirely alongside of the femoral vessels to the deep inguinal nodes, but a few may accompany the internal saphenous vein, and end in the nodes of the superficial inguinal group.

The **inguinal nodes** vary from twelve to twenty in number and are arranged in two groups, superficial and deep.

FIG. 565.—Nodes of the inguinal region with the afferent and some of the efferent lymphatics. (Poirier and Charpy.)

The **superficial inguinal lymph nodes** (*lymphoglandulae inguinales superficiales*) (Figs. 565 and 566), placed immediately beneath the superficial fascia in Scarpa's triangle, are of large size, and vary in number from ten to twenty. It is customary to divide these nodes into groups according to the region in which they are found. A horizontal line carried through the saphenous opening divides the nodes into two groups, a **superior group** and an **inferior group**. The nodes of the superior group (*lymphoglandulae inguinales*) form a chain immediately below Poupart's ligament. They receive as afferents lymphatic vessels from the integument of the penis, scrotum, perineum, buttock, and lower abdominal wall. The nodes of the inferior group (*lymphoglandulae subinguinales*) are placed on either side of the upper part of the saphenous vein, and receive as afferents the lymphatic vessels of the lower extremity and also some lymphatics from the penis, scrotum, perineum, and buttock.

The **deep inguinal nodes** (*lymphoglandulae subinguinales profundae*) (Fig. 565) vary from one to three in number, and are placed under the fascia lata, on the inner side of the femoral vein. When three are present, the lowest is situated just below the junction of the internal saphenous and femoral veins, the middle in the femoral (crural) canal, and the highest in the outer part of the femoral ring. The middle is the most inconsistent of the three, but the highest one, the **node of Cloquet**, or **Rosenmüller**, is also frequently absent. They receive as afferents the deep lymphatic trunks which accompany the femoral vessels, the lymphatics from the glans penis or glans clitoridis, and also some efferents from the superficial inguinal nodes.

Applied Anatomy.—Inflammation and supuration of the popliteal nodes are most commonly due to a sore on the outer side of the heel.

The inguinal nodes frequently become enlarged in diseases implicating the parts from which their lymphatics originate. Thus, in malignant or syphilitic affections of the prepuce and penis, or labia majora, in cancer scroti, in abscess in the perineum, or in similar diseases affecting the integument and superficial structures in those parts, or the subumbilical part of the abdominal wall, or the gluteal region, the upper chain of nodes is almost invariably enlarged, the lower chain being implicated in diseases affecting the lower limb.

The Lymphatic Vessels of the Lower Extremity.

The lymphatic vessels of the lower extremity consist of two sets, superficial and deep, and in their distribution correspond closely with the veins.

The **superficial lymphatic vessels of the lower extremity** are placed beneath the integument in the superficial fascia, and are divisible into three sets—trunks which follow the course of the internal saphenous vein, trunks which accompany the external saphenous, and trunks from the gluteal region. (1) Trunks which follow the course of the internal saphenous vein arise from a plexus on the dorsum of the foot, which plexus obtains lymphatics from all the toes, the sole, and both

FIG. 566. —The superficial lymphatics and nodes of the lower extremity.

borders of the foot. The internal trunks, three or four in number, pass to the superficial inguinal nodes. The external trunks run upward and inward and end in the internal trunks. (2) The trunks which follow the external saphenous vein number two or three, and they take origin from the heel and from the posterior half of the outer edge of the foot. They empty into the superficial inguinal nodes. (3) The lymph trunks from the gluteal region join vessels from the anus and enter the superficial inguinal nodes.

The **deep lymphatic vessels of the lower extremity** are few in number, and accompany the deep bloodvessels. In the leg they consist of three sets, the anterior tibial, peroneal, and posterior tibial, which accompany the corresponding bloodvessels, two or three to each artery; they ascend with the bloodvessels and enter the lymph nodes in the popliteal space; the efferent vessels from these nodes accompany the femoral vein and join the deep inguinal nodes; from these nodes vessels pass beneath Poupart's ligament and communicate with the chain of nodes surrounding the external iliac vessels. The deep lymphatic vessels of the gluteal and sciatic regions follow the course of the bloodvessels, and join the gluteal and sciatic nodes at the great sacrosciatic foramen.

THE LYMPHATICS OF THE PELVIS AND ABDOMEN.

The **lymphatics of the pelvis and abdomen** may be divided from their situation into (a) **parietal**, lying retroperitoneally and in close association with the larger bloodvessels; and (b) **visceral**, which are found in relation to the visceral arteries.

The **parietal nodes** (Fig. 567) include the following groups:

External iliac.	Lumbar {	Lateral aortic.
Internal iliac.		Preaortic.
Common iliac.		Retroaortic.

The **external iliac nodes** form three chains around the external iliac vessels. An *external chain* of three or four nodes lies between the artery and the Psoas muscle. A *middle chain* of three nodes lies upon the front surface of the external iliac vein. An *internal chain* of three or four nodes is placed to the inner side of the external iliac vein. An **obturator node** belongs to the inner chain of external iliac nodes. The external iliac nodes receive vessels from the superficial and deep inguinal nodes, from the glans penis or glans clitoris, deep lymphatics from the umbilicus and lower part of the belly wall, vessels from the superior portion of the vagina, the uterine cervix, the prostate gland, the bladder, the membranous portion of the urethra, and the internal iliac nodes, and the obturator node receives deep lymph vessels from along the course of the obturator vessels. The external iliac nodes send vessels direct to the common iliac nodes and also lymphatics to join vessels from the internal iliac nodes on their way to the common iliac group. The nodes along the epigastric artery and those along the deep circumflex iliac artery are accessory chains to the main group of external iliac nodes.

The **internal iliac or hypogastric nodes** (*lymphoglandulae hypogastricae*) surround the internal iliac vessels, and receive the lymphatics corresponding to the distribution of the branches of the internal iliac artery; *i. e.*, lymphatics from all the pelvic viscera, from the deeper parts of the perineum including the membranous and penile portions of the urethra, from the deep tissues of the posterior portion of the thigh, and from the buttocks. Their efferents pass to the common iliac nodes and also to the external iliac nodes.

The **sacral nodes** belong to this group, but are placed in the concavity of the sacrum; they receive lymphatics from the rectum and posterior wall of the pelvis.

The **common iliac nodes** are found about the common iliac artery and are divided into an **external group**, which lies upon the inner edge of the Psoas muscle; a **middle group**, behind the artery, and an **internal group**, which lies upon the front of the body of the fifth lumbar vertebra or upon the sacrovertebral junction. They receive vessels from the external and internal iliac nodes and their efferents pass to the lateral aortic nodes.

FIG. 567.—Iliopelvic lymph nodes. (Poirier and Charpy.)

The **lumbar nodes** (*lymphoglandulae lumbales*) are very numerous, and consist of right and left lateral aortic, preaortic, and retroaortic groups.

The **right lateral aortic nodes** are situated partly in front of the inferior vena cava, near the termination of the renal vein, and partly behind it on the origin of the Psoas, and on the right crus of the Diaphragm. The **left lateral aortic nodes** form a chain on the left side of the abdominal aorta in front of the origin of the Psoas and left crus of the Diaphragm. The nodes on either side receive (a) the efferents of the common iliac nodes; (b) the lymphatics from the testicle in the male and from the ovary, Fallopian tube, and body of the uterus in the female; (c) the lymphatics from the kidney and suprarenal body; and (d) the

lymphatics draining the lateral abdominal muscles and accompanying the lumbar veins. Most of the efferent vessels of the lateral aortic nodes converge to form the *right and left lumbar trunks* (trunci lumbales) which join the receptaculum chyli, but some enter the preaortic and retroaortic nodes, and others pierce the crura of the Diaphragm to join the lower end of the thoracic duct. The **preaortic nodes** lie in front of the aorta, and may be divided into *cæliac*, *superior mesenteric*, and *inferior mesenteric* groups, arranged around the origins of the corresponding

FIG. 568.—The ilio pelvic nodes (lateral view). (Poirier and Charpy.)

arteries. They receive a few vessels from the lateral aortic nodes, but their principal afferents are derived from the viscera supplied by the three arteries with which they are associated. Some of their efferents pass to the retroaortic nodes, but the majority unite to form a common trunk, the *truncus intestinalis*, which enters the receptaculum chyli. The **retroaortic nodes** are placed below the receptaculum chyli, on the bodies of the third and fourth lumbar vertebrae. They receive lymphatic trunks from the lateral and preaortic nodes, while their efferents terminate in the receptaculum chyli.

The Lymphatic Vessels of the Abdomen and Pelvis.

The lymphatic vessels of the walls of the abdomen and pelvis may be divided into two sets, superficial and deep.

The **superficial vessels** follow the course of the superficial bloodvessels and converge to the upper group of the superficial inguinal nodes. Those derived from the integument of the front of the abdomen below the umbilicus follow

the course of the superficial epigastric vessels, and those from the sides of the lumbar part of the abdominal wall pass along the crest of the ilium, with the superficial circumflex iliac vessels. The superficial lymphatic vessels of the gluteal region turn horizontally round the outer side of the buttock, and join the superficial inguinal nodes.

The **deep vessels** run alongside the principal bloodvessels. Those of the parietes of the pelvis, which accompany the gluteal, sciatic, and obturator vessels, follow the course of the internal iliac artery, and ultimately join the lateral aortic nodes.

Lymphatic Vessels of the Perineum and External Genitals.—The lymphatic vessels of the perineum and of the integument of the penis, and of the scrotum (or vulva), follow the course of the external pudic vessels, and terminate in the superficial inguinal nodes. Those of the glans penis (or glans clitoridis) terminate partly in the deep inguinal nodes and partly in the external iliac nodes.

The **visceral nodes** are associated with the branches of the coeliac axis, superior and inferior mesenteric arteries. Those related to the branches of the coeliac axis artery form three chains, gastric, hepatic, and splenic, which accompany the corresponding branches of the artery.

The nodes of the **gastric chain** (*lymphoglandulae gastricae superiores*) are divisible into three groups—viz.: (a) **upper gastric**, on the stem of the artery; (b) **lower gastric**, accompanying the descending branches of the artery along the cardiac half of the lesser curvature of the stomach, between the two layers of the small omentum; and (c) **paracardial**, “outlying members of the coronary chain, disposed in a manner comparable to a chain of beads around the neck of the stomach” (Jamieson and Dobson¹).

The nodes of the gastric chain receive their afferents from the lesser curvature and contiguous surfaces of the stomach; their efferents pass to the coeliac group of preaortic nodes.

The nodes of the **hepatic chain** (*lymphoglandulae hepaticae*) (Fig. 574) consist of the following groups: (a) **hepatic**, on the stem of the hepatic artery and along the common bile duct, between the two layers of the gastrohepatic omentum as far as the transverse fissure of the liver; the **cystic node**, a member of this group, is placed near the neck of the gall-bladder; (b) **subpyloric**, four or five in number, at the bifurcation of the gastroduodenal artery at the angle between the first and second parts of the duodenum; (c) one or two **retropyloric** nodes along the pyloric artery; (d) **right gastroepiploic** (*lymphoglandulae gastricae inferiores*), four to seven in number, between the two layers of the greater omentum, along the pyloric half of the greater curvature of the stomach. The nodes of the hepatic chain receive afferents from the pyloric portion of the stomach, duodenum, liver, gall-bladder, and the head of the pancreas; their efferents pass to the coeliac group of preaortic nodes.

The **splenic nodes** (*lymphoglandulae pancreaticolienales*) accompany the splenic artery and are situated in relation to the dorsal surface and upper border of the pancreas and in the lienorenal ligament. Their afferents are derived from the fundus of the stomach, from the spleen, and from the pancreas; their efferents pass to the coeliac group of preaortic nodes.

The **superior mesenteric nodes** comprise three groups—**mesenteric**, **ileocolic**, and **mesocolic**.

The **mesenteric nodes** (*lymphoglandulae mesentericae*) (Fig. 572) lie between the layers of the mesentery, and vary from one hundred to one hundred and fifty in number. One set is situated close to the wall of the small intestine, among the terminal twigs of the superior mesenteric artery; a second is in relation with the

¹ Lancet, April 20 to 27, 1907.

loops and primary branches of the vessel; while a third set of larger nodes lies along the trunk of the artery.

Applied Anatomy.—Enlargement of the mesenteric lymph nodes is seen in most diseased conditions of the intestinal tract, and is well marked in enteric fever, tuberculous ulceration or malignant growths of the bowel. The enlarged nodes can often be palpated through the wall of the abdomen.

The **ileocolic nodes** (Fig. 573), from ten to twenty in number, form a chain around the ileocolic artery, but show a tendency to subdivision into two groups, one near the duodenum and another on the lower part of the trunk of the artery. Where the vessel divides into its terminal branches the chain is broken up into several groups—viz.: (*a*) **ileal**, in relation to the ileal branch of the artery; (*b*) **anterior ileocolic**, usually of three nodes, in the ileocolic fold, near the wall of the

FIG. 569.—Lymphatics of colon. (Jamieson and Dobson.)

cecum; (*c*) **posterior ileocolic**, mostly placed in the angle between the ileum and the colon, but partly lying behind the cecum at its junction with the ascending colon; (*d*) **appendicular**, usually a single gland, between the layers of the meso-appendix, near its free edge; (*e*) **right colic**, along the inner side of the ascending colon.

The **mesocolic nodes** are numerous, and lie between the layers of the transverse mesocolon, in close relation to the transverse colon; they are best developed in the neighborhood of the hepatic and splenic flexures. One or two small glands are occasionally seen along the trunk of the right colic artery, and others are found in relation to the trunk and branches of the middle colic artery.

The superior mesenteric nodes receive afferents from the jejunum, ileum, cecum, appendix, and the ascending and transverse parts of the colon; their efferents pass to the preaortic nodes.

The **inferior mesenteric nodes** (Fig. 569) consist of: (*a*) Small nodes on the branches of the left colic and sigmoid arteries; (*b*) a group in the pelvic mesocolon

around the superior hemorrhoidal artery; and (c) a **pararectal** group in contact with the muscle coat of the rectum. Their afferents drain the descending colon, sigmoid flexure, and upper portion of the rectum; their efferents pass to the pre-aortic nodes.

FIG. 570.—General view of the subperitoneal lymphatic plexus of the stomach prepared by the method of Gerota. (Cunéo.)

The Lymphatic Vessels of the Abdominal and Pelvic Viscera.

These consist of: (1) Those of the subdiaphragmatic portion of the alimentary canal and its associated glands, the liver and pancreas; (2) those of the spleen and suprarenal bodies; (3) those of the urinary organs; (4) those of the reproductive organs.

1. **The lymphatic vessels of the subdiaphragmatic portion of the alimentary canal** are situated partly in the mucosa and partly in the seromuscular coats, but as the former system drains into the latter, the two may be considered as one.

The lymphatic vessels of the stomach (Fig. 570) are continuous at the cardiac end with those of the œsophagus, and at the pyloric end with those of the duodenum. They mainly follow the bloodvessels, and may be arranged in four sets. Those of the first set accompany the branches of the gastric artery, receiving tributaries from a large area on either surface of the stomach, and terminate in the nodes of the gastric chain. Those of the second set drain the fundus of the stomach, draining the area supplied by the vasa brevia and left gastroepiploic arteries, and ending in the splenic nodes. The vessels of the third set drain

the right portion of the greater curvature and end in the right gastroepiploic nodes, the efferents of which pass to the subpyloric group. Those of the fourth set drain the pyloric canal and pass to the hepatic and subpyloric nodes, and, in part, also to the coronary chain.

FIG. 571.—Lymphatic areas of the stomach. (Cunéo.)

Applied Anatomy.—Mikulicz pointed out the early infection of the nodes of the lesser curvature in pyloric cancer, and insisted that in operation for pyloric cancer the entire lesser curvature must be removed. Cunéo showed that in pyloric cancer the fundus and two-thirds of the greater curvature usually remain free from disease, because the lymph current is toward the pylorus and not from it. Of course, if the lymphatics become blocked, the lymph current may be reversed (regurgitation), and then infection of these parts can occur. William J. Mayo has noted the "lymphatic isolation" of the dome of the stomach. In operating for cancer of the pylorus, make the section of the stomach as directed by Hartmann, that is, a section which removes all of the lesser curvature and cuts the greater curvature well to the left of the subpyloric nodes.

FIG. 572.—Lymphatics of the small intestine. (Poirier and Charpy.)

The **lymphatic vessels of the duodenum** consist of an anterior and a posterior set which open into a series of small **pancreaticoduodenal nodes** on the anterior and posterior aspects of the groove between the head of the pancreas and the duodenum. The efferents from these nodes run in two directions, upward to the hepatic nodes and downward to the preaortic nodes around the origin of the superior mesenteric artery.

The **lymphatic vessels of the small intestine** (Fig. 572) are called **lacteals**, from the milk-white fluid they usually contain. They take origin in the intestinal villi and in lymphatic sinuses around the bases of the solitary follicles. Lymphatic plexuses exist in the submucous tissue, the muscular coat, and the subserous tissue. The lymphatic vessels pass between the layers of the mesentery, enter the mesenteric nodes, and finally unite to form two or three large trunks which terminate separately in the receptaculum chyli; frequently, however, they unite to form a single large trunk, termed the **intestinal lymphatic trunk** (Figs. 553 and 576).

The **lymphatic vessels of the large intestine** consist of three sets—those of the cecum, ascending and transverse colon, which, after passing through their proper nodes, enter the mesenteric nodes; those of the descending colon and sigmoid flexure, which pass to the lumbar nodes, and those of the rectum and anus, which pass to the sacral and superficial inguinal nodes.

FIG. 573.—Ventral view of the lymphatics of the cecum and appendix. (Poirier and Charpy.)

The **lymphatic vessels of the anus and rectum** take origin from two networks, one from the skin and mucous membrane and the other from the muscular coat. The lymph vessels from the skin at the anal margin pass to the superficial inguinal nodes. Some vessels from the skin of the anus ascend and reach the submucous plexus of the rectum, from which region lymph vessels pass to the pararectal nodes, to the nodes along the middle hemorrhoidal artery, and along the inferior hemorrhoidal artery, and to a pelvic node near the origin of the internal pudic artery. The efferents from these nodes terminate in the preaortic nodes around the origin of the inferior mesenteric artery.

The **lymphatic vessels of the liver** are divisible into two sets, superficial and deep. The former arise in the subperitoneal areolar tissue over the entire surface of the organ, and may be grouped into (a) those on the convex surface, (b) those on the inferior surface.

(a) On the **convex surface**. The vessels from the back part of this surface reach their terminal nodes by three different routes; the vessels of the middle

set, five or six in number, pass through the caval opening in the Diaphragm and end in one or two nodes which are situated around the terminal part of the inferior vena cava; a few vessels from the left side pass backward toward the œsophageal opening, and terminate in the paracardial nodes of the gastric chain; the vessels from the right side, one or two in number, run on the abdominal surface of the Diaphragm, and, after crossing its right crus, terminate in the preaortic nodes which surround the origin of the cœliac axis (*lymphoglandulae coeliacæ*). From the portions of the right and left lobes adjacent to the falciform ligament, the lymphatic vessels converge to form two trunks, one of which accompanies the vena cava through the Diaphragm, and ends in the nodes around the terminal part of this vessel; the other runs downward and forward, and, turning around the anterior sharp margin of the liver, accompanies the upper part of the ligamentum teres, and ends in the upper hepatic nodes. From the anterior surface a few additional vessels turn around the anterior sharp margin to reach the upper hepatic nodes.

FIG. 574.—Lymphatics of the inferior surface of the liver. (Sappey.)

Some of the lymph of the upper part of the liver traverses the Diaphragm along several lymphatic vessels which drain into some nodes on the superior surface of the Diaphragm, just behind the ensiform cartilage and also near the termination of the inferior vena cava; the efferents from the former pass to the internal mammary chain, a fact which may explain the involvement of the supraclavicular nodes, particularly of the left side,¹ secondary to an abdominal carcinoma.

(b) On the **inferior surface**. The vessels from this surface mostly converge to the transverse fissure, and accompany the deep lymphatics emerging from this fissure to the hepatic nodes; one or two from the posterior parts of the right and Spigelian lobes accompany the inferior vena cava through the Diaphragm, and end in the nodes around the terminal part of this vein.

The **deep lymphatics** of the liver converge to ascending and descending trunks. The ascending trunks accompany the hepatic veins and pass through the Dia-

¹ Osler, *Principles and Practice of Medicine*, 7th edition, 1909, page 485.

phragm to end in the nodes around the terminal part of the inferior vena cava. The descending trunks emerge from the transverse fissure, and end in the hepatic nodes.

The **lymphatic vessels of the gall-bladder** pass to the hepatic nodes in the transverse fissure of the liver; those of the **common bile duct** to the hepatic nodes along the duct and into the upper pancreaticoduodenal nodes.

The **lymphatic vessels of the pancreas** arise from a network about the pancreatic lobules. The collecting trunks anastomose freely among themselves and with the lymphatics of the duodenum, spleen, and in the mesentery and mesocolon;¹ some end in the pancreaticoduodenal nodes, and others in the preaortic nodes, near the origin of the superior mesenteric artery.

2. The lymphatics of the spleen and suprarenal glands.

The **lymphatic vessels of the spleen**, both superficial and deep, pass to the splenic nodes in the lienorenal ligament and along the superior border of the pancreas.

The lymphatic vessels of the **suprarenal glands** usually accompany the suprarenal veins, and end in the lateral aortic nodes; occasionally some of them pierce the crura of the Diaphragm and terminate in the nodes of the posterior mediastinum.

3. The lymphatic vessels of the urinary organs.

The **lymphatic vessels of the kidney** form three plexuses—one in the substance of the kidney, a second beneath its fibrous capsule, and a third in the perinephric fat; the second and third communicate freely with each other.

The vessels from the plexus in the kidney substance converge to form four or five trunks which issue at the hilum. Here they are joined by vessels from the plexus under the capsule, and, following the course of the renal vein, end in the lateral aortic nodes. The perinephric plexus is drained directly into the upper lateral aortic nodes.

The **lymphatic vessels of the ureter** run in different directions. Those from its upper portion end partly in the efferent vessels of the kidney and partly in the lateral aortic nodes; those from the portion immediately above the pelvic brim are drained into the common iliac nodes; while the vessels from the intrapelvic portion of the tube join the efferents from the bladder, or terminate in the internal iliac nodes.

The **lymphatic vessels of the bladder** (Fig. 575) originate in two plexuses, an intramuscular and an extramuscular, it being generally admitted that the mucous membrane is devoid of lymphatics.² The efferent vessels are arranged in two groups, one from the anterior and another from the posterior surface of the bladder. The vessels from the *anterior* surface pass to the external iliac nodes, but in their course minute nodes are situated. These minute nodes are arranged in two groups, an *anterior vesical* group, in front of the bladder, and a *lateral vesical*, in relation to the hypogastric artery. The vessels from the *posterior* surface pass to the internal, external, and common iliac nodes; those draining the upper part of this surface traverse the lateral vesical nodes.

The **lymphatic vessels of the prostate** (Fig. 575) terminate chiefly in the internal iliac and sacral nodes, but one trunk from the posterior surface ends in the external iliac nodes, and another from the anterior surface joins the vessels which drain the membranous part of the urethra.

Lymphatic Vessels of the Urethra.—The lymphatics of the *penile* portion of the urethra accompany those of the glans penis, and terminate with them in the deep inguinal and external iliac nodes. Those of the *membranous* and

¹ P. Bartels, Ueber die Lymphgefäße des Pankreas, Archiv f. Anat. u. Physiol., 1907.

² Some authorities maintain that a plexus of lymphatic vessels does exist in the mucous membrane of the bladder (consult Médecine opératoire des Voies urinaires, par J. Albarran, Paris, 1909).

prostatic portions, and those of the whole urethra in the female, pass to the internal iliac nodes.

4. The lymphatic vessels of the reproductive organs.

The lymphatic vessels of the testes consist of two sets, superficial and deep, the former commencing on the surface of the tunica vaginalis, the latter in the epididymis and body of the testis. They form several large trunks which ascend with the spermatic cord, and, accompanying the spermatic vessels into the abdomen, terminate in the lateral aortic nodes.

The lymphatic vessels of the vas deferens pass to the external iliac nodes; those of the vesiculæ seminales partly to the internal and partly to the external iliac nodes.

FIG. 575.—Lymphatics of the prostate. (Cunéo and Marcille.)

The lymphatic vessels of the ovary are similar to those of the testicle, and ascend with the ovarian artery to the lateral aortic nodes.

The lymphatic vessels of the Fallopian tube pass partly with those of the ovary and partly with those of the uterus.

The lymphatic vessels of the uterus (Fig. 1149) consist of two sets, superficial and deep, the former being placed beneath the peritoneum, the latter in the substance of the organ. The lymphatics of the cervix uteri run in three directions—transversely to the external iliac nodes, postero-laterally to the internal iliac nodes, and posteriorly to the common iliac nodes. The majority of the vessels of the body and fundus of the uterus pass outward in the broad ligaments, and are continued up with the ovarian vessels to the lateral aortic nodes; a few, however, run to the external iliac nodes, and one or two to the superficial inguinal nodes. In the unimpregnated uterus the lymphatic vessels are very small, but during gestation are greatly enlarged.

The lymphatic vessels of the vagina are carried in three directions—those of the upper part to the external iliac nodes, those of the middle part to the internal iliac nodes, and those of the lower part to the common iliac nodes. On the course of those from the middle and lower parts small nodes are situated. Some lymphatics from the lower part of the vagina join those of the vulva and pass to the superficial inguinal nodes. The lymphatics of the vagina anastomose with those of the cervix uteri, vulva, and rectum, but not with those of the bladder.

THE LYMPHATICS OF THE THORAX.

The lymph nodes of the thorax may be divided into parietal and visceral—the former being situated in the thoracic wall, the latter in relation to the viscera.

The parietal lymph nodes include the internal mammary, intercostal, and diaphragmatic nodes.

1. The internal mammary nodes are placed at the anterior extremities of the intercostal spaces, by the side of the internal mammary artery. They derive afferents from the mammary gland, from the deeper structures of the anterior abdominal wall above the level of the umbilicus, from the upper surface of the liver through a small group of nodes which lie behind the ensiform cartilage, and from the deeper parts of the anterior portion of the thoracic wall. Their efferents usually unite to form a single trunk on either side; this may open directly into the junction of the internal jugular and subclavian veins, or that of the right side may join the right subclavian trunk and that of the left the thoracic duct.

2. The intercostal nodes (*lymphoglandulae intercostales*) occupy the posterior parts of the intercostal spaces, in relation to the intercostal vessels. They receive the deep lymphatics from the postero-lateral aspect of the thorax; some of these vessels are interrupted by small lateral intercostal nodes. The efferents of the nodes in the lower four or five spaces unite to form a trunk, which descends and opens either into the receptaculum chyli or into the commencement of the thoracic duct. The efferents of the nodes in the upper spaces of the left side terminate in the thoracic duct; those of the corresponding right spaces, in the right lymphatic duct.

3. The diaphragmatic nodes lie on the thoracic aspect of the Diaphragm, and consist of three sets—anterior, middle, and posterior.

The anterior set consists of (a) two or three small nodes behind the base of the ensiform (xiphisternum), which receive afferents from the convex surface of the liver, and (b) one or two nodes on either side near the junction of the seventh rib with its cartilage, which receive lymphatic vessels from the front part of the Diaphragm. The efferent vessels of the anterior set pass to the chain of internal mammary nodes.

The middle set consists of two or three nodes on either side close to where the phrenic nerves enter the Diaphragm. On the right side some of the nodes of this group lie within the fibrous sac of the pericardium, in front of the inferior vena cava. The afferents of this set are derived from the middle part of the Diaphragm, those on the right side also receiving afferents from the convex surface of the liver. Their efferents pass to the posterior mediastinal nodes.

The posterior set consists of a few nodes situated on the back of the diaphragmatic crura, and connected on the one hand with the lumbar nodes and on the other with the posterior mediastinal nodes.

The superficial lymphatic vessels of the thoracic wall ramify beneath the skin and converge to the axillary nodes. Those over the Trapezius and Latissimus dorsi run forward and unite to form ten or twelve trunks which end in the

subscapular group. Those over the pectoral region, including the vessels from the skin covering the peripheral part of the mamma, run backward, and those over the Serratus magnus upward, to the pectoral group. Others near the lateral margin of the sternum pass inward between the rib cartilages and end in the internal mammary nodes, while the vessels of opposite sides anastomose across the front of the sternum. A few vessels from the upper part of the pectoral region pass upward over the clavicle to the supraclavicular group of cervical nodes.

The **lymphatic vessels of the mammary gland** (Fig. 562) originate in a plexus in the interlobular spaces and on the walls of the galactiferous ducts. Those from the central part of the gland pass to an intricate plexus beneath the areola (*sub-areolar plexus*), a plexus which also receives the lymphatics from the skin over the central part of the gland. Its efferents are collected into two trunks which pass to the pectoral group of axillary nodes. The vessels which drain the inner (mesal) part of the gland pierce the thoracic wall and end in the internal mammary nodes, while a vessel may occasionally emerge from the upper part of the gland and piercing the Pectoralis major, to terminate in the subclavicular nodes (Fig. 562).

The **deep lymphatics of the thoracic wall** consist of:

1. The lymphatics of the muscles which lie on the ribs; most of these terminate in the axillary nodes, but some from the Pectoralis major pass to the internal mammary nodes.

2. The **intercostal lymphatic vessels** which drain the Intercostal muscles and parietal pleura. Those draining the External intercostal muscles run backward and, after receiving the vessels which accompany the posterior branches of the intercostal arteries, terminate in the posterior intercostal nodes. Those of the Internal intercostal muscles and parietal pleura consist of a single trunk in each space. These trunks run forward in the subpleural tissue and the upper six open separately into the internal mammary nodes or into the vessels which unite them; those of the lower spaces unite to form a single trunk which terminates in the lowest of the internal mammary nodes.

3. The **lymphatic vessels of the Diaphragm**, which form two plexuses, one on its thoracic and another on its abdominal surface. These plexuses anastomose freely with each other, and are best marked on the parts covered respectively by the pleuræ and peritoneum. That on the thoracic surface communicates with the lymphatics of the costal and mediastinal parts of the pleura, and its efferents consist of three groups: (a) *anterior*, passing to the nodes which lie near the junction of the seventh rib with its cartilage; (b) *middle*, to the nodes on the œsophagus and to those around the termination of the inferior vena cava; and (c) *posterior*, to the nodes which surround the aorta at the point where this vessel leaves the thoracic cavity.

The plexus on the abdominal surface is composed of fine vessels, and anastomoses with the lymphatics of the liver and, at the periphery of the Diaphragm, with those of the subperitoneal tissue. The efferents from the right half of this plexus terminate partly in a group of nodes on the trunk of the corresponding inferior phrenic artery, while others end in the right lateral aortic nodes. Those from the left half of the plexus pass to the preaortic and lateral aortic nodes and to the nodes on the terminal portion of the œsophagus.

Applied Anatomy.—The fact emphasized by Robinson that the peritoneum is a great lymph sac explains the quick absorption of septic material and the rapid spread of infectious processes. If the exudate clots and blocks the lymph channels, absorption is slow and life may be saved. If it does not clot, absorption is rapid and death is certain. Whether it clots or not depends on the nature of the bacteria present. Fowler, impressed by the fact that absorption takes place most rapidly from the diaphragmatic region and least rapidly from the pelvic region, advises placing the victim of peritonitis in bed, with his head and body elevated.

A knowledge of the *lymphatics of the breast* and of the nodes into which the lymphatics drain is of the first importance to a surgeon. Certain surgical deductions from the anatomy of this region are perfectly obvious—viz.: (1) If the skin of the mammary gland is involved in carcinoma, the thoracic group of axillary nodes of the same side is involved. If the skin over the sternal margin of the gland is involved, the nodes of the opposite axilla may be cancerous, as from this point lymph vessels rise and pass across the midline. If the skin of the sternal margin is involved the prognosis is worse than if it is free, the opposite axilla may be cancerous, and the opposite breast may become diseased. (2) When lymphatic vessels become blocked by cancer cells the lymph backs up, flows backward instead of in its proper direction, and may cause infection in the most unsuspected situations. For instance, a block in the cutaneous lymphatics of a portion of the breast may lead to infection of the opposite breast and axilla, though, of course, it is not so likely to as is cancer of the skin of the sternal margin. By regurgitation of lymph the head of the humerus or the retrosternal structures may become diseased in mammary cancer. (3) If the nipple or areola is cancerous, the entire gland is sure to be diseased, as the lymphatic network of this region empties into the subareolar plexus, and most of the trunks coming from the gland also enter this plexus. (4) If the mammary gland is cancerous, all of the axillary nodes are regarded as diseased, as the main lymphatic channel from the breast reaches the nodes on the inner wall of the axilla upon the third digitation of the Serratus magnus. Furthermore, in many cases an accessory lymph channel comes off from the lower portion of the mammary gland and passes directly to the axilla. (5) The subclavian nodes are to be regarded as diseased, because in a certain proportion of cases (the exact proportion being uncertain) an accessory lymph channel comes off from the posterior surface of the mammary gland, passes through the great Pectoral muscle, and ascends between the greater and lesser Pectorals to reach the subclavian nodes. (6) The element which greatly interferes with the cure of mammary carcinoma is the existence of lymph channels which arise from the inner portion of the mammary gland, pierce the greater Pectoral and Internal intercostal muscles, and reach the internal mammary nodes. Mediastinal involvement is apt to be earlier in carcinoma of the inner portion of the breast than in carcinoma of other portions, and the prognosis is particularly bad in cancer of the inner portion of the breast. What is known as the *sternal symptom* of Snow is bulging of the sternum due to involvement of the thymus gland. (7) The sternal portion of the great Pectoral and the tissue between it and the lesser Pectoral muscle are to be regarded as diseased, because in some cases an accessory lymph channel from the breast penetrates the greater Pectoral and ascends to the subclavian nodes. This trunk has several interrupting or satellite nodes, the *retropectoral nodes*, in the tissue back of the great Pectoral muscle. (8) When the great Pectoral muscle is diseased, cancer cells soon spread widely through the sternal portion of the muscle, and this entire portion of the muscle becomes cancerous. The clavicular portion does not suffer early, but escapes until the cancer becomes extensive, as it is anatomically distinct from the sternal portion. If the fibres of the great Pectoral are extensively diseased, the thoracic group of axillary nodes, the subclavian nodes, and possibly the internal mammary nodes are involved. (9) The only operation in cancer of the breast which offers any real hope of cure is one which is done early and is radical. (10) It must be done early, because delay permits involvement of the mediastinum, and if the disease has entered the mediastinum operation is hopeless. If the sternum is bulged operation is useless, and nothing short of amputation at the shoulder-joint could be of help if the head of the humerus is enlarged by the disease. Even this radical procedure is of no avail, because the mediastinum is certainly involved if the head of the humerus is diseased. (11) If the lymph nodes above the clavicle are extensively diseased operation is useless, as in such cases the mediastinum is sure to be involved. (12) A radical operation means the removal of the skin of the breast with the nipple and areola, the subcutaneous tissue of this region, the entire breast, the sternal portion of the great Pectoral with its fascia, the retropectoral nodes and tissue, all the contents of the axilla except vessels and nerves, the nodes and cellular tissue beneath the anterior margin of the Latissimus dorsi, and the subclavian nodes. It is probably always wisest to open above the clavicle as well as below to facilitate the removal of nodes. It is seldom necessary to remove the clavicular portion of the greater Pectoral. The lesser Pectoral does not require removal, but it should be taken away, because of the added safety and speed thus obtained in cleaning the great vessels and because its retention does not improve the functional result. The surgeon must remember that the breast is a much larger organ than we used to think, and all of its irregular projections and outlying lobules must be removed (p. 787). Formerly, surgeons did not completely remove the breast, but only got rid of a large portion of it.

The **visceral lymph nodes** consist of three groups—viz., anterior mediastinal, posterior mediastinal, and tracheobronchial.

The **anterior mediastinal nodes** (*lymphoglandulae mediastinales anteriores*) are placed in the anterior part of the superior mediastinum, in front of the arch of the aorta and in relation to the innominate veins and the large arterial trunks

which arise from the aortic arch. They receive afferents from the thymic nodes; their efferents unite with those of the tracheobronchial nodes, to form the right and left bronchomediastinal trunks.

FIG. 576.—Deep lymph nodes and vessels of the thorax and abdomen (diagrammatic). Afferent vessels are represented by continuous lines, and efferent and internodular vessels by dotted lines. (Cunningham.)

The **posterior mediastinal nodes** (*lymphoglandulae mediastinales posteriores*) lie behind the pericardium in relation to the oesophagus and descending thoracic aorta. Their afferents are derived from the oesophagus, the posterior part of the pericardium, the Diaphragm, and convex surface of the liver. Their efferents mostly terminate in the thoracic duct, but some join the tracheobronchial nodes.

The **tracheobronchial nodes** form three main groups in relation to the bifurcation of the trachea—one on either side of the trachea above the bronchi and one in the angle between the bronchi (*lymphoglandulae tracheales*); other nodes, termed **interbronchial** (*lymphoglandulae bronchiales*), are found at the points of division of the larger bronchi. The afferents of the tracheobronchial nodes drain the lungs and bronchi, the thoracic part of the trachea and the heart; some of the efferents of the posterior mediastinal nodes also terminate in this group. Their efferent vessels ascend upon the trachea and unite with efferents of the internal mammary and anterior mediastinal nodes to form the **right and left bronchomediastinal trunks**. The right bronchomediastinal trunk may join the right lymphatic duct, and the left the thoracic duct, but more frequently they open independently of these ducts into the junction of the internal jugular and subclavian veins of their own side.

Applied Anatomy.—In all town dwellers there are continually being swept into those nodes from the bronchi and alveoli large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities. At first the nodes are moderately enlarged, firm, inky black, and gritty on section; later they enlarge still further, often becoming fibrous from the irritation set up by the minute foreign bodies with which they are crammed, and may break down into a soft slimy mass or may calcify. In tuberculosis of the lungs these nodes are practically always infested; they enlarge, being filled with tuberculous deposits that may soften, or become fibrous, or calcify. Not infrequently an enlarged tuberculous node perforates into a bronchus, discharging its contents into the tube. When this happens there is great danger of acute pulmonary tuberculosis, the infecting node-substance being rapidly spread throughout the bronchial system by the coughing its presence in the air-passages excites.

The **lymphatic vessels of the thoracic viscera** consist of those of the heart and pericardium, lungs and pleura, thymus and oesophagus.

The **lymphatic vessels of the heart** consist of two plexuses: (*a*) deep, immediately under the endocardium, and (*b*) superficial, subjacent to the visceral pericardium. The deep plexus opens into the superficial, the efferents of which form right and left collecting trunks. The *left* trunks, two or three in number, ascend in the anterior interventricular furrow, receiving, in their course, afferents from both ventricles. On reaching the auriculoventricular furrow they are joined by a large trunk from the back of the heart, and then unite to form a single vessel which descends between the pulmonary artery and the left auricle and ends in one of the tracheobronchial nodes. The *right* trunk receives its afferents from the right auricle and from the right border and posterior surface of the right ventricle. It ascends in the posterior auriculoventricular groove and then runs forward in the auriculoventricular groove, and passes up behind the pulmonary artery, to end in one of the tracheobronchial nodes.

The **lymphatic vessels of the lungs** originate in two plexuses, a superficial and a deep. The superficial plexus is placed beneath the visceral pleura. The deep accompanies the branches of the pulmonary vessels and the ramifications of the bronchi. In the case of the larger bronchi the deep plexus consists of two networks, one, submucous, beneath the mucous membrane, and another, peribronchial, outside the walls of the bronchi. In the smaller bronchi there is but a single plexus, which extends as far as the bronchioles, but fails to reach the alveoli, in the walls of which there are no traces of lymphatic vessels. The superficial efferents turn around the borders of the lungs and the margins of their fissures, and converge to end in some nodes situated at the hilum; the deep efferents are conducted to the hilum along the pulmonary vessels and bronchi, and end in the tracheobronchial nodes. Little or no anastomosis occurs between the superficial and deep lymphatics of the lungs, except in the region of the hilus.

The **lymphatic vessels of the pleura** consist of two sets—one in the visceral and another in the parietal part of the membrane. Those of the visceral pleura

drain into the superficial efferents of the lung, while the lymphatics of the parietal pleura have three modes of ending—viz.: (a) those of the costal portion join the lymphatics of the Internal intercostal muscles and so reach the internal mammary nodes; (b) those of the diaphragmatic part are drained by the efferents of the Diaphragm; while (c) those of the mediastinal portion terminate in the posterior mediastinal nodes.

The **lymphatic vessels of the thymus gland** terminate in the superior mediastinal, tracheobronchial, and internal mammary nodes.

The **lymphatic vessels of the œsophagus** form a plexus around that tube, the collecting vessels from which drain into the posterior mediastinal nodes.

THE NERVE SYSTEM.

THE SPINAL CORD AND BRAIN, WITH THEIR MENINGES.

THE nerve system of man is an apparatus by means of which he appreciates and becomes influenced by impressions from the outer world, reacts on these impressions, and hence is enabled to adapt himself to his environment. It is the organic substratum for those manifestations of nerve force engaged in the characteristic attributes of animal life—*sensation* and *motion*. Broadly stated, the nerve system connects the various parts of the body with one another and coördinates them into one harmonious whole in order to carry on the bodily functions methodically and to control the physiological division of labor throughout the organism. With the evolution of the higher forms of animal life through an immense phylogenetic past the nerve system has undergone remarkable differentiation and specialization, attaining its maximum as to dominant position and complexity of structure in the human species.

The description of the nerve system is assisted by the accommodation of physiological data to the anatomical basis in order to demonstrate more clearly and to render more practical our knowledge of the mutual relations of its structure and function. The cycle of events which accompanies nerve action is determined by impressions received by the peripheral organs, apperception and reflexes of these impressions in the lower nerve centres, correlation of these with other impressions in higher centres, as well as voluntary reactions or inhibitions, liberated in compliance with the organic or higher needs of the individual.

Conventionally, the nerve system is usually considered as consisting of (1) the **cerebrospinal system**, comprising (a) the **central nerve axis** (brain and spinal cord) and (b) the **peripheral nerves** (cranial and spinal), and (2) the **sympathetic nerve system**. This subdivision, like others formulated by various authors, is an arbitrary one. No part of the system stands isolated, and the manifold groupings and chainings of the units of the system intimately connect the central nerve organs with the peripheral nerve endings, the organs of special sense and the vegetative organs. The distinction between the central and the sympathetic systems has been too absolute, and the only justification for adhering to the classification given above is based upon the fact that the sympathetic system is preponderatingly related to the interconnection and coördination of the nutritive (digestive, respiratory, and blood and lymph) apparatus, and, therefore, exercises a special control over its activities.

Structurally considered, the nerve system consists of cell-elements peculiarly differentiated from all other tissue cells in that their protoplasm is extended, often to great distances from the nuclear region, in the form of processes. The cell-elements are held in place by supporting tissues, partly of ectodermal and partly of mesodermal origin, and receive an abundant blood supply.

The cell element of the nerve system is called the **neurone**. The neurone is

the *developmental, structural, and functional unit* of the nerve system. It is in reality a single cell presenting unusual structural modifications. It comprises not only the nerve-cell body with its numerous **protoplasmic processes** or **dendrites**, but also the **axone**, which may vary in length from a fraction of a millimetre to fully half a man's stature; so that, despite the delicacy of the axone, its bulk may be almost two hundred times greater than that of the cell body from which it proceeds. The long axones serve to make a connection with a peripheral or distant nerve cell, muscle cell, or gland cell, while the shorter axones of certain neurones divide into terminal branches in the immediate vicinity of its cell body, presumably to come into relation with other nerve cells in the same or adjacent groups.

Neurones, being devoted to the maintenance of functions manifested by various phenomena of nerve force, are differentiated in their polarity, both structurally and dynamically. Receptive neurones are so arranged as to receive afferent nerve impulses from other tissues; emissive or excitor neurones give out efferent nerve impulses. The former are generally termed **sensor neurones**, the latter **motor (excitomotor) neurones** if connected with muscle, **excitoglandular** if connected with gland cells. Were the nerve system made up solely of such initial and terminal neurones, the apparatus would be merely a system of reflex arcs. Such it is in low forms of animal life which, by their very organization, and because of the close juxtaposition of their sensor and motor elements, are compelled to react to stimuli from without. In higher forms, with more profoundly differentiated nerve systems, the sensor impression must pass through an interposed medium which is capable of either transmitting the molecular change in the form of an excitomotor impulse or, on the other hand, is capable of reducing or checking the impulse. In other words, reaction is not imperative; there is a freedom of choice exercised by intermediate neurones endowed with inhibitory function. The simple arc, composed of an afferent sensor neurone and an efferent motor neurone, would act independently of all other arcs were it not for the interposition of this intermediate neurone and of other association neurones which, by their relations toward similar arc elements, produce harmony of action. The basis, then, of the nerve system is a series of neurones, with projecting and association processes, coördinated for the purpose of performing specific actions manifested either by motion, by trophic changes, or by the apperception of stimuli of a chemical, mechanical (tactile and auditory), thermal, or photic nature. When we consider the profoundly complex manifestations of nerve phenomena in the mental and physical life of man it is not surprising to learn that his nerve system is made up of an immense multitude of aggregations of neurones.

Fundamental Facts Regarding the Development of the Nerve System.—

The nerve system is formed by a remarkable metamorphosis of the ectodermic layer of the developing ovum. Along the mid-dorsal line of the embryonic mass, a thickening of the ectoderm forms a well-defined layer of cells, the **neural plate**. The proliferative process passes rapidly from the cephalic toward the caudal end, and as development advances it is seen that the most intense growth energy takes place at the cephalic end, indicative of the higher functional potentiality of what is to become the brain. The neural plate undergoes a trough-like formation as its edges become elevated cephalad and laterally to form the **neural groove** (Fig. 577). The edges become more and more elevated and bend toward the median line until the margins of the groove coalesce to form a tube, the **neural tube**, which sinks into the subjacent mesodermal tissues. The fusion of the margins of the neural plate occurs first in the cervical region and rapidly continues both cephalad and caudad. The cephalic portion, destined to become the brain, expands and grows considerably, while the caudal portion elongates to form the spinal cord.

Eventually the neural tube, as it sinks into the subjacent mesodermal tissue,

severs all connection with the ectoderm from which it developed; but for a brief period the continuity is preserved in an attenuated septal mass, the **neural crest** (Fig. 577). The cell elements of this crest subsequently become detached from the superficial ectoderm, the continuity of which is again restored to form the integument. They then pass ventrad to either side of the neural tube, prolifer-

FIG. 577.—Diagrams showing development of neural tube and crest.

ate by mitosis, and accumulate in paired masses, corresponding in number to the segments of the body, to become, in part at least, the **cerebrospinal ganglion** cells of the afferent system, while other similarly paired masses migrate farther ventrad to a prevertebral position to form the **gangliated cord** and widely spread **plexuses of the sympathetic system**. From the tissues of the wall of the neural

FIG. 578.—Diagram showing development of a spinal nerve and its components, together with the spinal and sympathetic ganglia.

tube and its temporary crest the entire nerve system of complex and intricate structure is developed. The cavity of the tube shares in the developmental growth changes to become the ventricular system of the brain and central canal of the spinal cord. The major details of the development of the principal divisions will be considered in appropriate chapters.

Development of Nerve Tissue. 1. **In the Wall of the Neural Tube.**—The single layer of nucleated epithelial cells of ectodermal origin which makes up the wall of the neural tube early becomes modified into a layer of tall columnar cells called **spongioblasts** (Fig. 579). Their protoplasmic ends undergo differentiation in that the central ends become elongated and attenuated or collapsed to form a series of striated pillars with intervening spaces. The central ends retain their breadth, however, and form an internal limiting membrane. The ectal ends undergo differentiation to form a spongy felt-work or reticulum (*peripheral veil of His*); eventually these spongioblasts become (a) **ciliated ependymal cells** and (b) **neuroglia**.

In the intercellular spaces of the central zone there appear spherical cells of different structure and density. These are the **germinal cells**, seen in very early stages and proliferating rapidly by karyokinesis. They soon lose their spherical form, becoming pear-shaped as a protoplasmic process extends ectad. These pear-shaped cells are now termed **neuroblasts** (Fig. 579), the protons of the neurones, and as development advances they leave the central zone and migrate into the marginal reticulum to the positions in which they are found in the gray substance of the brain and spinal cord. The protoplasmic process is at first slightly bulbous and elon-

gates to form the axone extending toward other nerve-cells or to the peripheral tissue elements with which they become associated by the contiguity of the terminal arborizations into which the bulbous extremity develops. The precision with which the axones travel toward their allotted goal is one of the most remarkable manifestations of organic development. An American experimenter, Ross G. Harrison, has devised a method for directly observing the living, growing nerve. In isolated pieces of frog embryos the differentiation of the living nerve elements could be observed from day to day during several weeks. The bulbous end of the outflowing protoplasmic fibre, showing a faint fibrillation, was seen to reveal a continuous change of form particularly in a number of fine simple and branched filaments which were in constant ameboid

movement. Harrison's demonstration¹ is of great significance in connection with the "retraction theory" and other ideas related to the neurone doctrine.

2. **In the Neural Crest Tissues.**—The nerve tissue elements of the sympathetic system and of the ganglia of the cranial nerves and dorsal roots of the spinal nerves are derived from the neural crest. Omitting, for the present, the development of the sympathetic system, it is found that the cells of the paired masses which eventually become the cerebrospinal ganglia are at first somewhat spherical, then oval in form, sending out from either extremity or pole a protoplasmic process. One process migrates centrad, the other toward the tissues of the periphery. The central process penetrates the tissues of the neural tube and, assuming the typical form of an axone with its collaterals and end arborizations, comes into contiguous association with certain cells of the central axis. The peripheral process is in reality an unusually long dendrite, for it is centripetal in function; but owing to the fact that it is usually provided with a myelin sheath it is also termed the **peripheral axone of an afferent (or sensor) neurone**. The central processes of the cells of a single spinal nerve ganglion form the dorsal nerve roots; the peripheral processes constitute the afferent portion of a spinal nerve. The cells themselves are transformed from bipolar into apparently unipolar cells by the migration of the cell body to one side and the consequent approximation of the two processes to form a common pedicle in a T-shaped manner (Fig. 586).

Structure of the Nerve System.—The whole of the nerve system is composed of nerve tissue and supporting connective tissue. The neurones constitute the nerve tissue, while the supporting tissue is composed of the neuroglia and of white fibrous tissue derived either from the investing membrane or from the sheaths of its numerous vascular channels.

The Neurone.—The neurone or nerve cell element, whose individuality has already been pointed out, exhibits remarkable variations as to external characters, dimensions, and form. The neurone presents a concentrated or swollen cell mass and nucleus, formerly known as the **nerve cell (ganglion cell)** and still retaining the name. From this cell body are given off a number of processes of two distinct kinds: (1) protoplasmic processes which are commonly branched and generally called the **dendrites**; (2) a single, thinner, and paler process, the **axone** (*axis-cylinder process*; *Deiters' process*; *neuraxone*; *neurite*).

Varied Forms of Neurones.—Bearing in mind that each neurone includes not only the cell body and its dendritic processes, but also the axone or axis-cylinder process with all its ramifications, we may consider each of these divisions under separate heads.

1. **Nerve Cell Body. External Morphology.**—The bodies of nerve cells vary much in size, measuring from 4 to 135 microns or more in diameter. The largest cells are found in the ventral horns of the spinal cord, in the spinal ganglia, in the large pyramidal cell layer of the cerebral cortex, in the Purkinjean cell layer of the cerebellum, and in the column of Clarke (dorsal nucleus) of the spinal cord. Very small cells are found in the olfactory bulbs, in the granular layers of the cerebral and the cerebellar cortex, and in the gliosum cornualis of the cord.

Although all nerve cells begin in the embryonic ectoderm as spherical germinal cells, they later assume, in different regions, very different shapes. These external morphological relations

FIG. 581.—Showing some varieties of cell bodies of neurones (diagrammatic.) A. Unipolar (amacrine) cell from the retina. B. Bipolar cell from vestibular ganglion. C. have been best revealed by the methods of Ehrlich and Golgi. According to the number of processes arising from the cell body, neurones are referred to as (1) **unipolar**, (2) **bipolar**, and (3) **multipolar nerve cells**.

1. **Unipolar cells** are met with frequently in early stages of embryonic development, but are rare in the adult, being found only in the retina, olfactory bulb, and within the baskets of the Purkinjean cells of the cerebellum. They are called **amacrine cells**. The cells of the cerebro-spinal ganglia (excepting the cochlear and vestibular) are apparently unipolar, but they are developmentally and functionally of bipolar nature.

2. **Bipolar cells** are found almost exclusively in the peripheral sensor systems, as in the olfactory membrane, in the retina, in the cochlear and vestibular ganglia, and in the cerebro-spinal ganglia of the embryo.

3. **Multipolar cells** are the most numerous and form the principal elements of nerve centres throughout the system. They are termed multipolar because of the greater or less number of dendrites given off in addition to the single axone.¹

The terms "unipolar" and "multipolar" must be restricted to the morphological sense; dynamically all nerve cells are bipolar.

According to the relations of the axone we distinguish, after Golgi, two kinds of neurones:

I. Neurones with long axones which become the axis cylinder of a central or peripheral nerve fibre. The axones give off several collaterals which, like the parent stem, break into finely branched terminals or telodendria.

II. Neurones with relatively short axones which do not go into the formation of a nerve fibre, but break up into terminal twigs in the vicinity of the cell-bodies from which they arise. Type II is generally termed, for brevity's sake, the **Golgi cell**.

FIG. 582.—Purkinjean cell from human cerebellum, as seen in a plane transverse to the long axis of a cerebellar folium. *a*. Axone. *clt*. Collaterals. (Golgi method.)

FIG. 583.—Profile view of Purkinjean cell, in the plane of the long axis of a cerebellar folium.

According to the morphological relations of the dendrites, neurones are classified as follows:

(a) **Stellate cells**, the dendrites of which spring at intervals from the whole circumference of the cell body and pass toward all directions (motor cells in ventral horn and tract cells of the cord).

(b) Cells with one principal stout dendrite (among other lesser dendrites) which gives off side branches and ends in fine terminal twigs (pyramidal cells of cerebral cortex; mitral cells of olfactory bulb).

(c) **Arboriform cells**, giving off branched dendrites from both base and apex, resembling the roots and the branches of a tree; the axone often springs from the base of one of the root-like dendrites (pyramidal cells of the hippocampus).

¹ Exceptionally, more than one axone has been observed arising from a single cell, as in the Cajal cells of the cerebral cortex.

(d) Cells with **monopolar dendrites**. Several main dendritic stems spring from one pole of the cell and, undergoing frequent subdivision, break up into a fine terminal arborization. The axone springs from the opposite pole (Purkinjean cells of the cerebellum; granular cells of the *fasciola cinerea*).

2. **Nerve Cell Body. Internal Morphology.**—The nucleus of the nerve cell differs in no essential from the typical nuclear structure. Regarding the organization of the cytoplasm several conflicting views exist. In the present state of our knowledge concerning this still obscure field of investigation it may be said that the nerve cell protoplasm is roughly divided into a **peripheral exoplasmic portion** and a **central endoplasmic portion**. There is shown throughout the cytoplasm a tendency to fibrillar structure, more pronounced in the exoplasmic portion. Within the meshes of a more or less homogeneous ground substance, which pervades the whole, are deposited larger and smaller masses of a granular substance. Nerve cells fixed and stained by the methods of Nissl and Held show that the granule masses are "stainable" (**chromatophiles**; **tigroid bodies**; **Nissl bodies**), probably of the nature of a nucleoproteid (MacCallum) and looked upon as a sort of nutritive reserve. Many of the larger cells possess more or less pigmented material, adjacent to the nucleus. The cells of the **substantia nigra** (*intercalatum*) and of the **locus coeruleus** contain an abundance of such pigment granules.

The "unstainable" homogeneous ground substance of the cytoplasm is probably the more important functionally, for numerous delicate **neurofibrils** have, by special methods, been shown to traverse the cell body and its processes, crossing and interlacing, perhaps anastomosing with each other, and traceable into the axone.¹ Nissl, after years of painstaking investigation, has classified nerve cells into a great many different species in accordance with their reaction to staining agents.

FIG. 584.—Motor nerve cell from ventral horn of spinal cord of rabbit. The angular and spindle-shaped Nissl bodies are well shown. (After Nissl.)

FIG. 585.—Bipolar nerve cell from a spinal ganglion of the pike. (After Kölliker.)

FIG. 586.—Three stages in the development of a cell from a spinal ganglion.

The Dendrites.—The dendrites are attenuated processes, usually numerous, resembling in structure and staining reactions the cytoplasm, of which, as extensions, they increase the functional expanse of the surface of the cell body. Emerging by a broad base, they become

¹ That the neurofibrils form such an intracellular network and that the axones arise therefrom is disputed by Ramón y Cajal, Bielschowsky, and others.

narrower as they divide into many branches in a dichotomous or arborescent manner to end free, according to most observers, or to be joined with the dendrites of other neurones by means of minute fibrillæ (as claimed by Apathy) or by concrescence (Held). The contour of the dendrite, while occasionally irregular in some specimens, with **varicosities** along its course, is, as a rule, beset with numerous lateral buds called **gemmules**. Various hypotheses have been advanced in explanation of these appearances, it being held by some investigators that they are related to conditions of activity as contrasted to those of repose, while others believe them to be **artefacts** produced by the fixing and staining methods at present employed. However, it is no longer disputed that the function of the dendrites is receptive and conductive (or **cellulipetal**) for nerve impulses, although they probably serve the nutritional requirements of the cell body as well.

This functional distinction gives the clue to the correct interpretation of the central and peripheral prolongations of the cerebrospinal ganglionic neurones. The cells of these ganglia are at first bipolar in form, but gradually undergo transformation into apparently unipolar cells by the migration of the cell body to one side and the consequent approximation of the two processes to form a common pedicle in a T-shaped manner so typical of the spinal ganglion cell of the adult. The central branch invariably remains **cellulifugal**, the peripheral branch invariably remains **cellulipetal**, and as such is equivalent to the dendrites of all other neurones. It is merely a *modified* dendrite in that it courses a longer distance without branching until it reaches the periphery and is usually myelinic. Such a peripheral prolongation of the ganglion cell is also termed a **centripetal nerve fibre** or **myelinic (medullated) peripheral axone** of a **peripheral centripetal neurone**.

FIG. 587.—A. Myelinic axones in fresh state, showing a few nodes. B. Portion of a myelinic axone treated with boiling ether and alcohol to remove the myelin and leaving the neurokeratin network. a. Axone.

The Axone.—The axone is usually much longer than any of the dendrites, thin, pale, smooth, emerging from the nerve cell as a direct continuation of the neurofibrillar ground substance of the cell body, and devoid, so far as at present known, of chromatophile granules. Its calibre varies for the different cells, corresponding in general to the length of its course, but it is practically of uniform diameter throughout its extent. Axones may be extremely short or fully a meter in length. Most cells give rise to only one axone (**monaxonic neurones**), but in certain localities **diaxonic** (two axones) and **polyaxonic** (several axones) neurones are found. In a Golgi preparation axones stand out like pieces of black thread, taking a more direct course than do the irregular dendrites, and rarely branching before reaching the ultimate termination, although giving off **collaterals** along their course. The central axones of spinal ganglion (sensor) neurones are the principal exception to this rule in that they bifurcate in a Y-shaped manner after their entrance into the central nerve system. In the case of another group of neurones, **Golgi's Cell, Type II**, the axone is observed to break up into numerous

branches soon after its departure from the cell; such axones are called **dendraxones**. The axones and their collaterals end in terminal arborizations, the **telodendria**.

The axone is the distributive or emissive (cellulifugal) conductor of nerve impulses. There is, therefore, a functional opposition attributable to the two extremities of the neurone, based upon its *dynamic polarity* and upon a physiologic principle which is established by all experiments to which the nerve system is submitted, namely, that nerve impulses pass through the neurone in a definite direction which is invariable and admitting of anatomic localization.

The majority of the peripheral spinal and cerebral axones as well as those constituting the white substance of the brain and cord are invested by a myelin sheath.

The Collaterals (paraxones).—The collaterals are accessory branchings of the axones which are more numerous in the cytoproximal portion and are usually directed at right angles to the parent stem. Some axones possess few or no collaterals, while others possess many. The collaterals, especially those in the gray substance of the central axis, are frequently myelinic. They unquestionably play an important part in the grouping and chaining of neurones within the system, in yielding up to neighboring neurones a portion of the impulse that the cell has received by its dendrites and transmits along its axone to a distance.

Varieties of Axones.—Axones are divided into two main groups depending upon the presence or absence of a myelin sheath—**myelinic axones** and **amyelinic axones**, or **medullated** and **nonmedullated axones**.

Myelinic axones or **medullated axis-cylinder processes** are axones enveloped by a relatively thick sheath composed of semifluid phosphorized fat, which gives to the bundles of these structures their opaque, white appearance. The myelin sheath is in turn invested by a delicate membrane (**neurilemma**) in one group, while another group is devoid of such covering, giving rise to the further subdivision into (a) myelinic axones with a neurilemma; (b) myelinic axones without a neurilemma.

Myelinic axones with a neurilemma constitute the bulk of the cerebrospinal nerves, and, in lesser proportion, of the sympathetic nerves. The **myelin sheath** (*medullary sheath of Schwann*) (Figs. 587 and 588) does not invest the axone throughout its course nor in a uniform manner. The axone after its emergence from the cell body and likewise in its preterminal portion is naked; and the delicate external membrane or **neurilemma** comes in contact with the axone. The myelin sheath consists of a number of tubular segments demarcated by nodal intersections which are only 0.08 mm. apart in the very small myelinic axones, while for large axones the intervals may be 1 mm. or more. At the **nodes** (*constrictions of Ranvier*) the neurilemma dips into the constriction to come in contact with the axone, and any branches of the axone are invariably given off at such points. The interruptions in the continuity of the myelin sheath have been assumed to be provisions facilitating nutritive diffusion between the axone and the surrounding lymph, and here only may collaterals be given off. Each internodal myelinic segment is further characterized by oblique clefts, irregularly distributed—the **incisures of Schmidt-Lantermann**—seen only in fixed specimens and probably artefacts. Extraction of the fatty substance of the myelin sheath by boiling alcohol and ether brings out a fine network which resists trypsin digestion, and is termed **neurokeratin** on account of its resemblance to the keratin of epidermal structures.

The **neurilemma** (*primitive sheath of Schwann; neurolemma*), a delicate structureless membrane, encloses the myelin and the axone, wherever the myelin sheath is wanting. Against the

FIG. 588.—A. Amyelinic axones with a neurilemma only, the nuclei of which can be seen. B. inner surface of the neurilemma, and embedded as it were in the myelin, usually midway between two nodes, lies the oval-shaped **nucleus of the neurilemma**.

Myelinic axones are usually from 4 to 10 microns in diameter; the extremes range from 2 to 20 microns.

Myelinic axones without a neurilemma constitute the white substance of the brain and spinal cord, as well as the optic nerves. They differ from the axones just described in two particulars—the neurilemma is absent and there are no nodes interrupting the continuity of the myelin sheath. A network of neuroglia replaces the neurilemma as a supporting tissue.

Amyelinic axones with a neurilemma (*Remak's fibres; sympathetic nerve fibres*) constitute the majority of the sympathetic axones and the axones of the olfactory nerves. The myelin sheath is absent and the axone is invested, more or less completely, by a nucleated cellular sheath or neurilemma.

Amyelinic axones without a neurilemma are naked axones, most numerous in the central ganglia. Most axones of longer course are devoid of any sheath in the cytoproximal and pre-terminal portions, whatever investment they may receive in the intermediate portion.

NERVE CELL NIDI OR NUCLEI.

Nerve cells are more or less definitely grouped in the gray substance of the brain and cord to form what are conventionally termed "nuclei." Inasmuch as the term *nucleus* has long been given to the vesicular body in the interior of all cells, ambiguity would be avoided by designating such nerve cell groups by the term **nidi** (plural of *nidus*, "a nest").

"NERVE FIBRES" AND NERVES.

Prior to the general adoption of the neurone concept it was customary to designate the conducting elements of the nerve system by the term **nerve fibres** in distinction from the **nerve cells**. As has been pointed out above, the distinction no longer holds, but the designation "nerve fibre" is still retained in anatomic vocabulary and recurs so frequently in common parlance that, even with the new conception which has been formed of the architecture of the nerve system, the term cannot yet be entirely discarded in favor of "axone," although it probably will eventually.

Nerves are round or flattened bundles of axones which serve to bring the central axis into relation with the periphery and other tissues of the body. The nerves of the body are subdivided into two great classes—the **cerebrospinal**, which are attached to the cerebrospinal axis, and the **sympathetic** or **ganglionic nerves**, which are attached to the ganglia of the sympathetic. The cerebrospinal nerves consist of numerous nerve fibres (**myelinic axones**) collected together into small or large bundles or fasciculi and enclosed in a membranous sheath.

Structure of Nerves.—In structure the common membranous investment, or **sheath** of the whole nerve, which is called the **epineurium**, as well as the **septa** given off from it, and which separate the fasciculi, consists of connective tissue, composed of white and yellow elastic fibres, the latter existing in great abundance. The tubular sheath of the smaller fasciculi composing the nerve trunk, called the **perineurium**, consists of a fine, smooth, transparent membrane, which may be easily separated, in the form of a tube, from the fibres it encloses; in structure it consists of connective tissue which has a distinctly lamellar arrangement, being composed of several lamellæ, separated from each other by spaces containing lymph. The nerve fibres are held together and supported within the *fasciculus* by delicate connective tissue called the **endoneurium** (*sheath of Hentle*). It is continuous with septa which pass inward from the innermost layer of the perineurium, and consists of a ground substance in which are embedded fine bundles of fibrous connective tissue which run for the most part longitudinally. It serves to support the capillary vessels, which are arranged so as to form a network with elongated meshes. The cerebrospinal nerves consist almost exclusively of myelinic axones, the amyelinic axones existing in very small proportions.

The *bloodvessels* supplying a nerve terminate in a minute capillary plexus, the vessels composing which pierce the perineurium and run, for the most part, parallel with the fibres; they are connected by short, transverse vessels, forming narrow, oblong meshes, similar to the capillary system of muscle. Fine amyelinic axones accompany these capillary vessels, the *vasomotor fibres*, and break up into elementary fibrils, which form a network around the vessel. Horsley has also demonstrated certain myelinic fibres as running in the epineurium and terminating in small bulboid tactile corpuscles or *end-bulbs of Krause*. These nerve fibres, believed to be sensor, and termed *nervi nervorum*, are considered to have an important bearing upon certain neuralgic pains.

Nerves, in their course, subdivide into branches, and these frequently communicate with branches of a neighboring nerve.

The axones, so far as is at present known, do not coalesce, but pursue an uninterrupted course from the centre to the periphery. In separating a nerve, however, into its component fasciculi, it may be seen that they do not pursue a perfectly insulated course, but occasionally join at a very acute angle with other fasciculi proceeding in the same direction; from this branches are given off, to join again in like manner with other fasciculi. It must be distinctly understood, however, that in these communications the axones do not coalesce, but merely pass into the sheath of the adjacent nerve, become intermixed with its axones, and again pass on, to become blended with the axones in some adjoining fasciculus.

The communications which take place between two or more nerves form what is called a *plexus*. Sometimes a plexus is formed by the primary branches of the trunks of the nerves—as the cervical, brachial, lumbar, and sacral plexuses—and occasionally by the terminal fasciculi, as in the plexuses formed at the periphery of the body. In the formation of a plexus the component nerves divide, then join, and again subdivide in such a complex manner that the individual fasciculi become interlaced most intricately; so that each branch leaving a plexus may contain filaments from each of the primary nerve-trunks which form it. In the formation also of smaller plexuses at the periphery of the body there is a free interchange of the fasciculi and primitive fibres. In each case, however, the individual filaments or axones remain separate and distinct.

It is probable that through this interchange of fibres, every branch passing off from a plexus has a more extensive connection with the spinal cord than if it had proceeded to its distribution without such connections with other nerves. Consequently the parts supplied by these nerves have more extended relations with the nerve centres; by this means, also, groups of muscles may be associated for combined action, as is best exemplified in the formation of the limb plexuses.

The *sympathetic nerves* are constructed in the same manner as the cerebrospinal nerves, but consist mainly of amyelinic axones, collected into fasciculi and enclosed in a sheath of connective tissue. There is, however, in these nerves a certain admixture of myelinic axones, and the amount varies in different nerves, and may be known by their color. Those branches of the sympathetic which present a well-marked reddish-gray color are composed more especially of amyelinic axones, intermixed with a few myelinic axones; while those of a white color contain more of the latter and a few of the former. Occasionally, the gray and white cords run together in a single nerve, without any intermixture, as in the branches of communication between the sympathetic ganglia and the spinal nerves, or in the communicating cords between the ganglia.

The nerves, both of the cerebrospinal and sympathetic systems, convey impressions of a two-fold kind. The *afferent* or *centripetal nerves*, generally called sensor, transmit to the nerve centres impressions made upon the peripheral ends of their components, to produce reflexes in the lower centres while the mind, through the medium of the brain, becomes conscious of environmental conditions or changes. The *efferent* or *centrifugal* (in large part "motor") nerves transmit impulses from the centres to the parts to which the nerves are distributed; these impulses either excite muscle contraction or influence the processes of nutrition, growth, and secretion.

The *ganglia* may be regarded as separate small aggregations of nerve cells, connected with each other, with the cerebrospinal axis, and with the nerves in various situations. They are found on the dorsal root of each of the spinal nerves; on the sensor root of the trigeminus; on the facial and auditory nerves; and on the glossopharyngeal and vagus nerves. They are also found in a connected series along each side of the vertebral column, forming the gangliated cord or trunk of the sympathetic; and on the branches of that nerve, generally in the plexuses or at the point of junction of two or more nerves with each other or with branches of the cerebrospinal system. On section they are seen to consist of a reddish-gray substance, traversed by numerous white nerve fibres; they vary

considerably in form and size; the largest are found on the sensor root of the trigeminus and in the cavity of the abdomen; the smallest, not visible to the naked eye, exist in considerable numbers upon the nerves distributed to the different viscera. The ganglia are invested by a smooth and firm, closely adhering membranous envelope, consisting of dense areolar tissue; this sheath is continuous with the perineurium of the nerves, and sends numerous processes into the interior of the ganglion, which support the bloodvessels supplying its substance.

Origin and Termination of Nerves.—To the central and the peripheral ending of a nerve are usually given the names of “origin” and “termination.” These designations have been rendered inappropriate, in many cases, by the newer concept of neuron arrangement. They have not yet become obsolete, however, particularly in dissecting-room anatomy, and warrant description here with a certain degree of reserve alluded to above.

FIG. 589.—Diagrams of motor nerve endings in A. Striated muscle. B. Cardiac muscle. C. Nonstriated muscle. a. Axone. t. Telodendria. (After Huber, Böhm and Davidoff, and others.)

Origin.—The origin in some cases is single—that is to say, the whole nerve emerges from the nerve centre by a single root; in other instances the nerve arises by two or more roots, which come off from different parts of the nerve centre, sometimes widely apart from each other; and it often happens, when a nerve arises in this way by two roots, that the functions of these two roots are different; as, for example, in the spinal nerves, each of which arises by two roots, the ventral of which is motor and the dorsal sensor. The point where the nerve root or roots emerge from the nerve centre is named the **superficial** or **apparent origin**, but the axones of which the nerve consists can be traced for a certain distance into the nerve centre to some portion of the gray substance, which constitutes the **deep** or **real origin** of the nerve. The manner in which these fibres arise at their deep origin varies with their functions. The centrifugal or efferent nerve fibres originate in the nerve cells of the gray substance, the axones of these cells being prolonged to form the fibres. In the case of the centripetal or afferent nerves the axones grow inward either from nerve cells in the organs of special sense (*e. g.*, the retina) or from nerve cells in the ganglia. Having entered the nerve

centre, they branch and send their ultimate twigs among the cells, without, however, uniting with them.

Termination.—Axones terminate peripherally in various ways and may be most conveniently studied in the efferent and afferent systems respectively. The so-called peripheral terminations of afferent neurones are better called **peripheral nerve beginnings**, on account of their functional relations; the impulse is excited in the peripheral end and conducted centrad through the rest of the neurone.

FIG. 590.—Showing some varieties of peripheral terminations of afferent neurones (or "peripheral nerve beginnings"): A. Terminal fibrillae in epithelium (after Retzius). B. Tactile corpuscle (Meissner's, after Dogiel). C. Bulboid corpuscle (Krause's, after Dogiel). D. Lamellated corpuscle (Pacini's, after Dogiel, Sala, and others). E. Genital nerve corpuscle from human glans penis (after Dogiel). a. Axone. t. Telodendria.

Modes of Termination of Axones.—The ultimate terminals of the axones and their collaterals are called **telodendria** (or telodendria). So far as can be determined by present methods they invariably end "free," commonly by exhaustion through multiple division. This manifold branching presumably puts the neurone in a condition to influence the processes of many other neurones ("avalanche conduction" of Ramón y Cajal). In some localities the formation by axonic terminals of pericellular and peridendritic networks has been observed. Upon muscle

fibres the axone terminals form chains of flattened disks, the **motor end plates**. Among gland cells the terminal fibrils form more or less intricate plexuses.

Peripheral Nerve Beginnings of Centripetal Neurons.—Nerve beginnings of the centripetal (sensor) fibres are found in nearly all the tissues of the body. They are peculiarly differentiated and of various forms in different localities, and their function is apparently the conversion of mechanical, thermal, chemical, and other stimuli into nerve impulses. The organs of vision, hearing, smell, and taste possess variously modified nerve beginnings which are described under appropriate titles in the chapter on the Organs of Special Sense. The organs of the centripetal neurones collecting bodily impressions (tactile sense, muscle sense) and connected with the central axis are often very complicated structures. The principal varieties are:

- I. {
 - Terminal fibrillæ.
 - Tactile corpuscles (Meissner's).
 - "Ruffini's endings."
 - Lamellated corpuscles (Pacini's).
 - Bulboid corpuscles (Krause's).
 - Genital (nerve) corpuscles.
 - Articular (nerve) corpuscles.
- II. {
 - Neuromuscular spindles (Ruffini).
 - Neurotendinous spindles (Golgi).

Peripheral fibrillæ are best demonstrable in the epithelium of the skin, mucous membranes, and cornea. The axone is seen to break up into its constituent fibrillæ, which often present regular varicosities and anastomose with each other in a plexiform manner.

Tactile corpuscles (*corpuscula tactus*; *touch corpuscles of Meissner and Wagner*) consist of elongated oval lobules of delicate epithelioid tissue, invaded by one or more axones which divide into their primitive fibrils, each terminal branch ending free usually as a somewhat flattened, disk-like plate in among the wedge-shaped cells of the corpuscle. Tactile corpuscles occur in large numbers in the cutaneous papillæ of the finger-tips, in the conjunctiva and, less abundantly, in the rest of the skin; they appear to be concerned with the finer tactile sensations.

FIG. 591.—Nerve ending of Ruffini. (After A. Ruffini.)

Ruffini has described a special variety of sensor nerve beginning in the subcutaneous tissue of the human finger (Fig. 591). They are principally situated at the junction of the corium with the subcutaneous tissue; they are of oval shape, and consist of a strong connective-tissue sheath within which the axone divides into numerous varicose fibrils ending in small, free knobs.

Lamellated corpuscles (*corpuscula lamellosa*; *Pacinian corpuscles*; *Vater's corpuscles*; *Herbst's corpuscles*) are among the largest of the tactile end organs and are found chiefly in the palmar surface of the hand, the sole of the foot, the

genital organs, the serous membranes, and many other structures. Each corpuscle consists of a number of capsular connective-tissue lamellæ arranged more or less concentrically around a central granular protoplasmic core, pierced by a single axone which usually divides into two or more branches giving off collaterals of beaded appearance and terminating in rounded knobs.

Bulboid corpuscles (*corpuscula bulboidea*; *Krause's end bulbs*) are minute cylindrical or oval bodies, consisting of a capsule continuous with the perineurium which encloses a core (inner bulb) of semifluid, finely granular protoplasm. The axone is bulbed peripherally and quite free distally, or, as is frequently observed, divides into a number of branches, to each of which is attached an end bulb.

FIG. 592.—Middle third of a terminal plaque in the muscle spindle of an adult cat. (After Ruffini.)

The **genital corpuscles** (*corpuscula nervorum genitalia*) and the **articular corpuscles** (*corpuscula nervorum articularia*) very much resemble the bulboid corpuscles just described. The genital corpuscles form aggregations of from two to six knob-like masses in the penis and clitoris. The articular corpuscles are found in the synovial membranes of the joints.

Neuromuscular spindles (*muscle spindles of Kühne*) are found in nearly all the skeletal muscles and are most numerous in the Extrinsic muscles of the tongue, in the small muscles of the hand and foot, and in the Intercostal muscles. Most elaborate investigations upon these spindles have been conducted recently by Ruffini in Italy, Sihler, Huber, and De Witt in America. Neuromuscular spindles are usually found in the fibrous septa of the perimysium, and consist of the flattened nerve fibrils of centripetal axones arranged in one or all of three ways: (1) annular, where the fibrils surround the muscle fibres in rings; (2) spiral, and (3) dendritic or branched (Fig. 592). They are doubtlessly concerned with the so-called muscle sense.

Neurotendinous Spindles (*organs of Golgi*).—The nerves conveying sensor impulses from the tendons have a special modification of the peripheral fibres, in the form of numerous fibrils with branching end plates or of an annular and spiral arrangement resembling the neuromuscular spindles. They usually occur at the junction of the tendon bundles with the muscle fibres (Fig. 593).

The Neurone Doctrine.—The results of the investigations of Golgi, Cajal, Forel, and others prompted Waldeyer to enunciate a theory with regard to the nerve mechanism of the neurone. This hypothesis is generally known as the **neurone theory** and assumes that (1) each neurone is a distinct and separate entity; (2) the collaterals and other terminals of the neurone form no connections among themselves; (3) neurones are associated, and impulses conveyed, by **contact** or **contiguity** of the axonic terminals of one axone with the cell body or dendrites of another neurone. The theory postulates a nerve cell amebism analogous to the extension and retraction of the pseudopodia of an ameba, and the “retraction theory” has been propounded in explanation of certain functional dissociation phenomena attending nerve force manifestations.

FIG. 593.—Neurotendinous spindle organ of Golgi from the human tendo calcaneus (Achillis). (After Ciaccio.)

Opposed to the “neurone theory” or “contact theory” is the more recent **continuity theory** which is being earnestly advocated by Apathy, Bethe, and Nissl. In behalf of this theory it is claimed that the neurofibrils are continuous not only within the cell and its processes, but through an extracellular network as well. The dispute now being waged does not, however, affect our fundamental ideas regarding the individuality of neurones with regard to their dynamic condition.

The Supporting Tissue Elements of the Nerve System.—A fine meshwork of non-neural tissue, more or less dense in different localities, but apparently restricted to the central axis, serves to support the neurones. This sustentacular tissue is of two kinds: (1) the **neuroglia**; (2) **connective-tissue trabeculae** derived from (a) the **pia** or (b) **vascular channels**.

The Neuroglia.—The neuroglia consists of **glia cells** of varied forms and **glia fibres**. Glia cells are divisible into two species—**ependymal cells** and **astrocytes** of long-rayed and short-rayed type.

Ependymal cells are the columnar epithelial cells which line the neural canal throughout. In the embryonic condition each cell is seen to project a long multibranched filament toward the periphery of the neural tube, while the free end carries a tuft of cilia. In adult life both the cilia and the radial filament are apparently lost or very much reduced.

Regarding the structure of the glia cells proper as well as of the glia fibres there is a variance of opinion among different investigators. The **astrocytes**, as they are commonly revealed in Golgi preparations, may, as pointed out by Weigert and others, be due to an extension of the silver deposit upon glia-cell nuclei as well as upon adjacent filaments. Huber,¹ Hardesty,² and others regard neuroglia tissue as a syncytium resulting from an early fusion of the protoplasm of the cells of the neural tube which at first were individual and definitely bounded. The filamentous reticulum of glia fibres ordinarily seen in adult tissues seems to result from an increase of the fine threads of the spongioplasmic network of the original cell protoplasm. Neuroglia occurs in both gray and white substances as an all-pervading supporting tissue. In certain localities, as upon the surface of the brain and cord, the neuroglia tissue is disposed in the form of a thin layer.

¹ American Journal of Anatomy, 1901, pp. 45 to 61.

² Ibid., 1904, pp. 229 to 268.

Besides the neuroglia, the central nerve system contains as supporting tissues numerous fine and coarse septa or trabeculae derived from the investing pia, or from the sheaths of bloodvessels.

Chemical Composition.—The amount of water in nerve tissue varies with the situation. Thus, in the gray substance of the cerebrum it constitutes about 83 per cent., in the white substance from the same region about 70 per cent., while in the peripheral nerves, such as the sciatic, it may fall to 60 per cent.

The solids consist of neuroalbumins, neuroglobulins, nucleoproteins, neurokeratin (in the gray substance proteins constitute about one-third of the total solids), lecithins, cerebrosides (chiefly phrenosin), cholesterolin, unidentified organic sulphocompounds, aminofatty substances, nitrogenous extractives, and inorganic salts with some collagen, fat, etc., in the adherent connective tissue (W. J. Gies).

THE CENTRAL NERVE SYSTEM.

The central nerve system, as it is conventionally distinguished from the sympathetic system, is composed of a central axial aggregation of ganglia forming the brain and spinal cord, which are connected with the other tissues of the body by 43 pairs of nerves, of which 12 pairs are attached to the brain and 31 pairs to the spinal cord. The functional relations of the central mechanisms with the periphery are maintained by the essential cell elements of the nerve tissues, the neurones. The chief task in the study and analysis of the structure of the nerve system lies in the dovetailing of features visible to the naked eye with those visible only under high magnifying powers. By the combination of macroscopic with microscopic features the attentive student is enabled to resolve or reconstruct in the three dimensions of space, and see with his mental eye the opaque interior transparently resolved into intricate yet well-defined projecting and associating mechanisms. Assistance in such study may be derived from illustrations depicting hidden structures in accordance with this principle.

Preliminary Considerations. White Substance and Gray Substance.—The central axis of the nerve system contains two categories of substance, their difference to the eye being one of color. They are conventionally designated the white and gray substance. The white substance (*alba*), which forms about two-thirds of the neural axis, is the conducting substance, and its characteristic appearance is due to the myelin sheaths which invest the axones in it. The gray substance (*cinerea; grisea*) is the sentient and reacting mass containing the cell bodies of neurones. Its color is due to its translucency, its greater vascularity, and to a certain amount of pigment material in the cell elements. The white and the gray substance is not sharply demarcated everywhere, for although the white substance is exclu-

FIG. 594. — Neuroglia cells of brain shown by Golgi's method. A. Cell with branched processes. B. Spider-cell with unbranched processes. (After Andriezen.) (From Schäfer's *Essentials of Histology*.)

sively conducting substance, the gray is not exclusively ganglionic, for the former encroaches on the latter; in some localities, as in the ventral horns of the spinal gray, in parts of the cerebral cortex, in the reticular formation of the pons and medulla oblongata, and in the column of Clarke (dorsal nucleus), the admixture of myelinic fibres is considerable. Both white and gray substance is pervaded by the neuroglia.

The specific gravity of the cortical gray substance is 1.021; of the great ganglia, 1.034; of the gray substance in the cerebellum and mesencephalon, 1.040; and of the white substance, 1.028.

For convenience of study, and somewhat in correspondence with phyletic development, the central axis of the nerve system is divided into (1) the **spinal cord** and (2) the **brain**, grossly subdivided into (a) **medulla oblongata**, **pons**, and **cerebellum**; (b) **mid-brain**; and (c) **fore-brain**. This gross subdivision is arbitrary and the interrelations of the parts would be obscured were too much stress laid upon any mode of separation.

THE SPINAL CORD (MYELON; MEDULLA SPINALIS).

The **spinal cord** is the attenuated, nearly cylindrical part of the cerebrospinal axis which lies in the vertebral canal, occupying its upper two-thirds in the adult.

It extends from about the level of the atloöccipital articulation (or lower border of the pyramid decussation) to the level of the lower border of the body of the first lumbar vertebra, where it terminates in a slender filament of gray substance enveloped by pia, and, further caudad, by a sheath of dura which is attached to the dorsum of the coccyx. The spinal cord is continuous

FIG. 595.—Showing the relation of the spinal cord to the dorsal surface of the trunk. The vertebrae are shown in red outlines.

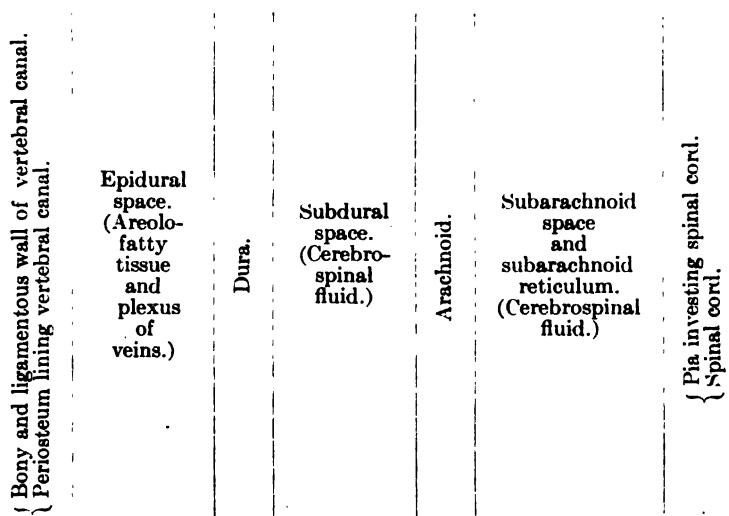

FIG. 596.—Ventral view of medulla oblongata and upper part of spinal cord. Dura and arachnoid cut along median line and folded aside. *A* and *B* are fairly constant velar folds of the arachnoid. (After Key and Retzius.)

cephalad with the medulla oblongata. Its length is 45 cm. (44 to 50 cm.) or eighteen to twenty inches in the male and 43.5 cm. (39.5 to 47 cm.) or sixteen to nineteen inches in the female. In the course of fetal development the spinal cord occupies the entire length of the vertebral canal up to the third month, but after this period it gradually recedes cephalad owing to the more rapid growth of the vertebral column, so that at birth the caudal end of the spinal cord has risen to the level of the third lumbar vertebra.

The spinal cord does not entirely fill the vertebral canal. A wide space or rather a concentric series of spaces intervene between its surface and the walls of the canal, affording a marked freedom of movement of the vertebral column without exerting undue tension upon the spinal cord. These spaces, three in number, which concentrically surround the cord, are demarcated by the three protective membranes—(1) *pia*, (2) *arachnoid*, and (3) *dura*—which are continuous with the like meninges of the brain. The arrangement of the spaces and the membranes may be shown thus:

The *pia* closely invests the entire surface of the spinal cord and sends septal ingrowths into its substance as well as a fold occupying the anterior median fissure. A leaf-like, serrated fold of *pia*, the *ligamentum denticulatum*, passes from each lateral border to the inner surface of the dural sheath and helps to support the cord within the subarachnoid space. The arachnoid and the *pia* are not separable in gross dissection as they merge insensibly, though usually described as distinct membranes. The arachnoid is in reality an exceedingly delicate and transparent web-like reticulum whose meshes constitute a relatively wide cavity filled with cerebrospinal fluid. The *dura* constitutes the outermost and thickest sheath, while the narrow interval between the *dura* and the vertebral canal is filled by a fine venous plexus, together with soft, areolofatty tissue. The tubular sheath of *dura* ends in a pointed *cul-de-sac* at the level of the lower border of the second sacral segment. Of the three spaces which surround the cord, only the two innermost contain fluid, and that of a serous character; the amount in the subdural space is very small, just sufficient to moisten the contiguous endothelial surfaces of the *dura* and *arachnoid*; that in the subarachnoid space is considerable. (For detailed description see section on the Meninges.)

Weight.—The weight of the spinal cord, exclusive of all nerve roots, averages 28 grams, or 1 ounce avoirdupois, being slightly less in the female. Including the nerve roots as ordinarily cut in postmortem procedure, the weight averages 45

grams in the male and 40 grams in the female. The ratio of weight in proportion to that of the brain among mammalia is lowest in the human species, being 1 to 51 in the male and 1 to 49.8 in the female. In the newborn the ratio is 1 to 115. Its specific gravity is 1.038.

External Morphology.—*In situ* the spinal cord exhibits slight curvatures in the sagittal plane, being convex ventrad in the transition from cervical to thoracic portion and slightly concave ventrad to the lumbar portion. Its position varies also according to the degree of curvature of the spinal column, being raised slightly (a few millimeters only) in flexion of the vertebral column.

The intrinsically segmental nature of the spinal cord is expressed by the association of each definite segment with the somatic segment supplied by its nerves. Thirty-one pairs of spinal nerves are commonly enumerated,

FIG. 597.—Showing the relations of the cord and nerve origins to the levels at which the nerves emerge through the intervertebral foramina (diagrammatic).

FIG. 598.—The cauda equina exposed within its dural sheath.

although two additional, rudimentary pairs, relics of a tailed vertebrate ancestry, are demonstrable.

The first pair of spinal nerves emerges between the occiput and atlas, and is designated the first cervical; the other cervical pairs are named after the lower of the two vertebræ which form the intervertebral foramen through which the

nerve emerges. Very inconsistently the pair emerging between the seventh cervical and first thoracic vertebræ is called the eighth cervical pair. The remaining spinal nerves are named after the upper of the two vertebræ forming the corresponding foramen. In all there are:

Cervical pairs	8
Thoracic pairs	12
Lumbar pairs	5
Sacral pairs	5
Coccygeal pairs	1
	<hr/> 31

All **spinal nerves** are made up of two roots by which they spring from the lateral aspects of the cord, symmetrically arranged, and these nerve root attachments are the only guides to the demarcation of the various segments of the spinal cord. The two roots are generally termed the **posterior** or **dorsal** (*afferent* or *sensor*) **root**, which enters the cord along the dorsolateral fissure, and the **anterior** or **ventral** (*efferent* or *motor*) **root**, which emerges along the ventrolateral fissure.

Although the cervical nerves pass outward through the intervertebral foramina at nearly a right angle to the long axis of the cord, those of the lower series slope more and more caudad or downward, so that the fifth lumbar pair emerges six vertebral bodies lower than it originates. In fact, the lumbar and sacral nerves descend as parallel bundles in a brush-like manner to form the **cauda equina**, enclosed by the dural sheath as far as about the middle of the sacral canal. The topographical relations of the levels of origin and exit of the spinal nerves to the spinous processes of the vertebra are shown in Fig. 597.

Corresponding with the degree of development of the periphery, the spinal cord is more massive in those segments which are associated with the limbs. Thus, in the ground-mole, the cervical portion is very much enlarged in conformity with the powerfully developed forelimbs, while in the kangaroo or the ostrich, with powerful legs, the lumbar portion of the spinal cord is proportionately enlarged. In man, both the cervical and lumbar portions are enlarged, and while the bulk of the lower limbs exceeds that of the upper, the cervical enlargement of the spinal cord is greater because it innervates a limb which is functionally more differentiated, capable of much more skilful and complex movements, and endowed with more acutely developed tactile sensibility.

The Enlargements of the Spinal Cord.—The spinal cord is marked by two spindle-shaped enlargements, in its cervical and lumbar portions, while the intervening thoracic portion is nearly cylindrical, being slightly reduced in its antero-posterior diameter. The **cervical enlargement** (*intumescentia cervicalis*) extends from the first or second cervical segment to the level of the second thoracic vertebra, acquiring a maximum breadth (13 to 14 mm.) at the sixth cervical vertebra. At its junction with the medulla oblongata its breadth is about 11 mm. The thoracic portion is about 10 mm. in breadth (minimum at a little below its middle) while its sagittal diameter is 8 mm. The **lumbar enlargement** (*intumescentia lumbalis*) begins at the level of the tenth thoracic vertebra, and acquires its maximum breadth (12 mm.; sagittal diameter = 9 mm.) opposite the twelfth thoracic vertebra. Below the lumbar enlargement the cord gradually tapers to form a cone (**conus**), the apex of which, at the level of the lower border of the body of the first lumbar vertebra, is continuous with the attenuated **filum**.

The cervical enlargement is characterized by a relatively greater breadth than the remaining portions of the cord which, on section, appear nearly circular.

Conus (*conus medullaris*).—The conus is the conical extremity of the cord. The lower three sacral segments and the coccygeal segment are usually included

under this term. Its diameter becomes reduced to 2 mm. ($\frac{1}{12}$ inch), to be continued below as the filum.

FIG. 599.—Transverse sections of spinal cord at different levels.

Ventral aspect. Dorsal aspect.
FIG. 600.—Diagram of the spinal cord and its fissures.

Filum (*filum terminale; nervus impar*).—The delicate terminal thread called the **filum**, continuous with the tapered end of the conus, is about 24 cm. (10 inches) in length. As far as the level of the second sacral vertebral segment it is enclosed, together with the cauda equina, in the tapering sheath of the dura. Within the dural sac it is called the **filum internum**, in contradistinction to the **filum externum**, which is an attenuated process of connective and glia tissue closely invested by a prolongation of the dura, which finally attaches to the periosteum of the dorsum of the coccyx. The **filum externum** occupies one-third of the total length of the **filum**. Morphologically, the **filum** is the caudal representative of the cord, and its intradural portion is usually accompanied by slender fascicles of nerve fibres, which are rudimentary second and third coccygeal pairs of spinal nerves.

FIG. 601.—Section of spinal cord of a four weeks' embryo. (His.)

Fissures and Grooves.—The spinal cord is a bilaterally symmetrical structure and exhibits a deep ventral fissure and a slight dorsal groove partially subdividing the cord into the right and left halves. The **ventral (antero-median) fissure** extends throughout the entire length of the cord, being shallower in the cervical and thoracic portions (less than one-third of the sagittal diameter) than in the lumbar portion. It is surfaced by a fold of pia which conveys the more important nutritive vessels to the depths of the cord substance. In the depth of this fissure lies the white (ventral) commissure of the cord. The **dorsal groove** has been regarded, erroneously, as being analogous to the ventral fissure. Unlike the ventral fissure, however, the pia does not descend into its depths, but passes continuously over it. The shallow groove marks the site of a septum made up of neuroglial and ependymal elements. An actual groove is best demonstrable in part of the lumbar cord and in the medulla oblongata, where it constitutes a veritable fissure between the clavæ.

Each lateral half is marked by the lines of root attachment of the spinal nerves. The dorsal nerve root fascicles enter the cord in linear series and in a depression or true sulcus termed the **dorsolateral fissure**. The ventral nerve root fascicles emerge, irregularly scattered, out of a greater circumferential area, and no true ventrolateral fissure can be said to exist. The line of emergence of the outermost fascicles is usually taken as an arbitrary boundary between the ventral and lateral districts of the cord, while the dorsolateral fissure more distinctly maps off the

lateral from the dorsal district. An additional fissure, observed most distinctly in the cervical and upper thoracic portions, termed the **dorsoparamedian fissure**, demarcates the two principal divisions of the dorsal columns, the **gracile** and the

FIG. 602.—A diagram of the component elements in the spinal cord and the nerve roots in a trunk segment to illustrate the four functional divisions of the nerve system. (After Johnston.)

cuneate columns. The dorsoparamedian fissure is an exceedingly shallow groove and is best denoted in sections of the cord by its continuance as a connective-tissue (*glia*) septum into the substance of the dorsal column. An analogous

FIG. 603.—Trans-section through neural tube, early and later stages, diagrammatic. Earliest stages shown on left side. On the right, the maturing neuroblasts are seen sending their axonic processes toward the periphery or to other regions of the central axis, and the central processes of the spinal ganglionic cells are seen to invade the dorsolateral region.

ventroparamedian fissure is sometimes observable close to the ventral fissure, demarcating the ventral (or direct) pyramidal fasciculus.

Columns of the Cord (*funiculi medullae spinalis*).—Each half of the spinal cord is thus divided, with respect to its white substance, into three chief columns

or funiculi. The **dorsal column** occupies the area between the dorsal septum and groove and the line of attachment of the dorsal nerve roots; this column in its turn is generally subdivided into the **funiculus gracilis** (*column of Goll*) and the **funiculus cuneatus** (*column of Burdach*) by the shallow dorsoparamedian groove and glia septum referred to above. The **ventral column** (*funiculus anterior*) occupies the area between the ventral fissure and the outermost fascicles of the ventral nerve roots—an arbitrary boundary line. The **lateral column** (*funiculus lateralis*) constitutes the remainder of the cord, between the posterior and anterior nerve root attachments. Each of these columns is subdivided into its component **bundles** or **fasciculi**, best studied in sections of the cord.

LOCATION OF THE SEGMENTS FOR
SENSIBILITY. MOTILITY.

FIG. 604.—Explanation of abbreviations: *tr. olf.*, olfactory tract; *c. g. l.*, lateral geniculate body; *p. r. cr. A.* indicate approximately the location of the reflex centres for the pupillary (*p*), the respiratory (*r*), cremasteric (*cr*), patellar (*pat*), and tendo-Achillis (*A*) reflexes. The vesical centre lies in the third and fourth sacral segments; the anal centre in the fourth and fifth (represented by circles); the centres for erection, ejaculation, labor pains (?) are probably also situated in this region. In reality, the divisions between the various segments are, of course, not so sharp as they are shown in the diagram, so that a given muscle or cutaneous region derives some of its controlling nerve-roots from the segments lying immediately above and below the principal segment. The sensor segment for any given region is regularly somewhat higher than the corresponding motor segment. (Jakob.)

Development of the Spinal Cord.—The elongated postcranial portion of the neural tube becomes the spinal cord, while the primitive cavity within is preserved as the central canal of

the cord. The metamorphosis of the neuroepithelial columnar cells has been described (p. 810). The lateral walls thicken considerably, the central slit-like canal widens as the walls bulge outward in an angular manner, and the central tubular gray becomes a fluted column with dorsal and ventral ridges (or horns) enveloped by a rapidly growing mantle of axone bundles which become myelinic in successive stages. The bulging of the thickening walls in the dorsal and ventral as well as lateral directions produces the ventral fissure and the postseptum.

The segmental nature of the spinal cord has been alluded to before with regard to the segmental derivation of the cerebrospinal ganglia and the disposition of the outgrowing nerve

Fig. 605.—Distribution of cutaneous nerves.

bundles. There is a further mode of division into longitudinal systems based upon functional relationships. Two main categories of activity characterize the mechanism of the nerve system and find somatic expression in its architectural plan: First, actions in relation to the external world (**somatic**—involving skin, muscle, skeleton, etc.); second, internal activities concerned with the processes of nutrition and reproduction (**visceral**—involving the alimentary tract, vascular [blood and lymph], excretory, and reproductive systems). In each there is a twofold activity on the part of the nerve system: reception of stimuli and motor responses. In the cord (and to some extent in the brain as well) the following functional divisions may be distinguished and located anatomically (Fig. 602):

Somatic *sensor* elements.
Somatic *motor* elements.

Visceral *sensor* elements.
Visceral *motor* elements.

This functional differentiation of the neural axis into sensor and motor divisions apparently finds organic expression in an important modification of the developing neural tube. Each lateral wall of the neural tube is early demarcated into a **dorsal** and a **ventral strip** or **lamina** and the slit-like central canal becomes more or less lozenge-shaped on trans-section, owing to the formation of a lateral longitudinal furrow within. The dorsal lamina or zone is preponderantly sensor in function, while the ventral zone is principally motor in function. This fundamental fact has been of the greatest aid in the correct interpretation of many hitherto obscure facts regarding the mechanism of the nerve system, and will be found to underlie our method of description throughout.

The muscular supply from motor segments of the cord is shown in Fig. 604, and the cutaneous supply in Fig. 605.

Internal Structure of the Spinal Cord.—If a transverse section of the spinal cord be made, it will be seen to consist of white and gray nerve substance. The white substance is made up of myelinated axones; the gray contains the cell bodies of neurones and nonmyelinated axones. The color of the gray substance, so-called, varies according to the degree of capillary injection and the age of the individual. It is usually of a faint, reddish-gray tinge, the gray preponderating in older persons, but various shades of red, yellow, and light-slate color may be noted.

FIG. 606.—Trans-section of the spinal cord at the mid-thoracic region.

Nor is the color uniform even in the same section. Around the central canal and at the periphery of the dorsal horn the gray substance is very translucent and is termed, according to its situation, the **gelatinosa centralis** (*gliosa centralis*) and **gelatinosa Rolandi** or **caput gliosum** (*gliosa cornualis*). The white substance surrounds the gray column as a variously thickened tunic, closely invested by the pia, which sends numerous delicate, vessel-bearing ingrowths into the substance of the cord. The relative area of the white substance, as seen on section, increases cephalad; the absolute area of both white and gray is the largest in the region of the enlargements (Fig. 607).

Gray Substance of the Cord (*entocinerea; substantia grisea centralis*).—A plastic conception of the gray substance of the cord is essential to an understanding of the internal architecture. The gray core must be imagined not alone in the relations in which it is conventionally studied, as exposed in trans-sections, but

also as a fluted column having a continuous extent throughout the cord. This gray column is drawn into ventral and dorsal ridges, connected respectively with the ventral and dorsal nerve roots, while the white substance fills out the irregularities and completes the nearly cylindrical outline of the cord (Fig. 608).

On viewing a trans-section, it is seen that the gray substance is so arranged as to present, in each lateral half of the cord, a crescentic or comma-shaped mass, the concavity of which is directed laterad. The two lateral masses are connected by a transverse bar or band of gray substance, termed the **gray commissure** (*commissura cinerea* [*grisea*]), and containing the central canal, which extends the entire length of the cord. The dorsal septum of the cord reaches quite to the

gray commissure, there being but a few white commissural fibres in the dorsal zone. Ventrad, however, a lamina of white substance, the **commissura ventralis alba**, separates the gray commissure from the ventral fissure (Fig. 606).

In trans-sections of the cord it is seen that the lateral crescentic gray masses, united across the middle line by a gray commissure, have the aggregate appearance of the letter H. Each crescentic mass presents projections which are more or less pronounced according to the segment of the cord under consideration. Broadly stated and without reference to special levels, the most marked projections are the **dorsal** and **ventral horns** or **cornua**.

The **dorsal horn**, directed dorsolaterad, is elongated and narrow, and its apex is composed of a translucent, V-shaped mass termed the **caput gelatinosa Rolandi** (*caput gliosum* would be a better term).

The attenuated apex of the dorsal cornu approaches the surface of the cord along the line of entrance of the dorsal nerve roots. The apex of the dorsal horn is wider in the regions of the enlargements and the gelatinosa is most marked in the higher cervical segments. The base or cervix of the dorsal horn is constricted somewhat except in the thoracic portion, where its greater breadth is due to the presence of the **nucleus dorsalis** (*Clarke's column*).

The **ventral horn** is shorter, thicker, and more blunt, and is separated from the ventral and lateral surfaces of the cord by a tolerably thick lamina of white substance. Its margin, in trans-sections, presents a dentate or stellate appearance due to the emergence of fascicles of efferent or ventral root axones on their way to the ventral surface of the cord.

What is known as the **lateral horn** projects as a lateral peninsular extension of the central gray nearly on the line of the gray commissure. It is best marked as a triangular projection in the upper thoracic segments. In the cervical enlargement it is merged with the greatly expanded ventral horn, but it again becomes prominent in the upper cervical segments.

The gray substance of the cord is not everywhere sharply demarcated from the white owing to the invasion of myelinic and amyelinic nerve fibres. Facing the lateral column, in the angle between the dorsal and ventral horns, small fascicles of white fibres are embedded in the gray so that it is broken up in a peculiar basket-work pattern termed the **reticula** or **reticular formation**. This gray network

FIG. 607.—Projection upon a plane of the absolute and relative extent of the gray and white substance of the cord as determined by successive sectional areas. Gray substance shown in black. (Adapted from the measurements of Stilling.)

is best marked in the cervical region and becomes more abundant in the medulla oblongata.

The mode of arrangement of the gray substance and its amount in proportion to the white vary in different parts of the cord. Thus, the posterior horns are long and narrow in the cervical region; short and narrower in the thoracic; short but wider in the lumbar region. In the cervical region the crescentic portions are small, and the white substance more abundant than in any other region of the cord. In the thoracic region the gray substance is least developed, the white substance being also small in quantity. In the lumbar region the gray substance is more abundant than in any other region of the cord. Toward the lower end of the cord the white substance gradually ceases. The crescentic portions of the gray substance soon blend into a single mass, which forms the only constituent of the extreme point of the cord.

FIG. 608.—Showing origin of two pairs of spinal nerves (schematic).

The **gray commissure** which connects the two crescentic masses of gray substance consists of myelinic and amyelinic nerve fibres and neuroglia. The fibres pass transversely, spreading out at various angles, into the lateral gray masses. In the gray commissure, and extending the whole length of the cord, is a minute channel, the **central canal** (*myelocoele*; *canalis centralis*), which is barely visible to the naked eye, but is proportionately larger in some of the lower vertebrates. Cephalad, in the medulla oblongata, it opens out into the fourth ventricle; caudad it is continued for a short distance into the filum, in which it ends blindly. The canal is very minute, less than 0.1 mm. (one-twenty-fifth inch), except in the terminal part of the conus, where it expands into a fusiform dilatation, the **sinus terminalis** (*rhombocoele*; *ventriculus terminalis* [Krause]). The central canal is lined by a layer of columnar cells which are seen to be ciliated in the embryo and are in all respects identical with the ependymal cells lining the ventricles of the brain. Surrounding the ependymal lining of the central canal and gradually merging into the spongy substance which constitutes the remainder of the gray commissure is a finely granular and reticulated substance, the **gelatinosa centralis**, almost entirely composed of neuroglia, with a few fine fibrils apparently proceeding from the ependymal cells, and having a translucent, gelatinous appearance.

The gray substance of the cord is composed of (1) the **gelatinosa** or **gliosa**, which envelops the head of the dorsal horn and which encircles the central canal of the cord; (2) the **spongiosa**, which forms the crescentic horns (except the heads of the posterior horns and the envelope of the central canal). Further, it may be stated that the gray substance consists of nerve-fibres of variable but smaller

FIG. 609.—Trans-sections of the spinal cord at different levels to show the topographical arrangement of the principal cell groups.

into **ventrolateral** and **dorsolateral** sub-groups, and supplying the muscles of the extremities; (4) a **central group** of cells in the lumbar and sacral regions.

In the **lateral horn**, which is most prominent in the thoracic and upper cervical segments, lies an **intermediate group** of cells, a long, slender column which is nearly restricted to the thoracic portion of the cord, but is seen to reappear in the

average diameter than those of the white column; (3) nerve cells of various shapes and sizes, with few or many processes; (4) bloodvessels, lymphatic channels, and connective tissue.

The **nerve fibres** of the gray substance of the posterior horn are for the most part composed of a dense interlacement of minute fibrils, intermingled with nerves of a larger size. This interlacement is formed partly by the axones and dendrites of the cells of the gray substance, and partly by fibres which enter the gray substance and which come from various sources.

The **nerve cells** of the gray substance are collected into groups (*nidi* or *nuclei*) as seen on transverse section, but they really form columns of cells placed longitudinally; or else they are found scattered throughout the whole of the gray substance (Fig. 609).

In the **ventral horn** four main groups of cells may be distinguished which are not wholly represented, however, in all regions of the cord: (1) A **ventral group** of cells, separable in the cervical and lumbar regions into **ventromedial** and **ventrolateral** sub-groups; (2) a **dorsomedial group**, situated in the cervix of the ventral horn, usually demonstrable in the thoracic portion as well as a few contiguous cervical and lumbar segments; (3) a **lateral group**, separable in the lower cervical and lumbar regions

upper three cervical and in the third and fourth sacral segments. The axones from these cells probably do not pass out with the ventral nerve roots, but rather course within the cord to terminate at various levels on the same as well as on the opposite side. A close connection with the sympathetic nerve system, and with vasomotor and sweat-gland nerves, has been suggested.

In the **dorsal horn** the most conspicuous group of cells is a columniform nucleus commonly termed **Clarke's column** (*nucleus dorsalis*), which extends between the seventh cervical and second (or third) lumbar segments of the cord. The cells are large and the group presents an oval outline in trans-sections, lying in the medial part of the cervix of the dorsal horn. The axones of these cells pass out of the gray into the lateral column of the cord to form the spinocerebellar tract, and convey tactile impulses to the cerebellum. It is represented in other regions of the cord by scattered cells which are aggregated to form the **cervical nucleus** opposite the third cervical nerve, and a **sacral nucleus** in the middle and lower part of the sacral region. The axones of these cells form the homolateral direct cerebellar tract.

The cells of the dorsal horn are not grouped very definitely, and for the purposes of description they are subdivided according to their location. The cells vary much in form and size and their branched axones pass toward other regions within the gray substance at various levels on the same or on opposite sides, or via the ground bundles. Many fibres of the dorsal nerve roots are in relation with the dorsal horn cells.

The various groups of cells enumerated above are frequently demarcated from neighboring groups by nerve fibre intervals, which may be straight, curved, interlaced, or loop-shaped.

Through the **gelatinosa Rolandi** (*gliosa cornualis*) pass numerous fine fibrils, chiefly the afferent dorsal nerve root fibres, but in addition this peculiar, gelatinous, and semitranslucent substance contains numerous small, stellate cells; the region is so densely filled with axones and collaterals, as well as neuroglia cells, that until staining methods became sufficiently developed the importance of this substance remained in dispute. In man the gelatinosa Rolandi shows convolutions feebly imitating those of the olive, and its structure is analogous. Dorsad of the gliosa lies the ultimate zone of the dorsal horn; this gray substance resembles the spongiosa in its essential characters.

The White Substance of the Cord (*substantia alba*).—The white substance of the cord, consisting chiefly of longitudinally disposed myelinic fibres, with blood-vessels, neuroglia, and connective-tissue septa, forms a thick mantle which invests the central gray column. When stained with carmine, a transverse section of the white substance is seen to be studded all over with minute dots surrounded by unstained circular areas. The dots are the transversely cut axones; the lighter areas are the myelin sheaths. The mass of white substance is closely invested by

FIG. 610.—Showing the dorsal nucleus (of Clarke), and its cervical and sacral extensions on one side, and the direct spinocerebellar tract on the other. The fibres of the tract ascend on the same side as the nucleus in which they arise.

a sheath of neuroglia immediately beneath the pia. Numerous septa, derived from the pia, but always coated by a thin layer of neuroglia, pass into the white substance to separate the respective bundles of fibres and are often interwoven between individual nerve fibres, acting as a supporting framework in which they are embedded. In addition to the longitudinal fibres there are shorter and less numerous transverse fibres collected into the so-called **commissure bundle** or **white commissure**.

The **longitudinal fibres** constitute the conducting tracts. Although a purely anatomical examination fails to reveal the functional relations in these fibre bundles, the structural alterations which ensue (in accordance with the laws of Waller) in the distal portion of a neurone whose proximal portion has been destroyed, the progressive myelinization of separate tracts in the embryo and infant (as proved by the researches of Meynert and Flechsig), the comparative anatomy method and electrophysiological experimentation have rendered possible the demonstration of the origin and destination of the various conducting systems or tracts with almost mathematical accuracy. While some fibres pursue a lengthy course, serving as conduction paths between the brain centres and the various spinal centres, others are shorter and serve to associate different spinal levels—in juxtaposition or relatively not far distant. It must be borne in mind that the gray substance, intercalated as it is in the course of the impulses which pass to and fro in the cord, contains the neural elements which are either (a) the source or (b) the destination of these impulses, and thus complete the nerve cycle requisite for the organization of the functions belonging to the cord. The motor and sensor phenomena, though interacting, depend upon distinct nerve elements which, because of their functional relationship, or because of the direction in which they convey impulses, are generally referred to as **motor** or **efferent** and **sensor** or **afferent** neurones; and in the spinal cord usage has sanctioned the employment of the terms **descending** and **ascending** for tracts conveying motor and sensor impulses, respectively. Anatomically speaking, however, it is preferable to describe the tracts with reference to their origins and termini (as cerebrospinal, spinothalamic, etc.), when known, or to their topographical relations as studied in trans-sections of the cord.

For the purposes of description it is convenient to classify the longitudinal fibres into three general systems: (1) The *cerebrospinal system* of axones forming conduction paths for efferent impulses from the cerebrum to the spinal centres for peripheral organs, and axones for afferent impulses received in the spinal centres from the periphery and conveyed in turn to the cerebrum. (2) The *spinocerebellar system*, consisting of conduction paths, afferent and efferent between the cerebellum and the spinal centres. (3) *Numberless association systems* strictly confined within the cord (or only extending into the medulla oblongata), composed of shorter or longer axones which serve to associate not only different levels of the same spinal segment, but also the different segments that are in juxtaposition or more remotely situated. These spinal association axones form bundles in close contact with the central gray column and are termed the **fasciculi proprii** or **ground bundles**.

Tracts of the Spinal Cord.—In the dorsal column there are the following tracts:

Ascending:

1. Fasciculus gracilis (Golli).
2. Fasciculus cuneatus (Burdachi).

Descending:

1. Comma tract (Schultze).
2. Median oval tract (Flechsig).

Associating:

1. Fasciculus dorsalis proprius.
2. Dorsal cornucommissural tract.
3. Septomarginal tract (Bruce).

Another tract, usually described as belonging to the lateral column, but functionally more intimately related to the sensor neurone system of the dorsal column is the *fasciculus marginalis* (of Spitzka and Lissauer, described on page 840).

The great majority of the axones constituting the dorsal column are the afferent (sensor) axones arising from the spinal ganglion cells, entering the cord by the dorsal roots. These dorsal root axones bifurcate in the region of the dorsal horn, one branch ascending a little obliquely at first, then vertically, while the other branch takes a similar downward course for a shorter distance (Fig. 613). As additional groups of fibres are contributed by each successive dorsal nerve root the mass of white substance in the dorsal column accumulates as the cord is ascended, though it must be noted that not all of these afferent fibres traverse the whole of the cord above, but end in relation with cells in the gray substance at various levels. The successive accessions of afferent fibres are disposed in a laminated manner so that the lumbar fibres come to lie laterad of the sacral bundle, the thoracic laterad of the lumbar, and so on as the cord is ascended. A section of the cord at its highest level would therefore traverse a collection of bundles derived from all of the dorsal nerve roots of the cord, arranged as shown in Fig. 612.

In the upper segments of the cord it is possible to distinguish a division of the dorsal column into two principal fasciculi owing to the presence of a distinct connective-tissue septum which passes into the substance of the dorsal column along the dorsoparamedian groove. These fasciculi are termed the *fasciculus gracilis*, or Goll's column, and the *fasciculus cuneatus*, or Burdach's column; in the consideration of the external morphology of the cord, these have already been referred to as the *funiculus gracilis* and *funiculus cuneatus*, respectively.

It has been noted that even in the fresh cord, when sectioned, the gracile bundle has a different tinge and stains more deeply with carmine than does the cuneate bundle.

The caudal or descending branches of the bifurcate dorsal root axones are considerably shorter than the ascending branches. They terminate in the gray substance in relation with its cells and, by numerous collaterals which are shorter or longer and given off at various intervals, serve to associate different levels of the cord. Some of these collaterals cross the median line in the dorsal (gray) commissure to come into relation with neurones of the opposite side. Certain of the longer descending branches show a tendency to collect into a feebly marked bundle along the mesal border of the cuneate fasciculus, called, because of its outline in trans-sections—as seen in cases of descending degeneration from injury at a higher level—the *comma tract of Schultz*. A similar bundle, situated along the dorsal septum, best demonstrable in the lumbar cord, and with its fellow

FIG. 611.—Formation of the fasciculus gracilis. Spinal cord viewed from behind. To the left, the fasciculus gracilis is shaded. To the right, the drawing shows that the fasciculus gracilis is formed by the long fibres of the posterior roots, and that in this tract the sacral nerves lie next the mesal plane, the lumbar to their outer side, and the thoracic still more laterally. (Poirier.)

of the opposite side of the oval outline as seen on section, is called the **oval bundle of Flechsig** (*tractus cervicolumbalis* [Edinger]; *dorsomediales Sakralfeld* [Obersteiner]).

FIG. 612.—Sections of the spinal cord at the level of the sixth cervical, sixth thoracic, and third lumbar segments, the conducting tracts being indicated on the right side of each section: C, Comma tract of Schultze. H, Olivospinal tract of Helweg. M, Marginal tract of Spitzka-Lissauer. O, Oval field of Flechsig.

Marginal Tract.—Not all the axones of the dorsal nerve root enter the dorsal column. Another group elsewhere described passes into the dorsal horn as

well as toward Clarke's column, while a third group of fibres forms the so-called **marginal tract**,¹ situated close to or among the entering fibres of the dorsal roots, but frequently described as lying in the lateral column. The tract is demonstrable in all levels and is made up of successive increments of relatively short axones (traversing not more than three or four segments) to end in relation with the cells in the *gelatinosa Rolandi*.

Ground Bundle of the Dorsal Column.—A zone of fibres contiguous with the dorsal face of the gray column, and termed the **fasciculus dorsalis proprius** or dorsal

FIG. 613.—Ramifications of the central processes (axones) of afferent neurones entering the spinal cord as seen in longitudinal section (schematic): D.R. Axones of dorsal roots. b. Their bifurcation. clt. Collaterals. t. Telodendria ending in proximity of cells in the gray substance. F.C. Axones of gracile and cuneate fasciculi.

ground bundle, is composed of axones arising from the smaller cells of the dorsal horn, which, after entering the white substance and bifurcating into ascending and descending branches, come into relation with other levels of the gray column by means of collaterals and terminating in it after a comparatively short course. They are therefore to be regarded purely as association or "longitudinal commissural" fibres. The **dorsal cornucommissural tract** (*ventrales Hinterstrangsbündel* [Strümpell]; *zone cornucommissurale* [Marie]), occupying a triangular interval at the apex of the transsected dorsal column, and the **septomarginal tract** [of Bruce], in apposition with the postseptum, belong to this category of association bundles. Both tracts are most evident in the lumbar portion of the cord.

¹ First described by F. C. Spitzka (1885) and Lissauer (1886), and usually bearing the name of the latter.

In the **lateral column** the following tracts may be enumerated:

Ascending:

1. Dorsolateral spinocerebellar tract (Flechsig).
2. Superficial ventrolateral spinocerebellar tract (Gowers).
3. Spinothalamic tract.
4. Spinomesencephalic tract.

Descending:

1. Crossed pyramidal tract.
2. Rubrospinal tract.
3. Cerebrospinal tract (Marchi and Löwenthal).
4. Lateral vestibulospinal tract.
5. Olivospinal tract of Helweg.

Associating:

1. Fasciculus lateralis proprius.

The **dorsolateral spinocerebellar** or **direct cerebellar tract** (of Gratiolet and Flechsig) lies at the periphery, laterad of the crossed pyramidal tract. Its axones arise from the cells of Clarke's column and ascend uninterruptedly to the medulla oblongata, and thence to the vermis of the cerebellum in its inferior or postpeduncle. The tract becomes more massive as the cord is ascended (Fig. 610).

The **superficial ventrolateral spinocerebellar tract**, or **tract of Gowers**, also courses along the periphery, but farther ventrad. The origin of its axones is yet in dispute; they probably arise from cells in the gray substance of both sides, in the zone between the dorsal and ventral horns as well as from some of the ventral horn cells. The destination of the axones of this tract is equally uncertain, but most of the fibres have been traced through the dorsolateral region of the medulla oblongata and the pontile reticula, whence it turns dorsimesad, to enter the cerebellum through the superior medullary velum and ends in the dorsal vermis. A lesser portion of the tract has been traced to the quadrigeminal bodies, while other groups of axones end in various levels of the gray substance.

The **spinothalamic** and **spinomesencephalic** (*tractus spinotectalis*) tracts are not gathered into compact bundles, but are rather scattered among the fibres of the lateral column just mesad of the superficial ventrolateral spinocerebellar tract (Gowers). The axones of both systems arise from cells in the dorsal horn and its cervix of the opposite side, coursing through the white ventral commissure and ascending the cord, the spinothalamic fibres ending in the thalamus, the spinomesencephalic fibres ending in the region of the quadrigeminal bodies. The two tracts are collectively called **tractus spinotectalis et thalamicus**.

The **crossed pyramidal tract** (*lateral cerebrospinal fasciculus*) occupies an approximately triangular or oval area in the dorsal portion of the lateral column, just mesad of the direct cerebellar tract, except in the lumbar cord, where it lies at the surface. The axones of this tract arise from the pyramidal cells of the cerebral cortex (motor area) of the opposite side. After having descended through the internal capsule, crista, pons, to the pyramis of the medulla oblongata, the major portion (85 to 90 per cent.) of the fibres derived from one-half of the brain decussate with those of the other half, crossing the median line to descend in the lateral column of the cord. The fibres which do not decussate constitute the direct pyramidal tract in the ventral column. As the crossed pyramidal tract descends it diminishes in size as its axones become distributed to the ventral horn, where they terminate either in contiguity with the ventral motor cells which give rise to the fibres of the ventral (motor) nerve roots, or else in contiguity with the dendrites of interposed neurones, which, in turn, convey the impulse to several associated motor neurones presiding over the actions of associated muscles. The bundle becomes exhausted as a distinct strand at the level of the fourth sacral segment.

The **rubrospinal, cerebellospinal, lateral vestibulospinal, and olivospinal tracts** consist of descending axones which are intermingled so that their mutual topographical relations cannot at present be described. Collectively they constitute the **fasciculus intermedius** of Löwenthal and Bechterew (*intermediolateral tract of Bruce and Campbell*) and they lie ventrad of the crossed pyramidal tract and mesad of the combined spinothalamic and spinomesencephalic tracts.

The **rubrospinal tract** (*Monakow's tract; prepyramidal tract*) originates in the red nucleus in the tegmentum of the mid-brain of the opposite side and its axones terminate in relation with ventral horn cells. In their course these fibres are seen to invade the area of the crossed pyramidal tract.

The **cerebellospinal tract** (*Marchi's tract*) is supposed to arise in the cortex of the cerebellar hemispheres, to become distributed to the motor centres in the ventral horn.

The **lateral vestibulospinal tract** arises in the lateral nucleus of the vestibular nerve (*Deiters' nucleus*), and by its relations with spinal centres establishes a connection with the equilibratory apparatus.

The **olivospinal tract of Helweg** (*Helweg's Dreikantenbahn; Bechterew's Olivenbündel*) is found only in the higher segments of the cord, at its periphery and just laterad of the emergence of the ventral nerve roots. Its connections and functional direction are uncertain; some investigators have traced its fibres between the olive and certain ventral horn cells; Obersteiner suggests a relationship with the pyramidal tract. The coincidence, in point of time, of the myelinization of both tracts is significant in this connection.

Several other descending tracts ending in the spinal cord and arising in higher centres like the corpora quadrigemina, central gray substance of the mesencephalon, and the cerebellum have been recently described by Held, Boyce, and Bechterew.

Ground Bundle of the Lateral Column (*fasciculus lateralis proprius*).—This lies in the concavity of the lateral aspect of the gray column and consists of axones of neurones having a purely commissural function. In the regions where the reticula is best marked it is subdivided into a group of smaller bundles by numerous glial septa.

In the **ventral column** are described the following tracts:

Descending:

1. Direct pyramidal tract.
2. Sulcomarginal tract.
3. Ventral vestibulospinal tract.

Associating:

1. Association axones between spinal centres and several cranial nerve nuclei.
2. Fasciculus ventralis proprius.

The **direct pyramidal tract** (*fasciculus cerebrospinalis ventralis; fasciculus of Türck*) is the uncrossed portion of the pyramidal tract below the decussation in the medulla oblongata, and constituting only 10 to 15 per cent. of the fibre system arising in the motor cortex of the same side. It is a small, oblong bundle, as seen on trans-section, lying parallel with the ventral fissure, from which it is separated in the higher segments by the relatively narrow sulcomarginal tract. The tract diminishes in bulk as the cord is descended, to disappear in the thoracic portion of the cord; though, in rare instances, it has been observed to extend throughout the lumbar portion as well. This diminution and eventual disappearance of the tract is due to the successive decussations of its fibres throughout its course, for, with a few exceptions, these cross in the ventral white commissure to come into relation with the ventral horn cells (motor cells) of the opposite side. This partial longitudinal extension of the pyramidal decussation and consequent formation of an uncrossed, ventrally situated pyramidal tract is peculiar to the primate order of vertebrates.

The **sulcomarginal tract** (*tractus tectospinalis*) is a thin bundle whose axones arise in the corpora quadrigemina of the opposite side, immediately decussating and descending through the medulla oblongata, to be distributed to various spinal centres in a manner not yet accurately ascertained. This tract, which is most developed in the cervical region of the cord, is assumed because of its proximity to the lower optic, ocular muscle, and acoustic nuclei.

The **ventral vestibulospinal tract** (*Löwenthal's tract; anterior marginal fasciculus; ventral cerebellospinal tract*) lies at the periphery of the ventral column, extending, as seen on trans-section, from the ventral root zone to the ventral fissure. Its axones arise from (1) the lateral (Deiters') and (2) superior (Bechterew's) nuclei of the vestibular nerve; and (3) from the nucleus fastigii of the cerebellum. Their termination about the ventral horn cells has been traced as far as the sacral region of the cord.

As in the lateral column, and continuous with the like formation, there is in the ventral column an **intermediate zone** of mixed systems of axones which serve to associate various levels of the cord with ganglionic masses in the medulla oblongata, as well as with the cerebellum and corpora quadrigemina. The nuclei of the trigeminus, facial, auditory, glossopharyngeal, and vagus nerves, together with the olive and the cerebellum, seem most intimately associated with the spinal centres for movements of the head and neck.

Ground Bundle of the Ventral Column.—The white substance of the ventral column contiguous with the central gray is made up of intersegmental axones of association connecting different levels of the cord.

The **ventral (white) commissure** (*commissura ventralis alba*) is composed of myelinic fibres which decussate with or cross each other and, on trans-section, are seen to form a narrow band connecting the ventral columns of the two sides. The axones composing it are chiefly (1) those arising from ventral horn cells, which after crossing the midline, course horizontally or cephalad and caudad to come into relation with neurones at the same or at different levels of the gray substance; (2) the decussating axones of the direct pyramidal tract; (3) numerous collaterals from the ventral and lateral column axones. The white commissure is most massive in the enlargements where the associations of the limb centres are necessarily greater in number.

Myelination of the Axones of the Cord.—The acquisition of the myelin sheath is not cotemporary for all axones in the cord, but is characterized by a regular progression in the myelination of separate fasciculi. As a rule, those axone systems which are concerned with simpler or intrinsically spinal reflexes become myelinic or "mature" at an earlier stage of fetal development than do those concerned in the more elaborate connections of the cord with the brain.

According to Flechsig and Trepinski the order of myelination is as follows:

1. Ventral and dorsal roots during fifth month.
2. Ground bundles during sixth month.
3. Dorsal columns during fifth to seventh month.
4. Direct spinocerebellar tract, seventh month.
5. Ventral spinocerebellar (Gowers') tract, seventh to eighth month.
6. Olivospinal (Helweg's) tract, ninth month or later.
7. Pyramidal (crossed and direct) tracts, at or soon after birth.

The order of myelination of the separate fasciculi is indicated in Fig. 614.

Summary. The Gray Substance.—The gray substance consists, aside from its supporting tissues, of sentient and reacting nerve cells, with their dendrites and axones, and of the terminals of axones entering from without. These nerve cells may be classified as follows:

(a) Nerve cells whose axones pass directly out of the cord. These lie in the ventral horn, are "motor" in function, and their axones form the ventral nerve

roots. Certain nerve cells situated in the cervix of the ventral horn are believed to send splanchnic efferent axones in company with the motor axones in the ventral root, while very few similar efferent axones leave by means of the dorsal root.

(b) Nerve cells whose axones pass into the white substance, usually bifurcating into a shorter descending and a longer ascending branch. Two kinds of cells are distinguished:

1. Strand or tract cells whose axones (ascending branches) traverse the cord, to come into relation with higher centres in the brain.
2. Association cells whose axones, after a comparatively brief course in the white substance, reënter the gray substance and serve to coördinate different levels of the cord.

FIG. 614.—Diagram showing the order of myelinization of the various tracts in the spinal cord (cervical level). The tracts are named on the right side; the Roman numerals on the left side correspond with the enumeration given in the text. H. Olivospinal tract of Helweg. M. Marginal tract.

The tract cells may be further divided into two categories—**homolateral** and **contralateral tract cells**. Homolateral cells are those whose axones enter the white columns of the same side; contralateral cells are those whose axones traverse the white (ventral) commissure to the other side. Tract cells exist in all parts of the gray substance, and are termed, according to their situation, **ventral**, **lateral**, and **dorsal horn cells**. The contralateral tract cells preponderate in the dorsal horn, its cervix, and in the intermediate zone, and, on account of their course, are also called **commissural cells**.

(c) Nerve cells of Golgi's type II, or cells with short, multibranched axones.

The motor ventral horn cells and the splanchnic efferent cells differ, therefore, from the other categories in that they alone send their axones out of the central axis to the periphery. The tract cells, commissural cells, and the Golgi type II cells are strictly confined to the central axis; the tract cells serve to coördinate the separate units of the spinal neurone system with higher centres; the association cells maintain the paths of conduction between higher and lower cell complexes; while the cells of Golgi's type II are limited to a narrower field of nerve activity as nerve links in the chaining together of neurones.

White Substance.—The white substance consists essentially of axones the great majority of which are disposed longitudinally. These axones comprise:

(a) Axones arising in the cerebral cortex, the gray ganglionic masses in the mid-brain, pons, and cerebellum, and descending to their terminations in different levels of the cord.

(b) Axones which, conversely, arise in the gray substance of the cord (tract cell axones), to terminate in the higher brain centres.

(c) Axones which coördinate different levels of the cord with each other (association cell axones).

(d) Axones which, arising from the spinal ganglion cells of the dorsal nerve roots, enter the cord and ascend in the dorsal columns.

Dissection.—To dissect the cord and its membranes it will be necessary to lay open the whole length of the vertebral canal. For this purpose the muscles must be separated from the vertebral grooves, so as to expose the spinous processes and laminae of the vertebrae; and the latter must be sawed through on each side, close to the roots of the transverse processes, from the third or fourth cervical vertebra above to the sacrum below. The vertebral arches having been displaced by means of a chisel and the separate fragments removed, the dura will be exposed, covered by a plexus of veins and a quantity of loose areolar tissue, often infiltrated with serous fluid. The arches of the upper vertebrae are best divided by means of a strong pair of cutting bone-forceps or by a rachitome.

Applied Anatomy.—*Contusion* of the spine may cause an effusion of blood or traumatic zonal inflammation of the spinal cord with paralysis which may disappear without surgical intervention. *Concussion* ("railway spine") is followed by temporary or rarely permanent impairment of function. *Punctured wounds* are usually caused by the knife, and are most commonly inflicted upon the cervical and upper thoracic divisions and more often involving one-half of the cord. The course is generally an aseptic one; operation is indicated when infection of the cord ensues or when there is a compression from hemorrhage. This may be relieved by lumbar puncture (p. 68) with a large needle. *Hemorrhage* into the substance of the cord (*hematomyelia*) usually occurs in the 4-6 cervical segments. If the hemorrhage is confined to the gray substance, there is wasting of muscle and anesthesia of the pectoral limb; the reflexes below the lesion are abolished. If the white substance is involved, paraplegia below the level of the lesion ensues. The cord may be injured by *fracture* or *dislocation* of *vertebra* (p. 69). *Gunshot wounds* are usually of serious nature. Operation is indicated by symptoms of compression by the bullet or by fragments of bone. If the compression is due to accumulated blood, lumbar puncture may be resorted to.

The cord usually shares in the congenital malformation known as *spina bifida*, resulting from failure of coalescence of the margins or lateral ridges of the neural plate. The defect may be complete (*rachischisis totalis*) or confined to a few segments of the cord. *Tumors* of many varieties, originating in the vertebra, meninges, or even in the substance of the cord itself (glioma, tuberculoma, etc.), give rise to many sensor and motor disturbances which afford a clue to the localization of such growths as indicated on page 831. *Inflammation* of the spinal cord (*myelitis*) may follow any of the acute specific fevers, occasioning more or less complete paralysis and anesthesia. In *infantile spinal paralysis* (*acute anterior poliomyelitis*) due to a bacterial infection which results in the destruction of ventral horn (motor) cells and consequent permanent paralysis and nutritional disturbances of the limbs whose centres are thus affected. Further, the muscles which normally antagonize the affected groups of muscles tend to assume a state of spastic contraction. The deformity thus produced may be relieved by tenotomy, transplantation of tendons, or even amputation. *Syringomyelia* is a chronic condition in which an abnormal proliferation of the spinal neuroglia takes place, generally near the central canal and in the cervical enlargement, and later this mass becomes absorbed, leaving an irregular cavity in its place. This gives rise to a number of interesting symptoms, such as analgesia (or insensitiveness to pain), inability to distinguish between heat and cold, progressive atrophy of the muscles of the hands and arms, trophic changes in the bones and joints, and painless whitlows.

THE MEMBRANES OF THE CORD.

The membranes which envelop the spinal cord are three in number. The most external is the *dura*, a strong fibrous membrane which forms a loose sheath around the cord. The most internal is the *pia*, a cellulovascular membrane which closely invests the entire surface of the cord. Between the two is the *arachnoid*, an avascular membrane which envelops the cord and is connected to the pia by slender filaments of connective tissue.

The Spinal Dura (Dura Spinalis) (Figs. 615, 617).

The spinal dura represents only the meningeal or supporting layer of the cranial dura. The endocranial or endosteal layer ceases at the foramen magnum dorsally, but reaches as low as the third cervical vertebra ventrad; below these levels its place is taken by the periosteum. The dura forms a loose sheath which surrounds the cord and the cauda equina, and is loosely connected with the vertebral periosteum and the ligaments by a quantity of lax areolar tissue and a plexus of veins, the **meningorachidian veins** (*plexus venosi vertebrales interni*). The space containing the fat and veins is called the **epidural space** (*cavum epidurale*). The situation of the veins between the dura and the periosteum of the vertebra corresponds therefore to that of the cranial sinuses between the endocranial and supporting layers. The dura is attached to the circumference of the foramen magnum and to the axis and third cervical vertebra; it is also fixed to the posterior

FIG. 615.—The spinal cord and its membranes.

FIG. 616.—The dentate ligament. The dura has been opened and turned back. The ventral surface is seen. (Hirschfeld.)

common ligament, especially near the lower end of the spinal canal, by fibrous slips; it extends below as far as the second or third piece of the sacrum, where its cavity terminates, and, ensheathing the filum terminale, constitutes the **filum dursæ spinalis** (Fig. 598), and descends to the dorsum of the coccyx, to blend with the periosteum. This part of the dura is called the **coccygeal ligament** (Fig. 617). The dura is much more capacious than is necessary for its contents, and its size is greater in the cervical and lumbar regions than in the thoracic. Its inner surface is smooth. On each side may be seen the double openings which transmit the two roots of the corresponding spinal nerve, the fibrous layer of the dura being continued in the form of a tubular prolongation on them as they pass through these apertures. These prolongations of the dura are short in the upper part of the vertebral column, but gradually become longer below, forming a number of tubes of fibrous membrane, which enclose the sacral nerves, and are contained in the vertebral canal.

The chief *peculiarities* of the dura of the cord, as compared with that investing the brain, are the following: The dura of the cord is not closely adherent to the bones of the vertebral canal, and is not, as is the cranial dura, the internal periosteum of the vertebræ. The vertebræ have an independent periosteum. It does

FIG. 617.—The filum terminale (schematic). (Poirier and Charpy.)

not send partitions into the fissures of the cord, as the cranial dura sends partitions into certain fissures of the brain. Its fibrous laminae do not separate to form venous sinuses, as in the cranium. It contains no arachnoid villi (*Pacchionian bodies*).

Structure.—The dura consists of white fibrous and elastic tissue arranged in bands or lamellæ, which, for the most part, are parallel with one another and have a longitudinal arrangement. Each surface is covered by a layer of endothelial cells. It is sparingly supplied with vessels, and some few nerves have been traced into it.

The Arachnoid (*Arachnoidea Spinalis*) (Figs. 596, 615).

The arachnoid is exposed by slitting the dura and reflecting that membrane to either side. It is a thin, delicate, tubular membrane which invests the surface of the cord, and is connected to the pia by slender filaments of connective tissue. Above, it is continuous with the cranial arachnoid; on each side it is continued on the various nerves, so as to form a sheath for them as they pass outward to the intervertebral foramina. The outer surface of the arachnoid is in contact with the inner surface of the dura, and the two are, here and there, joined together by isolated connective-tissue trabeculæ. These trabeculæ are especially numerous on the dorsal surface of the cord. For the most part, however, these membranes

are not connected together, and the interval between them is named the **subdural space** (*cavum subdurale*). The subdural space contains a very small amount of lymph-like fluid. *There is no communication between the subdural and the subarachnoid spaces.* The subdural space is prolonged laterad for a short distance on each emerging nerve and communicates with the lymph tract of the nerve. The inner surface of the arachnoid is separated from the pia by a considerable interval, which is called the **subarachnoid space** (*cavum subarachnoideale*). The space is largest at the lower part of the spinal canal, and encloses the mass of nerves which forms the cauda equina. Cephalad it is continuous with the cranial subarachnoid space, and communicates with the general ventricular cavity of the brain by means of openings in the pia, in the roof of the fourth ventricle, the **foramen of Majendie** or **metapore** and **foramina of Key and Retzius**. It contains an abundant serous secretion, the **cerebrospinal fluid** (*liquor cerebrospinalis*). This secretion is sufficient in amount to expand the arachnoid, and thus to distend completely the whole of the space included in the dura. The subarachnoid space is occupied by trabeculae of delicate endothelial-covered connective tissue, connecting the pia on the one hand with the arachnoid on the other. This is named **subarachnoid tissue**.

In addition to this the space is partially subdivided by a longitudinal membranous partition, the **septum posticum** or the **dorsal fenestrated septum** (*septum subarachnoideale*), which serves to connect the arachnoid with the pia, opposite the dorsomedian fissure of the spinal cord. It is a partition, but an incomplete and cribriform partition, which consists of bundles of white fibrous tissue interlacing with each other, and is coated with endothelium. The **dentate ligament** (*ligamentum denticulatum*), which runs from the pia to the dura on either side of the cord, divides the subarachnoid space into an **anterior or ventral** and a **posterior or dorsal space** (*cavum subarachnoideale anterius et posterius*), which joins like spaces in the cavity of the cranium. The **external spinal veins** (*venae spinales externae*) lie in the subarachnoid space.

Structure.—The arachnoid is a delicate membrane made up of closely arranged interlacing bundles of connective tissue in several layers. It contains many elastic fibres, and is covered on each side by endothelial cells. The arachnoid contains neither vessels nor nerves.

The Pia of the Cord (Pia Spinalis).

The pia of the cord is exposed on the removal of the arachnoid (Figs. 615 and 616). It covers the entire surface of the cord, to which it is very intimately adherent, forming its neurilemma, and sending a fold into its ventral fissure. It also forms a sheath for each of the filaments of the spinal nerves, and invests the nerves themselves. A longitudinal fibrous band extends along the middle line on its ventral surface, the **linea splendens**; and a somewhat similar band, which forms the **ligamentum denticulatum**, is situated on each side. At the point where the cord terminates the pia becomes contracted, and is continued caudad as a long, slender filament, the **filum terminale** (Fig. 617), which descends within the sheath of the dura and the arachnoid and through the centre of the mass of nerves forming the **cauda equina**. It unites with the dura and arachnoid about the level of the third sacral vertebra, and as the **central ligament of the spinal cord**, the **coccygeal ligament**, or the **filum durae spinalis** the fused membranes extend caudad as far as the base of the coccyx, where they blend with the periosteum. It assists in maintaining the cord in its position during the movements of the trunk. It contains a little gray nerve substance, which may be traced for some distance into its upper part, and is accompanied by a small artery and vein. At the upper part of the cord the pia presents a grayish, mottled tint, which is due to yellow or brown pigment cells scattered among the elastic fibres.

Structure.—The pia of the cord is less vascular in structure, but thicker and denser, than the pia of the brain, with which it is continuous. It consists of two layers; an outer, resembling the arachnoid, composed of bundles of connective-tissue fibres, arranged for the most part longitudinally; and an inner (*intima pia*), consisting of stiff circular bundles of the same tissue, which present peculiar angular bends. It is covered on both surfaces by a layer of endothelium. Between the two layers are a number of cleft-like lymphatic spaces which communicate with the subarachnoid cavity, and a number of bloodvessels which are enclosed in perivascular sheaths, derived from the inner layer of the pia, into which the lymphatic spaces open. The pia contains the anterior or ventral spinal artery and its branches, the two posterior or dorsal spinal arteries, and numerous veins which pass to the external spinal veins. It is also supplied with nerves, which are derived in part from the sympathetic and in part from the cerebrospinal nerves. These nerves supply the walls of the bloodvessels and enter the cord with the vessels.

FIG. 618.—Transverse section of the spinal cord and its membranes. (Gegenbauer.)

Both the arachnoid and the pia may be referred to by the compound name *pia-arachnoid*, inasmuch as these meningeal components are with difficulty separable from each other.

Both the arachnoid and the pia may be referred to by the compound name *pia-arachnoid*, inasmuch as these meningeal components are with difficulty separable from each other.

The **dentate ligament** (*ligamentum denticulatum*) (Figs. 596 and 616) is a narrow, fibrous band, situated on each side of the spinal cord, throughout its entire length, running from the pia to the dura, and separating the ventral from the dorsal roots of the spinal nerves. It has received its name from the serrated appearance which it presents. Its inner border is continuous with the pia at the side of the cord. Its outer border presents a series of triangular, dentated serrations, the points of which are fixed at intervals to the dura. These serrations are twenty-one in number on each side, the first being attached to the dura opposite the margins of the foramen magnum between the vertebral artery and the hypoglossal nerve, and the last near the lower end of the cord. Its use is to support the cord.

Applied Anatomy.—Evidence of value in the diagnosis of meningitis may be obtained by the operation of *lumbar puncture*, that is, by puncturing the theca of the cord and withdrawing some of the cerebrospinal fluid, and the operation is regarded by some as curative, under the supposition that the draining away of the cerebrospinal fluid relieves the patient by diminishing the intracranial pressure. Lumbar puncture may give important diagnostic aid after a head injury by disclosing bloody cerebrospinal fluid. The operation is performed by inserting a trocar of the smallest size below the level of the fourth lumbar vertebra. In an adult the cord terminates at the lower border of the first lumbar vertebra, and in a child opposite the body of the third lumbar vertebra. The canal may be punctured below the fourth vertebra without much risk of injuring its contents. The point of puncture is indicated by laying the child on its side and dropping a perpendicular line from the highest point of the crest of the ilium; this will cross the upper border of the spine of the fourth lumbar vertebra. In a child the puncture is made just below this spine; in adults, one-half an inch to one side of the end of this spine. However the preliminary puncture is made, the needle penetrates the dura in the midline. In entering the needle it should be directed upward and forward in a child; upward, forward, and slightly inward in an adult.

THE BRAIN OR ENCEPHALON.

The brain is that greatly modified and enlarged portion of the cerebrospinal axis which, with its membranes, almost completely fills the cavity of the cranium. It is a complex organ in which reside the highest functions—consciousness, ideation, judgment, volition, and intellect—together with the centres of special sense and for the mechanisms of life (respiration and circulation), and it is the agent of the will.

General Appearance and Topography of the Brain.—Corresponding to the varieties of cranial form, the shape of the fresh or the successfully preserved brain varies from the ovoid to the nearly spherical form, as viewed dorsally. The frontal pole is usually narrower, though more squarely formed; while the parieto-occipital portion is more massive, but more sharply pointed in each half. The outline is often rather that of an irregular pentagon with its angles rounded off. A dorsal view shows only the extensive convex surface of the two great convoluted **cerebral hemispheres** (*hemicerebra*) separated by a median cleft, the **intercerebral fissure** (*fissura longitudinales cerebri*). On divaricating the cerebral halves it is seen that the separation is not a total one, for in the depths of the fissure a broad commissural mass of white fibres—the **corpus callosum**—joins the cerebral hemispheres. Frontad the longitudinal fissure is continued to the ventral or basal aspect of the brain; caudad it passes into the **fissura transversa cerebri** (*tentorial hiatus*) or interval, separating the cerebrum from the cerebellum.

In a lateral view the continuity of the spinal cord with the medulla oblongata, then the pons and cerebellum are seen in part, overlapped by the cerebrum. Prominent is the temporal lobe with its rounded pole, separated from the frontal and parietal lobes by a deep cleft, the **sylvian fissure**, in whose depths—overlapped by the opercula of the adjacent lobes—lies the **island of Reil** or **insula**.

A ventral view presents many of the subdivisions of the brain. Here is seen the continuity of the spinal cord, with the short and slightly expanding **medulla oblongata** lying ventrad of the cerebellum and somewhat buried in its vallecule or depression between the lateral hemispheres, which alone are visible. The **cerebellum** is a grayish-colored mass of considerable size and easily recognized by its foliated appearance, due to the numerous parallel and closely set curved fissures. A mass of white fibres, the **pons**, passes transversely from one cerebellar hemisphere to the other, ventrad of the upper portion of the medulla oblongata. Above the pons are seen two large bundles, the **crura cerebri**, one on either side, diverging to pass into the cerebral halves. The interval between the divergent crura cerebri and temporal poles laterad and the orbital portions of the cerebrum frontad contains a number of important structures. Encircling the crura cerebri and meeting in the fore part of the fossa are the **optic tracts**, decussating in the median plane to form the **optic chiasm** and continuing frontad as the **optic nerves**. The arch of the optic tracts and optic chiasm and the crura cerebri enclose the **intercrural space**, in which may be seen (1) the **posterior perforated space** (*postperforatum*; *substantia perforata posterior*); (2) the **corpora albicantia** (*c. mammillaria*; *c. candicantia*); (3) the **tuber cinereum** and the **stalk of the pituitary body**. A groove marking the lateral boundary of the fossa along each crus is termed the **oculomotor sulcus**, as the root fibres of the oculomotor nerve have their superficial origin therein. The **posterior perforated space** is a gray area with numerous minute apertures for the entrance of postperforant branches of the posterior cerebral artery. The **corpora albicantia** are two small, pea-like, white eminences closely set side by side. The **tuber cinereum** is a conical projection between the corpora albicantia and the optic chiasm, to which the hypophysis (*pituitary body*), resting in the sella of the sphenoid, is attached. In the removal of the brain from the skull the stalk of the hypophysis is usually torn through and an orifice, the **lura**, leading to the infundibular recess of the third ventricle, is thus exposed. In the interval between the optic tract and the orbital surface of each cerebral hemisphere is a small, depressed, triangular area of gray substance leading laterad into the basisylvian fissure and dotted with numerous apertures for the minute basal branches of the middle cerebral artery and called the **anterior perforated space** (*preperforatum*).

If the optic chiasm be drawn somewhat ventrad, a delicate gray lamina, the **lamina terminalis** (*terma*; *lamina cinerea*) is seen attached to the dorsal surface

of the optic chiasm and passing dorsad into the intercerebral cleft to the region of the anterior commissure.

Parallel to the mesal border of the orbital surface of each cerebral hemisphere lie the **olfactory tract and bulb**, torn away from the fila olfactoria as these pass through the lamina cribrosa of the ethmoid. The olfactory tract may be traced to its root area, the **olfactory trigone**, just frontad of the anterior perforated space.

The superficial origin of nearly all of the **cranial nerves** may be seen upon the basal aspect of the brain (Fig. 619). These nerves, their superficial attachments to the brain, and the foramen of exit in the skull are enumerated in the following table:

TABULATION OF THE CRANIAL NERVES, THEIR SUPERFICIAL ATTACHMENTS TO THE BRAIN, AND THE FORAMINA OF EXIT IN THE SKULL.

NERVE.	SUPERFICIAL "ORIGIN" OR ATTACHMENT TO THE BRAIN.	FORAMEN OF EXIT FROM THE SKULL.
I. Olfactory fila.	Olfactory bulb and tract.	Ethmoidal cribrosa.
II. Optic nerve.	Optic chiasm.	Optic foramen.
III. Oculomotor nerve.	Oculomotor groove along medial border of crus.	Sphenoidal fissure.
IV. Trochlear nerve.	Valve of Vieussens laterad of frenulum.	Sphenoidal fissure.
V. Trigeminal nerve.	Prelateral part of pons.	(a) Ophthalmic ramus, superior orbital fissure. (b) Maxillary ramus, foramen rotundum. (c) Mandibular ramus, foramen ovale.
VI. Abducent nerve.	Postpontile groove (prepyramidal part).	Sphenoidal fissure.
VII. Facial nerve.	Postpontile groove (laterad of abducent nerve in preolivary part).	Porus acusticus internus; meatus acusticus internus; facial canal; stylomastoid foramen.
VIII. Acoustic nerve.	Postpontile groove (laterad of facial nerve).	Porus acusticus internus.
IX. Glossopharyngeal nerve.	Dorsolateral groove of medulla oblongata.	Jugular foramen.
X. Vagus nerve.	Dorsolateral groove of medulla oblongata.	Jugular foramen.
XI. Spinal Accessory nerve.	(a) Encephalic part: Dorsolateral groove of medulla oblongata. (b) Spinal part: Lateral column of spinal cord, between ventral and dorsal roots of cervical nerves as far as the fifth and sixth cervical nerves.	Jugular foramen.
XII. Hypoglossal nerve.	Pyramido-olivary groove.	Canalis hypoglossi ("anterior condylar foramen").

The olfactory, optic, and acoustic nerves are *afferent* or *sensor nerves*.

The trigeminal, glossopharyngeal, and vagus nerves are *mixed nerves*.

The oculomotor, trochlear, abducent, facial, spinal accessory, and hypoglossal nerves are *efferent* or *motor nerves*.

Dimensions.—The sagittal or occipitofrontal diameter of the white male adult brain averages 16 to 17 cm. (6.4 to 6.8 inches), the maximum width in the parietal region averages 13 to 14 cm. (5.2 to 5.6 inches), while the maximum height is about 12.5 cm. (5 inches). The dimensions of the female brain are usually somewhat less. The brains of dolichocephalic individuals are naturally longer and narrower than those of brachycephalic, and other differences in size and shape are found in conformity with the cranial configuration and other factors.

FIG. 619.—Basal aspect of the brain showing the superficial origin of the cranial nerves. The Roman numerals indicate the nerves.

The Development of the Brain and the Usual Classifications of its Subdivisions.—The cephalic region of the embryonic neural plate is characterized, as already pointed out (p. 808), by a rapid process of expansion and intensity of growth energy which seems to indicate the higher functional potentiality of what is to become the brain. The fusion of the margins of the neural plate, proceeding rapidly cephalad and caudad from about the cervical region, soon effects the complete closing in of the brain portion of the neural tube and its complete separation from the overlying ectoderm. For a brief period prior to the completion of the tube formation there exists a minute opening affording communication between the interior of the neural tube and the surrounding amniotic cavity; this temporary passage is called the **neuropore** (Fig. 620), and is morphologically the cephalic end of the tube. Its adult position is probably in the hypophyseal region.

The simple brain tube expands very early in intrauterine life in a sac-like manner, with the formation of three dilatations or pouches—the **primary brain vesicles**—demarcated by two constrictions.¹ The vesicles are designated respectively the

Fore-brain (Prosencephalon).

Mid-brain (Mesencephalon).

Hind-brain (Rhombencephalon or Metencephalon).

FIG. 620.—Brain tube of embryo salamander, sagittal section, showing neural segmentation (neuromeres): F. I.-III. Fore-brain neuromeres. M. I.-II. Mid-brain neuromeres. H. I.-VI. Hind-brain neuromeres. (Adapted from Kupffer.)

FIG. 621.—Brain tube of chick (25½ hours), showing partly closed brain tube with eleven folds or neuromeres. (After C. Hill.)

FIG. 622.—Scheme showing the connection of the several parts of the brain.

This classification has been found acceptable from every comparative standpoint in brain morphology, but attempts have been made to establish a further segmentation into definite anatomical divisions regarding which opinions and usages differ widely and have proved to be a hindrance rather than an aid to the homologization of brain structures in the vertebrate series. The difficulties in formulating a satisfactory schema of the segmental divisions of the brain will be overcome, perhaps, only by distinguishing the **neuromeres** or **neural segments** conforming to the general segmental plan of the vertebrate body. The existence

of a neuromerism that is akin to the metamerism or serial segmentation of the body, or to the branchiomerism characterizing the arrangement of the branchial arches, is indicated in several ways, but thus far only the earliest embryonic

¹ The constriction between mid- and hind-brain has been called the *isthmus rhombencephali* by Prof. His, and he regards it as coordinate with the other segments recognized by him; the region, however, no more deserves a definitive segmental value than would the cephalic constriction even if it were dignified by the term *isthmus prosencephali*.

stages and the disposition of certain of the cranial nerves afford a clue to the definitive segmentation of the brain. According to the most recent researches, as many as eleven, sixteen, and even more neuromeres have been established in various vertebrate brains. The hind-brain alone shows from six to eight such neural segments (Figs. 620 and 621). The whole matter is yet so obscure that confusion will be avoided by restricting our description to the three primary divisions and their derivatives without insisting upon the recognition of further definitive segments proposed by various authors in consequence of preconceived ideas obtained from the complicated adult structure of the brain. At this transitional period the student is, however, obliged to be familiar with the commonly accepted—yet provisional—schemes of segmentation and a comparative view is given in the following table:

Brief Consideration of the Phases of Development of the Brain Tube.

I. **Fore-brain.**—The cephalic or fore-brain vesicle widens and expands most rapidly and attains to a comparatively large size even before the mid- and hind-brain vesicles become markedly defined. A series of remarkable developmental changes ensue in the following order: (a) **Optic vesicles** appear as two diverticula, each budding from either side of the primary fore-brain vesicle, their distal ends growing considerably and coming into contact with the overlying epidermis, while the proximal or attached ends assume a stalk-like shape. The distal sac-like end becomes invaginated and forms the retina of the eye, while the stalk upon obliteration of its cavity forms the optic nerve. It is necessary to state here that as development proceeds the optic stalks become relatively shifted caudad and form more intimate connections with the thalamus and mid-brain.

(b) A second pair of budding vesicles arises cephalad in the dorsal portion of the fore-brain vesicle and is destined to develop into the ponderous cerebral hemi-

spheres with their great ganglia, growing with great rapidity and exceeding in this respect all other parts of the brain. The growth of these **secondary fore-brain vesicles** is principally in the distal parts, and in this manner each forms a great pouch whose interior communicates with the primary neural cavity through a small opening, the **foramen of Monro** (*porta*). It must be remembered that in

FIG. 623.—Chick embryo of thirty-three hours' incubation, viewed from the dorsal aspect. $\times 30$.
(From Duval's Atlas d'Embryologie.)

these initial stages the vesicles are all extremely thin-walled, but later the walls thicken or hypertrophy to a marked degree, so that the neural cavity becomes relatively small.

(c) Meanwhile (in the fourth week) the most cephalic portion of the fore-brain also becomes differentiated. As the enlarging vesicles of the cérébral hemisphere crowd upon the median, slower-growing portion, there is observed, on either

side, the development of a groove or furrow, the primary arcuate fissure, which demarcates the olfactory region (*rhinencephalon*) into a cephalic and a caudal portion. The cephalic portion develops into a blind tubular diverticulum, which grows cephalad to form the **olfactory bulb and tract**, its central cavity becoming obliterated (persistent in certain other mammals), while the caudal portion forms the roots of the olfactory nerves, the **anterior perforated space** or **preperforatum** and the **subcallosal gyre**.

(d) At the ventral margin of the hemispherical or secondary fore-brain vesicle an excessive proliferation of cells results in the production of several ganglionic masses—the **basal ganglia**, of which the largest are the **lenticular nucleus** (*lenticula*) and **caudate nucleus** (*caudatum*).

(e) The median cephalic terminal wall intervening between the large hemispherical vesicles persists as a thin and relatively undeveloped lamina, the **lamina terminalis**.

(f) The remainder of the fore-brain undergoes great hypertrophy in its lateral walls to form the **optic thalami**, while the ventral portion develops moderately to form the **hypothalamus**, **tuber cinereum**, **posterior lobe of pituitary body**, and **corpora albicantia**. The dorsal wall fails to develop, and remains epithelial except at a point immediately adjacent to the quadrigeminal lamina of the mid-brain; here a diverticulum grows out to form the **pineal body** or **epiphysis** (a rudimentary structure in man, but undoubtedly of functional use in ancestral vertebrates).

(g) The cavity of the primary fore-brain vesicle undergoes alterations in form as the secondary metamorphoses of its walls proceed in the course of development. The hollow cerebral buds so rapidly outstrip all other parts of the brain that their internal cavities, the **lateral ventricles**,

FIG. 624.—Plan showing the mode of formation of the ventricles of the brain and the central canal of the spinal cord: A. Prosencephalon. B. Thalamencephalon. C. Mesencephalon. D. Metencephalon. E. Myelencephalon. F. Central canal of cord. G. Lateral ventricle. H. Foramen of Monro. (After Gerrish.)

FIG. 625.—Transverse section of a portion of a chick embryo of twenty-nine hours incubation. (From Duval's Atlas d'Embryologie.)

become the most spacious of the ventricular system. The great hypertrophy of the thalamic ganglia in the lateral walls of the primary fore-brain determine the

sagittally placed, slit-like form of the so-called **third ventricle**. The cavities of the optic and olfactory buds become obliterated.

II. **Mid-brain**.—The second primary vesicle becomes somewhat later differentiated and takes a less prominent part in the adult brain. Its dorsal wall goes into the formation of four eminences, the **corpora quadrigemina**, while the lateral and ventral sections grow considerably to form the **crura cerebri**. The neural cavity within the mid-brain persists as the narrow **aqueduct** joining the third and fourth ventricles.

III. **Hind-brain**.—The third primary brain vesicle is demarcated from the mid-brain by a marked constriction to which has been given the term **isthmus rhombencephali**. The hind-brain is specially characterized by the great expansion of its thinned-out, membranous dorsal wall caudad, while cephalad the dorsal wall becomes very much thickened as the **proton** or **fundament of the cerebellum**.

The ventral and lateral parts undergo thickening to form the **pons** and **medulla oblongata**.

FIG. 626.—Trans-section of head of chick embryo of forty-eight hours' incubation. $\times 55$.
(From Duval's *Atlas d'Embryologie*.)

Flexures of the Brain Tube.—The difference in growth rate of the different parts of the brain tube and the marked disproportion between the rapid brain growth and slower head growth causes the encephalic neural tube to become sharply bent upon itself at certain points. The first flexure to occur is involved in a bending of the entire head and takes place in the region of the mid-brain; this flexure is termed the **cephalic flexure**. A second bending of the tube occurs at the junction of the spinal cord and hind-brain; this is termed the **cervical flexure**, and is so pronounced in the fifth week of intrauterine life that the brain tube and spinal cord form a right angle with each other. A third flexure is produced, in consequence of the other two, in the region of the future pons, and is therefore called the **pontile flexure**. Subsequently the cervical and pontile flexures are obliterated by a gradual straightening of this portion of the brain axis.

Dorsal and Ventral Laminæ or Longitudinal Zones of the Brain.—Quite like the longitudinal division of the developing spinal cord, there is a differentiation of the brain tube into dorsal and ventral zones, though much less clearly shown. The limiting furrow between the two is not demonstrable in the fore-brain; at least it is disputed, on good grounds, that it exists there. It is claimed even that three such longitudinal divisions exist on each side (Kupffer) and the formation of the cranial nerves is not quite comparable to the spinal nerves, although there is a fair homology with their dorsal-sensor and ventral-motor functional differentiation, despite their frequent admixture in some cranial nerves or the total absence of the one category in others. Thus the motor elements do not extend higher than the mid-brain and the dorsal division preponderates in the more highly organized parts of the brain, becoming predominant in the higher vertebrate species—particularly in man.

In its simplest expression the brain is a tube like the rest of the central nerve axis, but a remarkably modified one. There is the same primitive ependymal

FIG. 627.—Profile view of the brain of human embryos at three several stages, reconstructed from sections. *A.* Brain of an embryo of about fifteen days. *B.* Brain of an embryo about three and a half weeks old. *C.* Brain of an embryo about seven and a half weeks old. (After His.)

lining throughout its interior; there is likewise a central tubular gray mass of ganglionic tissue which, however, undergoes nuclear differentiation in some

portions, atrophies in others, while in certain localities it is crowded away from the central cavity by the intrusion of white fibre masses which are chiefly commissural. A total atrophy occurs in a part of the dorsal wall of both fore-brain and hind-brain; partial atrophy is observable in the floor of the third ventricle, near the optic chiasm, once perhaps the optic centre in the earliest of the ancestral vertebrates, but atrophied in higher forms as the visual tract became secondarily projected in the mid-brain. Great hypertrophy characterizes the growth of the ganglionic gray in the floor of the lateral ventricle (cerebral vesicle), resulting in the formation of nugget-like masses, the **caudate**, **lenticular**, and **amygdaline nuclei**. The central gray of the primary fore-brain also undergoes great hypertrophy, but in the lateral walls only, to form the large, compact thalami.

FIG. 628.—Medial section of brain of human fetus during the third month. (After His.)

As in the cord, fibre masses develop ectad of the central tubular gray in some localities, while in other regions the ganglionic gray remains at the surface and the white conducting substance is developed on its inner aspect. Thus we have, secondarily, the formation of superficial gray matter as the **cortex** (or rind) of the cerebrum and cerebellum. The isolation of ganglionic gray masses from the primitive central tubular gray and their differentiation into nerve cell nidi is also observable in the reticular ganglionic formation of the medulla oblongata and pons as well as in the roof of the mid-brain. Certain aggregations of gray ganglionic tissue are intercalated in the course of fibre strands, receive an admixture of these, and are regarded as terminal, interrupting, or as condensing stations not unlike some very complex relay telegraph system. The **olive**, **dentate nucleus**, **red nucleus**, the **nuclei of the gracile and cuneate funiculi**, the basketwork intercalations of the **reticular** and **lemniscus fields** belong to this intrafascicular type of ganglionic structures.

The plan of structure of the brain differs, therefore, from the comparatively simple arrangement of the gray and white substance in the spinal cord. In the brain the gray substance is not centrally situated throughout, and there is a tendency to nuclear differentiation of great and small ganglionic masses. These are connected with each other and with the centres in the cord by longitudinal strands of fibres of greater and less length, as well as by transverse associating fibres

FIG. 629.—Three stages in the development of the medulla oblongata, showing the metamorphosis of the rhomboidal lip. (Modified after His.)

uniting the bilateral nuclei of the same ganglionic category; with the periphery they gain connection through the cranial nerves and (*via* the spinal cord) the spinal nerves.

In tracing the various structures of the brain from the medulla oblongata to the cerebral cortex we follow anatomically what nature has done in the evolution of the highest type of brain from that of the simplest and most ancient vertebrate. In the medulla oblongata lie the centres which exert a very direct influence over those of the entire cord. The striate bodies and the thalami form a connecting link between the higher cerebral cortex and the medulla oblongata and cord below. The extensive cerebral cortex, an aggregation of psychic centres and therefore the seat of the will, controls the activities of the fore-brain ganglia (corpus striatum, thalamus) and the cerebellar cortex, and these in turn preside over the functions

of lower centres, as in the way of motor responses to external impressions; such reactions may be delayed or immediate according to the exercise of the will power residing in the cerebral cortex.

This control by the will is intensified the higher we ascend the animal scale; the pyramidal tract, which originates in the cerebral cortex and threads its way to the motor centres of the spinal cord without interruption along the brain axis, is better developed in man than in any other animal. In the course of evolution the lower or more automatic ganglia and tracts remain relatively about the same in mass as in other mammalia, but the higher, more intellectual ganglia surpass these in growth, so that there is an apparent but not real diminution of the automatic systems observed in the human brain.

FIG. 630.—Schematic representation of the chief ganglionic categories. Accurate topographical relations and interconnections are shown in other figures.

It has been seen from the foregoing brief accounts of the development of the nerve system that the most prominent feature is the redundant growth of the cephalic or brain end of the neural tube. Comparative neuroanatomic researches have thrown much light upon the probable genesis of this remarkable characteristic. The ancestral vertebrate, built upon the segmental type, was a swimming animal, and its locomotion took place in the direction of its long axis. In its progress through the water the cephalic (or anterior) segments were those which first encountered the foreign objects floating in the same medium. It was for these segments to determine the quality of the objects encountered—whether

they were inimical or indifferent or beneficial to its individual ends. The sensor periphery, in consequence of the demands of evolution, underwent specialization in the development of olfactory and gustatory organs for testing the quality of the food and of the surrounding medium; optic organs for perceiving rays of light; auditory organs for the appreciation of certain oscillations of the surrounding medium; while others, strictly tactile in nature, underwent elaboration as such in the development of sensitive antennæ or tentacles. Motor contrivances, useful in the quest for food or in encounters with the enemy, were developed in the way of powerful jaws and masticatory muscles. In brief, a remarkable specialization and differentiation of structure attended the development of the head end, and with it the central organ of control kept pace. In the human species we find certain of these structural characteristics in a highly developed condition, while others have dwindled or disappeared in the course of evolution. Thus, in the myxinoid fishes and the lamprey the cerebral hemispheres themselves are mere appendages of the olfactory lobes; the sense of smell was probably the most important in lower animals. In the brain of man conditions are reversed and the olfactory system is seen to have dwindled to an extreme degree as compared with the immense size of the cerebrum; this in conformity with the relatively slight use made of the smell sense in the mental life of man. Other organs of special sense, however, became augmented, and these, together with the nerve mechanisms controlling the vital functions (respiration, circulation), required a more and more elaborate central nerve organ for the harmonious interaction of the several elements. This central organ or brain developed, in bulk and complexity, hand in hand with the increase of the intellectual faculties. Man's most manifest distinction from other animals has resulted from a remarkable evolutionary growth in brain size and brain power; and as the brain is the material organ of mental and moral manifestations, we find in mankind the highest degree of superiority and culture—not only as compared with the nearest related apes, but of the civilized and progressive races as compared with the primitive and unprogressive races.

FIG. 631.—Scheme showing the connection of the several parts of the brain.

DESCRIPTIVE ANATOMY OF THE ADULT HUMAN BRAIN.

Morphologically considered, the brain consists of a common trunk (or brain axis) from which the two cerebral hemispheres crop out like swollen terminal buds, while the cerebellum is an excrescence of the trunk itself. The axially situated brain axis or "brain stem"¹ comprises, roughly speaking, the axial parts of all

¹ Also "brain isthmus," a loosely used term. It may here be remarked that most extant accounts of the anatomy of the brain overemphasize the distinction of brain parts from each other. Some authors follow one or another system based upon the theories of the segmentation of the brain tube; others divide the brain into (a) rhombencephalon or hind-brain and (b) cerebrum, comprising mid- and fore-brain. None of the classifications proposed are, as already pointed out, quite satisfactory. The continuity of the parts can only be interrupted arbitrarily, and such procedure leads to a too narrow conception of brain structures single and apart rather than serial and connected.

three primary divisions of the brain tube—(a) **medulla oblongata**, (b) **pons**, (c) **mid-brain**, (d) **thalamic division of fore-brain**. In this brain stem lie the majority of the ganglionic masses enumerated above, together with the nerve tracts uniting the various cell nests in (presumable) automatic coördination as well as the great nerve tracts connecting the spinal gray with the cerebral hemispheres, the **thalami**, **cerebellum**, and the ganglia of the medulla oblongata (including the cranial nerve nuclei), and still other tracts connecting the medulla oblongata with the cerebral hemispheres, the cerebellum, and the special ganglia of the pons and mid-brain.

Parts Derived from the Hind-brain (Rhombencephalon). External Morphology.

The Medulla Oblongata (*oblongata*; *spinal bulb*; *postoblongata* of Wilder; *myelencephalon*).—The medulla oblongata is the continuation cephalad of the spinal cord, the transition lying at the level of the foramen magnum and marked by the decussation of the pyramids. Its cephalic limit is sharply defined ventrad by the rounded margin of the pons, while its dorsal surface is sunk into the cerebellar vallecula. The length of the medulla oblongata along its ventral surface is $\frac{4}{5}$ to 1 inch (20 to 25 mm.); its maximum width at the pontile end is $\frac{3}{4}$ inch (17 to 18 mm.), and half as much at its transition into the spinal cord; its maximum

FIG. 632.—Ventral view of pons and medulla oblongata, showing the attachments of certain cranial nerves on one side. * The inter-radicular pons tract or corpus pontobulbare, described in the text.

thickness is about 15 mm. ($\frac{3}{8}$ inch). Its expansion as it approaches the pons gives it the form of a truncated cone. The ventral surface rests upon the basilar groove of the occipital.

Fissures.—The ventral and dorsal fissures of the cord are continued upon the medulla oblongata, making it a bilaterally symmetrical structure. The **ventral** or **ventromedian fissure** (*fissura mediana anterior*) at the level of the foramen magnum is interrupted by a number of obliquely intercrossing fibres, called the

decussation of the pyramids. Beyond this interruption the ventral fissure passes cephalad to end at the ventrocaudal border of the pons in a recess called the **postpontile recess** or **foramen cecum**.

The **dorsal** or **dorsomedian fissure** (*fissura mediana posterior*) is of short extent upon the medulla oblongata, for the neural cavity is here expanded into a rhomboidal fossa whose dorsal wall, profoundly atrophied, is represented only by a delicate membranous lamina; the dorsal fissure rapidly becomes shallower as it ascends, to cease at the caudal apex of the "fourth ventricle."

Like the spinal cord, the surface of each half of the medulla oblongata is divided into three longitudinal districts by fissures called the **ventrolateral** and **dorsolateral fissures**. Of these, the latter only is a continuation of the fissure of the same name in the spinal cord.

The **ventrolateral fissure** (*sulcus lateralis anterior*) of the medulla oblongata demarcates the ventral column (pyramid) from the lateral column as well as the olive, and the roots of the hypoglossal nerve, arranged in linear order, emerge from this fissure.

(The ventrolateral fissure of the spinal cord becomes obscured as it ascends into the oblongatal region, for cephalad of the emergence of the ventral roots of the first cervical nerve a band of superficial arcuate fibres usually obliterates all traces of the furrow.)

The **dorsolateral fissure** (*sulcus lateralis posterior*) of the medulla oblongata is directly continuous with the same-named fissure of the spinal cord, and the root bundles of the spinal accessory, vagus, and glossopharyngeal nerves are attached along the bottom of this fissure. Unlike the dorsal roots of the spinal nerves, the root bundles of these three cranial nerves are not all composed of afferent fibres arising in extraneous ganglionic cells and entering the medulla oblongata, for the accessory nerve is purely efferent and the vagus contains both afferent and efferent fibres.

Areas.—The ventrolateral and dorsolateral fissures with their rows of nerve fascicles divide the surface of the medulla oblongata on each side into three districts which appear to be continuous with the three columns of the spinal cord; they are not so in reality, however, owing to the rearrangement of the fibre tracts and the central ganglionic mass in the myel-oblongatal transition. This portion of the brain axis is sculptured into several eminences and depressions; of the eminences, some, like the olives, the tubercula cineræ, and the clavæ, are due to the accumulation of gray substance beneath the surface at that point; others, like the pyramids and restiform bodies, are due to the prominence at certain points of the surface of the great nerve tracts.

AREAS OF THE MEDULLA OBLONGATA.

- I. Ventral Area:
Pyramid.
- II. Lateral Area:
(a) Lateral tract.
(b) Olive.
- III. Dorsal Area, marked by slight furrows dividing it into:
(a) Funiculus gracilis.
(b) Funiculus cuneatus.
(c) Funiculus lateralis and tuberculum cinereum.

The last three structures mentioned appear to become fused cephalad to continue as the **restiform body** or **restis**; in reality the restiform body is formed in a different manner.

I. The **Pyramids** (*pyramides medullae oblongatae*) constitute the oblongatal portion of the direct cerebrospinal efferent tracts conveying (voluntary) motor impulses from the precentral cortex, through the internal capsule, crusta, and ventral pons to descend in the crossed and direct pyramidal tracts to the efferent (motor) cell groups in the ventral horns of the spinal gray. In their external appearance in the medulla oblongata they are moderately constricted at their pontile ends, appear to become somewhat expanded, to again taper as they pass, partly into the ventral columns of the cord, partly, by decussation, into the lateral columns. The pyramids are separated from each other by the ventral (or ventro-median) fissure except where this is more or less completely obliterated by the decussating bundles. Each pyramid is bounded laterally by a slight furrow, the **ventrolateral** or **pyramido-olivary groove**, in which arise the hypoglossal nerve roots and which separates the pyramid from the olive. The pontile end of each pyramid is frequently traversed by a band of arched fibres (*fibrae arcuatae ectales*); *ponticulus* of Arnold (not the *ponticulus* of Henle), the **ectal arcuate fibres**.

The **decussation of the pyramids** (*decussatio pyramidum*) is a term given to the obliquely intercrossing bundles seen at the oblongata-myelom transition. The extent to which this decussation occurs and the degree of its visibility varies in different individuals. While in most cases the majority (90 per cent.) of the fibres cross the median line in this decussation to continue as the crossed or lateral pyramidal tract, it is sometimes observed that a larger share of the fibres pass into the direct or uncrossed pyramidal tract with a corresponding reduction of the crossed tract. Occasionally the decussating bundles are so deeply situated in the ventral fissure as not to be visible.

II. The **Lateral Area** of the medulla oblongata is continuous with that of the spinal cord, and is bounded by the dorsolateral and ventrolateral fissures. It is composed of the **ventrolateral spinocerebellar tract**, or **tract of Gowers** (*fasciculus anterolateralis superficialis*), the **ventrolateral ground bundle** (*fasciculus proprius anterolateralis*), and the **direct spinocerebellar tract** (*fasciculus cerebellospinalis* [*Flechsig*]), while it is invaded from above by the crossed pyramidal tract. The olive is interpolated in the cephalic part of this area.

The **olive** (*oliva*; *olivary body*) is a prominent, elongated oval mass bulging from the cephalic part of the lateral area of the medulla oblongata, bounded by shallow grooves, of which one, for the hypoglossal nerve roots (ventrolateral fissure) separates it from the pyramid, while the other, containing the nerve fascicles of the vagus, glossopharyngeal and spinal accessory nerves, separates the olive from the restiform body. From the pons it is separated by a shallow groove in which a band of arched fibres is sometimes seen. Numerous white fibres (**external or ectal arcuate fibres**) emerging from the ventral fissure and traversing the pyramid loop across the lower parts of the olive to enter the restiform body. The olive is formed by the olivary nucleus, embedded in a thin layer of white matter.

The olive is about 12 mm. ($\frac{1}{2}$ inch) in length and 5 mm. ($\frac{1}{4}$ inch) in breadth.

III. **Dorsal Area.**—(a) The **funiculus gracilis** is the direct continuation of the tract of the same name in the spinal cord. It is a narrow white band placed along the dorsomedian fissure, and separated from the funiculus cuneatus by the **dorso-paramedian furrow** (*sulcus intermedius posterior*). At the caudal apex of the rhomboidal fossa (fourth ventricle) each funiculus gracilis diverges from the median plane, presenting at this point a club-like enlargement, the **clava**. The prominence of the funiculus gracilis (and clava) is due to the gray **nucleus funiculi gracilis** beneath the surface.

(b) The **funiculus cuneatus** is the direct continuation of the tract of the same name in the spinal cord. It enlarges as it ascends, exhibiting a slight eminence or enlargement, the **cuneate tubercle** (*tuberculum cinereum*), which is marked only in the medulla oblongata of young individuals, and is due to the **nucleus funiculi cuneati** beneath the surface.

(c) The *funiculus lateralis* is a longitudinal prominence which gradually enlarges cephalad into a slight tubercle, the *tuberculum cinereum* (*tuberculum Rolandi*), marking the approach of the gelatinosa to the surface so as to form a prominence at a level with the lower border of the olive.

The *restiform body* (*restis; corpus restiforme*) occupies the upper dorsolateral area of the medulla oblongata on each side, lying between the floor of the fourth ventricle and the roots of the vagus and glossopharyngeal nerves. This structure might at first glance appear to be the continuation of the three funiculi just described. But as a matter of fact it is made up of the *direct spinocerebellar tract*, a set of *external or ectal arcuate fibres* (*fibrae arcuatae externae*) and a set of *internal or ental arcuate fibres* (*fibrae arcuatae internae*). Each restiform body assists in forming the lower part of the lateral boundaries of the fourth ventricle and then enters the cerebellum as the inferior peduncle of that body.

The Pons (*pons Varolii*).—The pons is a prominent white mass on the ventral aspect of the brain stem which is interposed between the medulla oblongata and the crura cerebri. It is convex from side to side and its fibres, running chiefly in a transverse arched direction, are gathered into rounded, compact strands on either side, to continue as the middle peduncles into the white substance of the corresponding cerebellar hemisphere. The fibre bundles of the pyramidal tracts thread their way through the pons on either side of the median plane and small aggregations of gray substance (*nuclei pontis*) are packed in the intervals between the transverse pontile and longitudinal pyramidal fibre bundles.

The Basilar Surface (*pars basilaris pontis*).—The basilar or ventral surface of the pons is in relation with the basilar process of the occipital and the dorsum sellae of the sphenoid. A shallow mesal groove lies between the eminences produced by the pyramidal tracts in their course through the pons. The groove is called the *basilar groove* (*sulcus basilaris*), as the basilar artery is usually accommodated in it; the artery is not, however, a factor in the production of the groove. The large sensor and small motor root bundles of the *trigeminal nerve* pierce the mass of the pons near the anterior pontile border, and a line drawn from this nerve root to that of the facial nerve is usually employed as an arbitrary boundary between the pons proper and the middle peduncle of the cerebellum. The *abducent nerve* emerges from the posterior pontile border (prepyramidal part); the *facial and acoustic nerves* are attached farther laterad.

While most of the superficial fibre bundles of the pons are seen to arch transversely, certain small compact bundles¹ are seen to extend in an obliquely longitudinal direction from the region of the trigeminal nerve root to and among the roots of the facial and acoustic nerves.

The Pars Dorsalis Pontis (*preoblongata; pars metencephalica medullae oblongatae*).—The *pars dorsalis pontis*, or tegmental part, is not sharply demarcated from the medulla oblongata or the tegmentum and crusta of the mid-brain, and the margins of the pons on the ventral surface afford only arbitrary boundary lines; for in the vertebrate series the pons varies greatly in width and its margins can hardly be accepted as the boundaries of a definite brain segment. The dorsal surface of the *pars dorsalis pontis* is continuous with that of the oblongatal ventricular surface, and its description more properly belongs to a consideration of the anatomy of the fossa rhomboidalis or "floor of the fourth ventricle."

Fourth Ventricle of the Brain (*ventriculus quartus*).—In a previous section on brain development it has been pointed out how the growth changes and differentiations in the hind-brain differ from those of the rest of the neural tube in that there is a marked disproportion in the degree of growth in the dorsal and ventral walls. While the ventral wall thickens greatly throughout to form the pons oblon-

¹ Called the *inter-radicular pons tract* by F. C. Spitzka (1884), and more recently described as part of the *corpus pontobulbare* by Essick (American Journal of Anatomy, vii, 1).

gata, the dorsal wall hypertrophies in its cephalic portion to form the cerebellum, while caudad thereof the roof atrophies and expands and becomes so attenuated as to be represented merely by a thin epithelial membrane. The outward folding of the walls of the neural tube in this region creates an expansion of the central cavity in the form of a rhomboidal fossa roofed in by the cerebellum and a thin epithelial layer. A time-honored custom enumerates this as the fourth of a system of ventricles of which the other three lie in the fore-brain.

A cast of the cavity (Fig. 689) shows it to be irregularly pyramidal, with a lozenge-shaped base and ridge-like apex extending from side to side, corresponding to the acute-angled *recessus tecti* in the fastigium ("gable roof") formed by the valve of Vieussens and superior medullary velum. Such a cast also indicates the ventral extension of the cavity from the lateral angles of the rhomboidal base in the form of the lateral recesses.

It is customary to describe for the fourth ventricle a **roof** and a **floor**, although an examination of a sagittal section of a brain hardened *in situ* shows the floor to be in a *vertical plane in the erect attitude*. Caudad the cavity is continuous with the minute central canal of the spinal cord and postoblongata (in part); cephalad it passes into the aqueduct or mesocele. The dorsal wall or "roof" is formed

FIG. 633.—Varieties of fourth ventricle.

by the *valvula (of Vieussens)*, the *superior peduncles*, *tela choroidea ventriculi quarti*, and *fastigium of the cerebellum*. The ventral wall or "floor" is the *rhomboidal fossa* occupied by the expanded central gray of the pre- and postoblongatal portions of the hind-brain.

"Floor" of the Fourth Ventricle (*fossa rhomboidea*).—The "floor" of the fourth ventricle is lozenge-shaped and exhibits regional elevations, depressions, and color differences which are in relation with the deep anatomy of the medulla oblongata and tegmentum of the pons (preoblongata). It is divided longitudinally into symmetrical halves by a median groove, and each lateral half is subdivided into a larger cephalic and a smaller caudal triangle by white, transverse striae, composed of bundles of myelinic fibres connected with the acoustic tract and appearing to sink beneath the surface near the median groove. The portion occupied by these *striae acusticae* (*striae medullares*; *striae transversales*) is termed by His the *pars intermedia* as distinguished from the *pars superior* and *pars inferior*, or frontal and caudal triangles respectively. Much variation is met with in regard to the course and degree of prominence of the striae acusticae (Fig. 633). There may be none visible or as many as twelve distinct bundles; bilateral symmetry is the exception, and not infrequently one or more bundles run obliquely cephalolaterad—

the *striae obliquae* (*conductor sonorus*). This irregularity of the acoustic striae has led to another mode of division of the "floor" for descriptive purposes—each side to be divided into a median and a lateral area, indicated by a more or less well-marked groove, the *lateral furrow* (*sulcus limitans*), connecting the superior and inferior (*ala cinerea*) foveae. This groove probably corresponds to one of the interzonal sulci of the embryonic tube, and in a gross way it separates the motor and sensor fields of the "floor." The median area is usually a continuous ridge which is quite accentuated in the cephalic division as the *eminentia abducentis* (*e. teres*), while caudad it becomes narrowed as it approaches the closed part of the medulla oblongata. The convergence of the median and lateral furrows at the caudal apex of the rhomboidal fossa gives the appearance of the point of an ancient writing reed or quill pen; hence the term *calamus scriptorius*.

In the caudal quarter triangle a middle area is occupied by an elongated triangular field whose depressed apex is directed frontad. A slight oblique ridge, the *funiculus separans*, composed chiefly of neuroglia, separates the *area postrema* caudadly from the *trigonum vagi* or *ala cinerea* of a pronounced grayish color. The whole depression has been termed the *fovea inferior*. Mesally lies a narrow triangular field with its apex directed caudad and with slightly raised surface—the *trigonum hypoglossi*. This area is resolved into two fields by a single or double formation of oblique rugae affording a "feathered" appearance to the lateral field, the *area plumiformis*. Laterad of the *trigonum vagi* lies the caudal portion of the lateral area of the "floor," also called (in part) the *area vestibularis* (*area acustica*) and crossed over its middle by the *striae acusticae* when these are present. The *area vestibularis* is an irregularly triangular raised surface with its convex base toward the median line, and extending laterally to the attachment of the tela choroidea and into the lateral recess. In the fetus and in certain lower vertebrates the area is more prominent and is designated the *tuberculum acusticum s. vestibularis*.

The "frontal" division of the floor or triangular quarter-field is marked by a depression at about its middle, the *superior fovea*, from which the slight "lateral furrow" runs caudad, and but for the intervention of the striae would reach the inferior fovea. Cephalad of the superior fovea, and continuing some distance along the aqueduct, is the *locus caeruleus*, which owes its color to the refraction of the pigmented cells, the *substantia ferruginea*, by the milky-white ependyma. At this altitude, the medial elevation between the superior fovea and the median sulcus is accentuated into a fairly pronounced eminence, the *eminentia abducentis* (*eminentia teres*), overlying the nucleus of the abducent nerve and the genu of the root of the facial nerve. The portion of the median sulcus intervening between the *eminentia abducentia* is correspondingly depressed to form the *fovea mediana*.

The ventricular features enumerated above correspond in a crude way to the deep structures of the pons oblongata, and most of the cranial nerve nuclei are held in a rhomboidal frame formed by the superior and inferior peduncles. The surface markings are only imperfect replicas of the subjacent structures; the various cell nests overlap each other more or less and their relations can best be studied in the projection shown in Fig. 634.

Membranous Portion of the "Roof" of the Fourth Ventricle.—The caudal extension of the hypertrophied cerebellum hides from view the whole of the rhomboidal fossa, but this structure, as before stated, forms but a part of the actual dorsal wall or "roof." This includes the converging *superior peduncles*, the *velum medullare anterius* intervening between these, the *fastigium of the cerebellum*, the *velum medullare posterius*, and the *tela choroidea ventriculi quarti*.

The *velum medullare posterius* is a thin and narrow lamina of white substance continued laterad as the flocculi of the cerebellum. At its caudal edge, *i. e.*, where nerve tissue ceases, the ependymal or ventricular lining epithelium and the

pia over this portion coalesce to form a delicate membrane—the **tela chorioidea**—attached along the caudolateral boundary line of the rhomboidal fossa. Along this attachment there is another intrusion of nerve substance between the ependymal and pial layers; this reinforced lamina is usually termed the **ligula** and may be traced to the clava and cuneate tubercle, thence laterad over the restiform body to bound the lateral recess. The structure is probably a vestige of the secondary rhomboidal lip and has actually been found to be a part of the pontobulbar body referred to above. Another small semilunar lamina of nerve tissue bridges the caudal apex of the fourth ventricle and is called the **obex**. This structure is often devoid of nerve tissue, and is then a mere membranous lamina.

Except in rare instances, the tela chorioidea is perforated a short distance from the calamus region. The opening is of variable shape and size; it permits of communication between the ventricular cavity and the subarachnoid space and is termed the **foramen of Majendie** (*metapore; apertura medialis ventriculi quarti*).

FIG. 634.—Surface markings and topography of the principal nuclei of the floor of the fourth ventricle. (Modified from Streeter.)

Similar apertures at the extremities of the lateral recesses, and called the **foramina Luschke** (*apertura lateralis ventriculi quarti*) also permit of a tidal flow of the cerebrospinal fluid.

The **choroid plexuses of the fourth ventricle** (*metaplexuses*) are highly vascular infoldings of the tela chorioidea, one on either side of the median plane, from each of which offshoots extend laterad into the lateral recesses. As the choroid plexuses of the brain are always formed by infoldings or invaginations of the membranous portions of the brain tube, the ependymal continuity upon them is nowhere interrupted.

Internal Structure of the Medulla Oblongata.—While the spinal cord remains a closed tube with centrally situated gray, the medulla oblongata opens out on the dorsal aspect so as to uncover its part of the neural canal as the “floor” of the fourth

ventricle. This involves a tilting of the functionally differentiated gray segments and, after a gradual transition in the medulla oblongata, the **motor gray** is to be

FIG. 635.—Scheme of roof of fourth ventricle.

sought nearest the middle line, the **mixed gray** just ectad, while the **sensor** is the outermost of all. Instead of the ventral, lateral, and dorsal horns of each half of the spinal cord, we have an **entol**, **middle**, and **ectal cornu** in each half of the medulla oblongata. The positions alone have changed; the functional relations to nerve roots having corresponding functions are homologous. Thus, the motor hypoglossal nucleus is placed in the mesal part of the ventricular floor, while the terminal nuclei of the afferent vagus, glossopharyngeal, and auditory nerves lie in the lateral part.

Another cardinal change in the internal structure of the medulla oblongata, accompanying the preponderating development of the cerebrum and great basal ganglia, is caused by interrupting and decussating fibre systems which seek passage through the brain stem and encroach more or less on its primitive architecture.

While in the spinal cord there is a perfect continuity of the central tubular gray, we find in the medulla oblongata more pronounced peninsular and isolated insular nuclei or ganglionic gray masses.

FIG. 636.—Schema of the pyramidal decussation

Pyramidal Decussation (*decussatio pyramidum*).—An important change in the internal structure is caused by the passage of the fibres of the pyramidal tract as these pass to the same and opposite sides of the cord, the latter category forming

FIG. 637.—Transverse section of the medulla oblongata at its lower end. (Testut.)

FIG. 638.—Transverse section of the medulla oblongata at the decussation of the pyramids. (Testut, after Duval.)

FIG. 639.—Diagram showing the course of the lemnisci (fillets) and their decussation.

the pyramidal decussation. In consequence of this passage of white (crossed pyramidal) fibres through its substance the ventral gray horn is broken up into a coarse network, while one portion of it, the **caput cornu**, is entirely separated from the rest; only a small portion of the base of the cornu remains intact close to the ventrolateral aspect of the central canal. The caput cornu, thus separated, is displaced laterally, and comes to lie close to the caput cornu dorsalis, which has also shifted its position. In consequence of this breaking up of the greater part

FIG. 640.—Transverse section of the medulla oblongata at the crossing of the lemnisci or fillets. (Testut.)

of the ventral gray cornu by white fibres a coarse network is formed in the anterior and lateral areas of the medulla oblongata, which is named the **formatio reticularis**.

The **gelatinosa Rolandi** (*gliosa cornualis*) of the dorsal horn is continued into the oblongata, but becomes insignificant, relatively, in the pars dorsalis pontis. The spinal root of the trigeminal nerve is in ectal relation with the gelatinosa Rolandi; at higher levels the spinal root of the vestibular nerve intervenes.

FIG. 641.—Transverse section of the medulla oblongata at the lower end of the olives. The roof of the fourth ventricle is not represented. (Testut, after Duval.)

Decussation of the Lemnisci (fillets).—A similar change, dorsad and cephalad of the pyramidal decussation, is caused by the decussation of axone bundles arising in the nuclei of the gracile and cuneate fasciculi (Goll and Burdach). At this level the base of the dorsal gray cornu undergoes change in the form of two thick dorsal peninsular outgrowths which form the nuclei of termination of the axones in the gracile and cuneate fasciculi; externally these gray masses produce the eminences of the clava and cuneate tubercle. The axones from these nuclei stream mesad and cephalad in a series of concentric arches, decussating in the raphé with the bundles of the opposite side to form the **decussation of the lemnisci**¹ or

¹ Also called "mesal lemnisci" in contradistinction to the "lateral lemnisci"—of different origin.

sensor decussation. Cephalad of this decussation the lemnisci are two bundles of fibres coursing on either side of the raphé between the olives, and just dorsad of the pyramids; their further course toward the cerebrum will be described farther on.

FIG. 642.—Transverse section of the medulla oblongata at the middle of the olives. The roof of the fourth ventricle is not represented. (Testut, after Duval.)

With the extension of the central gray to form the floor of the fourth ventricle, the caput cornu dorsale is displaced ectad so as to almost reach the surface, where it forms a projection, the *funiculus lateralis (Rolandi)*, which enlarges cephalad into a distinct prominence, the *tuberculum cinereum*. At a higher level

FIG. 643.—Trans-section of the medulla oblongata at about the middle of the olive.

the caput is separated from the surface by the **spinal root of the trigeminal nerve** and by the **external arcuate fibres** (Fig. 643). The cervix of the cornu becomes broken up into a reticular formation by the decussating fibres. A portion of the base is placed ectad of the nucleus funiculi cuneati and is called the **accessory cuneate nucleus**, supposed to be a continuation of Clarke's column.

The **formatio reticularis** (Fig. 643) consists of diffusely scattered gray substance in a meshwork of white fibres. It is far more abundant in the medulla oblongata than in the cord. In trans-sections of the medulla oblongata it is seen to be divided by the hypoglossal nerve root fascicles into a mesal and a lateral field. In the mesal field the gray substance is scanty, and white fibres—principally longitudinal ones—preponderate; this is called the **formatio reticularis alba** in contradistinction to the lateral grayer reticulated field, the **formatio reticularis grisea**. Its numerous nerve cells mostly possess short axones and for the most part exercise associative functions for the constantly active centres of respiration (nuclei of the vagus, phrenic, facial, etc.). Certain axones of longer course are collected into a small compact bundle just ventrad of the ventricular floor and central canal (and aqueduct in the mid-brain), and known as the **medial longitudinal fasciculus** (*posterior longitudinal bundle*). This tract is in intimate association with the cranial nerve nuclei. The **formatio alba** is principally made up of this tract and the lemniscus (interolivary stratum).

The **raphé** (Fig. 643) is situated in the middle line of the medulla oblongata above the decussation of the pyramids. It consists of nerve fibres intermingled with nerve cells. The fibres have different directions, which can only be seen in suitable microscopic sections, thus: (1) Some run dorsoventrad; these are continuous with the external or superficial arciform fibres. (2) Some are longitudinal; these are derived from the arciform fibres, which on entering the raphé change their direction and become longitudinal. (3) Some are oblique; these are continuous with the internal or deep arciform fibres which pass from the raphé.

The nerve cells of the raphé are multipolar; some are connected with the dorsoventral fibres, others with the superficial arcuate fibres.

The **restiform body** succeeds the *gracile and cuneate nuclei* in the dorsolateral part of the medulla oblongata. Its fibres converge from various sources and ultimately enter the cerebellum as its inferior peduncle. For a description of these fibre systems see the section on the "peduncles of the cerebellum."

The **nucleus of the olive** or **inferior olivary nucleus** (*nucleus olivarius inferior*) is a corrugated lamina of gray substance whose extent nearly corresponds to that of the external elevation called the olive. It can be compared to a hollow oval sac or purse, slit on its mesal aspect and the edges of the slit everted. The opening is called the hilum. Numerous fibres stream into the interior through the hilum, while others cut through the lamina to join the fibre arches of the reticular field and then pass toward the restiform body.

What are known as **accessory olivary nuclei** (*nuclei olivarii accessorii*) are smaller detached or semidetached portions of the olivary nucleus named, according to their position, the **dorsal** and **medial accessory olivary nuclei** (*nuclei olivarii accessorii, dorsalis et medialis*).

The olivary nuclei play an important part as relay stations in cerebellar connections. A considerable mass of fibres, the **olivocerebellar fibres** (*fibrae cerebello-olivares*), originate in the olivary nucleus of one side to enter the cerebellum along the restiform body of the opposite side. A much less number of fibres, running contrariwise, reach the olivary nuclei from the opposite cerebellar hemispheres—the **cerebello-olivary** (*vestibulo-olivary tract*) **fibres**. Each olivary nucleus is the terminus of the thalamo-olivary fibres, and Helweg's olivospinal tract is believed to originate therein.

The Arcuate Fibre Systems.—The arcuate fibre systems comprise two sets of fibres according as they course dorsad or ventrad of the olivary nuclei:

1. The **internal** or **deep arcuate fibres** comprise the olivocerebellar fibres, just described, and a number of commissural systems for the association of the tegmental reticular gray ganglia and cranial-nerve nuclei. Others pass cerebralward, others to the cerebellum.

2. The **external** or **superficial arcuate fibres** take origin (*a*) from the gracile and cuneate nuclei and enter the restiform body of the same side; (*b*) from the same nuclei of the opposite side, decussating in the raphé and sweeping ventrad over the pyramid and olive, forming a thin layer over them and ultimately reaching the restiform body. Many of these fibres are interrupted, on each side, in the **nucleus arcuatus**, a thin, isolated lamina of gray substance lying on the ventral aspect of the pyramid.

The **nucleus lateralis** is seen in the lateral column (lower part of medulla oblongata) as a diffuse gray mass lying between the gelatinosa Rolandi and the olive; it gradually disappears cephalad.

The **nucleus intercalatus** (of *Staderini* and *Van Gehuchten*) forms the elongated, wedge-shaped elevation in the medial triangle of the caudal portion of the ventricular floor called the **area plumiformis** (p. 869); the nucleus derives its name from its (intercalated) position between the hypoglossal and dorsovagal nuclei. Its functional connections are not yet precisely known.

A **nucleus postremus** has been described (J. T. Wilson) as lying subjacent to the area postrema.

The **nucleus funiculi teretis** lies close to the median sulcus in the altitude of the acoustic striæ, and seems to bear an intimate relation to these.

Summary of the Gray Masses in the Medulla Oblongata:

*Central tubular gray (in "closed" part).

*Gray floor of fourth ventricle (in "open" part).

*Gelatinosa Rolandi or gliosa.

*Nucleus funiculi gracilis.

*Nucleus funiculi cuneatus.

*Nucleus funiculi cuneati accessorius.

*Nucleus lateralis.

*Nucleus olivaris inferior.

*Nucleus olivaris accessorius dorsalis.

*Nucleus olivaris accessorius medialis.

*Nucleus arcuatus.

Nucleus nervi hypoglossi.

*Nucleus intercalatus.

*Nucleus postremus.

Nucleus vagi (alae cinereae).

Nucleus vestibularis (spinal division).

*Nucleus funiculi teretis.

Nucleus ambiguus.

Nucleus tractus solitarii.

Nucleus tractus spinalis n. trigemini.

*Formatio reticularis.

In the foregoing enumeration of the gray masses of the medulla oblongata, those marked with an asterisk have been described above; the remaining structures relate to the deep connections of the cranial nerves, and will be discussed in detail under that head.

Internal Structure of the Pons and Pars Dorsalis Pontis.—Trans-sections of the pons also pass through the tegmental part of the pons. To consider first the internal structure of the pons proper (or pars basilaris pontis): The pons is composed chiefly of (1) transverse fibres arranged in coarse bundles, (2) longitudinal fibres gathered in compact bundles, and (3) diffusely scattered masses of gray substance among the fibre bundles, the nuclei pontis.

The **transverse fibres**, corresponding to the large size of the cerebellum, are more abundant in man, relatively, than in any other animal. They form a massive series of bundles coursing ventrad of the brain axis from one cerebellar hemisphere

to the other. At the caudal border of the pons they embrace the pyramidal tracts as well, but farther cephalad the transverse pontile fibres are seen to intersect

FIG. 644.—Vertical transverse section of the pons, at its upper part.

the pyramidal tracts, breaking these up into pyramidal fasciculi; still farther cephalad the pyramidal tracts are wholly embedded in the mass of transverse

FIG. 645.—Transverse section of pons near its junction with mid-brain. (Higher level than Fig. 644.)

pontile fibres, so that these in turn, with reference to the location of the pyramidal tracts, may be divided into a superficial and a deep set. Laterad they are gathered together to form the middle peduncles (described on p. 892).

The **longitudinal fibres** consist chiefly of the pyramidal tracts, which are solid strands at their entrance to and exit from the pons, but are broken up into lesser bundles at its middle. A certain number of the pyramidal fibres, as well as other cerebropontile fibre tracts, terminate in relation with the cells of the nuclei pontis, as well as certain of the efferent cranial nerve nuclei. This fact accounts for the demonstrable diminution in bulk of the pyramidal tract in its course through the pons.

The **nuclei pontis** are small aggregations of gray substance (which in serial sections show them to be continuations of the arcuate nuclei) diffusely scattered among the fibre systems of the pons proper. They are intercalated in the course (1) of tracts passing from one cerebellar hemisphere to the other, and (2) of descending cerebropontile tracts. The cells of the pontile nuclei send their axones chiefly to the opposite cerebellar hemisphere and play an important part as links in the complex chain of the neurone systems which make the cerebellum such an important organ of sensomotor coördination.

In the contact zone of pons proper and the pontile tegmentum lies a group of transversely decussating fibres with interspersed gray masses with large cells called the **trapezium**. This body will be more fully described in connection with the central auditory paths.

The **tegmental part of the pons** is of much smaller bulk than the pons proper, as seen on trans-sections. On the dorsal surface is spread a layer of gray substance covered by ependyma, which forms the floor of the cephalic part of the fourth ventricle. Beneath this gray substance lies the **formatio reticularis** divided into symmetrical halves by the **raphé**—continued from the medulla oblongata. Embedded in the formatio reticularis are various isolated masses of gray substance and various more or less compact fibre tracts. Among the gray masses are several of the cranial nerve nuclei, to be described in a separate section, and the following:

The **superior olivary nucleus** (*nucleus olivarius superior*) is a small gray mass or aggregation of several smaller masses situated laterad of the trapezium, intercalated in the path of the trapezial fibres and forming a link in the central acoustic chain (Fig. 649).

The **nucleus incertus** (Streeter) is an aggregation of gray substance in the floor of the fourth ventricle near the median sulcus and forming a slight, rounded elevation which extends to the aqueduct. Its functional relations are unknown.

Fibre Tracts in the Pars Dorsalis Pontis.—Among the fibre tracts in the tegmental part of the pons the chief ones are (1) the **medial lemnisci**, (2) the **lateral lemnisci**, (3) the **medial longitudinal bundle**, and (4) the **superior peduncles of the cerebellum**.

Each **medial lemniscus**, or **medial fillet**, in its passage through the tegmental part of the pons is gathered into a compact, ribbon-like bundle along the contact zone of the tegmentum and pons proper, lateroventrad of the trapezium, some fibres of which traverse it on their way toward the **raphé**. The medial lemniscus has been described in the medulla oblongata as occupying the field between **raphé** and inferior olivary nucleus (the interolivary stratum); in its ascent the medial lemniscus gradually trends laterad, so that it almost reaches the surface (Figs. 639 and 645).

The **lateral lemniscus** is a constituent of the central auditory path, and will be described more fully on pages 883 and 901. In trans-sections above the level of the trigeminal nuclei the lateral lemniscus is seen as a flattened band spreading over the surface (externally the **trigonum lemnisci**) ectad of the superior peduncle. Its fibres are interrupted by an intercalated **nucleus of the lateral lemniscus**.

The **medial longitudinal bundle** (*posterior longitudinal bundle*) maintains its position just ventrad of the central gray, close to the **raphé**.

The **superior peduncle of the cerebellum** or **prepeduncle** is seen in trans-sections to be a very compact bundle of crescentic outline with the concavity turned

toward the ventricular cavity. Its dorsimesal edge is joined to the superior medullary velum; its ventral border is sunk into the tegmentum, and in its ascent it becomes submerged laterally beneath the lateral lemniscus, dorsally beneath the quadrigeminal plate of the mid-brain.

Summary of the Gray Masses in the Pars Dorsalis Pontis:

Nucleus of Abducent Nerve.

Nucleus of Facial Nerve.

Afferent and Efferent Nuclei of Trigeminal Nerve.

Nucleus of Spinal Root of Trigeminal Nerve.

Nuclei of Acoustic Nerve	{ Cochlear Division Vestibular Division	{ Dorsal Nucleus.
		{ Ventral Nucleus.
		{ Medial Nucleus.
		{ Lateral Nucleus.
		{ Superior Nucleus.

*Superior Olivary Nucleus.

Nucleus of Trapezium.

*Reticular Ganglionic Formation.

*Nucleus Incertus.

Nucleus of Lateral Lemniscus.

Those marked with an asterisk have already been described; the remaining structures relate to the deep connections of several cranial nerves to be described in the succeeding section.

Central Connections of the Cranial Nerves Attached to the Hind-brain.—

Eight of the twelve pairs of cranial nerves are attached to the hind-brain portion of the central axis. Their superficial or apparent origin and the cranial foramina of exit are enumerated in the table on page 852. In coördination with the internal descriptive anatomy of the hind-brain the central connections of these eight cranial nerves must now be considered. They comprise:

Purely efferent or motor nerves	{	XII. Hypoglossal nerve.	Motor to muscles of tongue.
		XI. Spinal accessory nerve.	(a) Motor accessory to vagus nerve;
			(b) Motor to Trapezius and Sternomastoid muscles.
		VII. Facial nerve (proper).	Motor to muscles of scalp and face.
		VI. Abducent nerve.	Motor to External rectus muscle of eyeball.
Mixed nerves	{	X. Vagus nerve.	Sensomotor to respiratory tract and upper part of alimentary tract.
		IX. Glossopharyngeal nerve.	Sensor to tongue (and motor?) to Stylopharyngeal muscle.
		V. Trigeminal nerve.	Sensor to face, tongue, teeth; motor to muscles of mastication.
Purely afferent or sensor nerve	{	VIII. Acoustic nerve.	(a) Cochlear division for hearing.
			(b) Vestibular division for equilibrium.

Another nerve which pursues a remarkably aberrant course, becoming associated with three of the above-mentioned cranial nerves, is the *nervus intermedius*, known peripherally as the *chorda tympani*. It is chiefly sensor (taste) in function, but also contains efferent fibres which are excitoglandular for the submaxillary and sublingual salivary glands.

In the hind-brain axis lie certain gray masses which are functionally homologous with the nuclear masses in the different parts of the spinal central gray.

These defined nests of nerve elements, from their relations to the cranial nerve roots, are called the **cranial nerve nidi** or **nuclei**. Their analogy to the origins of the spinal nerves extends to the shape and character of their cell elements and their differentiation into (a) **nuclei of origin** and (b) **nuclei of termination** or **recipient nuclei**.

The **nuclei of origin** or **motor nuclei** are cell clusters from which arise the axones of efferent nerves or the efferent components of the mixed nerves. Some of these nuclei are in line with the basal portion of the ventral gray horn in the cord below and are termed, owing to their situation near the mesal plane, the **medial nuclei of origin**. Other nuclei are isolated cell columns in the line of the **caput cornu ventrale** detached by the decussation of the pyramids, termed, from their position in the tegmental substance, the **lateral nuclei of origin**. The different nuclei of origin of the efferent cranial nerves are under the dominance of the cerebral cortex by way of the cortico-tegmental (or corticobulbar) path—usually included in the pyramidal tract.

The **nuclei of termination** or **sensor cranial nerve nidi** are likewise repetitions in structure of the dorsal horn of the spinal gray, but with less regularity and definiteness of position. Thus, while the *gelatinosa* Rolandi of the cord is continuous with the nucleus of the spinal root of the trigeminal nerve, other recipient or afferent nuclei are more or less isolated in the tegmental substance, while the two (lateral and ventral) nuclei of the cochlear nerve actually lie on the surface of the brain stem.

The afferent impulses carried in by the sensor cranial nerves excite impulses in the neurones of the nuclei of termination; their axones enter the tegmental substance as arcuate fibres, cross the mesal plane to join the lemnisci to connect with the thalamus and posterior quadrigeminal body and *via* thalamus and posterior quadrigeminal body with the cerebral

FIG. 646.—The cranial nerve nuclei schematically represented in a supposedly transparent brain stem, dorsal view. Motor nuclei in red; primary terminal nuclei of afferent (sensor) nerves in blue. (Optic and olfactory centres are omitted.)

cortex. The location of the various cranial nerve nuclei in the brain stem may be understood by a reference to the diagrams in Figs. 634, 646, 647, and 648.

Hypoglossal Nerve Nucleus.—The nucleus of origin of the hypoglossal nerve is a rod-like cell column close to the mesal plane, extending for about 7 mm. ($\frac{1}{4}$ inch) in the caudal portion of the fourth ventricle, while its extraventricular portion extends about 5 mm. ($\frac{1}{2}$ inch) caudad of the tip of the calamus. Its efferent axones course ventrad between the *formatio reticularis alba* and *grisea*, thence

between the olivary and medial accessory olivary nuclei, sometimes mesad of the latter, to emerge between pyramid and olive. None of the fibres decussate across the middle line, but the nuclei are coordinated by commissural fibres. Axones from cortical cells (ventral third of precentral gyre) terminate in relation with the cells of the hypoglossal nucleus.

The hypoglossal nucleus permits of subdivision into groups: (a) a medial and (b) a lateral sub-group. The lateral group innervates the Palatoglossus and Pharyngoglossus, while the medial nuclear group innervates the remainder of the tongue muscles (Lingualis transversus and inferior, Genioglossus and Hyoglossus).

The Spinal Accessory Nerve Nucleus.—The spinal accessory nerve is also a purely motor or efferent nerve whose axones arise from an attenuated nucleus, with large multipolar cells, in direct continuation with the nucleus ambiguus (of the

FIG. 647.—Nuclei of origin of the cranial motor nerves schematically represented in a supposedly transparent brain stem, lateral view.

ninth and tenth nerves) cephalad, and with the dorsolateral cell column of the ventral horn of the upper five or six segments of the cord. The **oblongatal portion** of the nucleus gives rise to the encephalic root of the accessory nerve and its axones join the vagus to innervate the laryngeal muscles. Hence it may also be termed the **nidus laryngei** (in contradistinction to the **nidus pharyngei** or **nucleus ambiguus**, whose axones join the vagus and glossopharyngeal nerves to be distributed to the pharynx). The ventrolateral division of this cell column is believed to be the cardioinhibitor centre. The axones from the **spinal nucleus** are distributed to the Trapezius and Sternomastoid muscles.

The nucleus of the spinal accessory nerve is likewise under the dominion of the cerebral cortex by way of the pyramidal tract, and a reflex arc is completed by afferent axones from the dorsal roots of the spinal nerves.

The **Vagus and Glossopharyngeal Nuclei** are usually considered in their aggregate, justified not only by their similarity in origin and central connections, but also by the uncertainty which prevails regarding their peripheral interlacement and complex terminations. Both nerves are in greater part afferent, but also contain efferent axones.

1. **Afferent Portions.**—The afferent axones of the vagus arise from the cells in the **jugular ganglion** and **ganglion nodosum** (ganglion of the trunk); the afferent axones of the glossopharyngeal arise from the cells in its **ganglion superius** and **ganglion petrosus**. The root fascicles of both nerves enter the medulla oblongata along its dorsolateral groove, and the axones then undergo bifurcation into ascending and descending rami, similar to those of the dorsal roots of the spinal nerves.

FIG. 648.—Primary terminal nuclei of the afferent (sensor) cranial nerves schematically represented in a supposedly transparent brain stem, lateral view. The optic and olfactory centres are omitted.

The ascending rami end in the **nucleus alae cinereae** (*nucleus vagi et glossopharyngei*); the descending rami collect to form a compact bundle called the **tractus solitarius** or **trineural fasciculus**,¹ and terminating in a gray cell column called the **nucleus of the solitary tract**²—a caudal prolongation of the nucleus alae cinereae. Both tract and nucleus become attenuated caudad, to disappear in the fourth cervical segment (relation with phrenic nerve nucleus), while cephalad it has been traced as far as the region of the locus caeruleus (relation with trigeminal nerve nuclei).

From the cells of the nucleus alae cinereae and nucleus tractus solitarii axones

¹ There are other "solitary" fasciculi in the nerve system, and the name "trineural fasciculus" aptly characterizes a tract which has for its object the mutual interchange of functions among the central nuclei of the accessory, vagus, and glossopharyngeal nerves.

² The nucleus of the solitary tract lies to the mesal side of the tract. Another nucleus has been described by Mellus, lying lateral of the tract.

pass across the raphé to the contralateral interolivary stratum to join the medial lemniscus, establishing connections with the thalamus and cortex; other axones join the tractus nucleocerebellaris.

2. **Efferent Portions.**—The efferent components of the vagus and glossopharyngeal nerves come from two sources—(a) the **dorsal efferent (vagal) nucleus** and (b) the **nucleus ambiguus**.

The **dorsal efferent nucleus** lies ventromesad of the principal nucleus alae cinereae and laterad of the hypoglossal nucleus. The axones from its cells pass obliquely ventrolaterad to enter the root fascicles of the vagus and to become distributed to the œsophagus, stomach, trachea, and bronchi. Whether the glossopharyngeal nerve receives efferent axones or not is still in debate.

The **nucleus ambiguus** (*nidus pharyngei*—so termed in contradistinction to the *nidus laryngei*) is a rod-like mass of large, multipolar cells seen, in trans-sections, lying in the gray, reticular formation midway between olive and fasciculus solitarius and apparently a cephalic continuation of the accessory nerve nucleus. The axones arising from its cells run dorsimesad at first, then turn abruptly ectad to join the vagus (and glossopharyngeal?) nerve-root fascicles, becoming distributed to the pharyngeal muscles, œsophagus, Cricothyroid, and the other Laryngeal muscles.

The Acoustic Nerve Nuclei.—The acoustic nerve consists of a cochlear and a vestibular division; the former is concerned with the sense of hearing, the latter with the sense of equilibrium.

1. The **cochlear or true auditory nerve** arises in the bipolar cells of the cochlear spiral ganglion; its axones terminate in (a) the **dorsal nucleus** (*tuberculum acusticum*), a pyriform mass on the dorsolateral aspect of the restiform body, and (b) the **ventral nucleus**, somewhat detached from the former.

From the dorsal nucleus cells arise the axones which compose the **striae acusticae**, myelinic fibre bundles traversing the ventricular surface to near the median sulcus, dipping into the tegmental substance, crossing to the opposite side in the raphé, and eventually joining the lateral lemniscus to end in the posterior quadrigeminal body and internal geniculate body.

From the ventral nucleus cells arise the axones which course transversely to form the trapezium at the contact zone of the pons proper and tegmentum. Additional axones from cells in the superior olives of both sides and in the trapezium itself increase the bulk of this tract; some of the primary axones end in relation with these cells. These axone groups form the contralateral **lemniscus lateralis**, which contains the intercalated **nucleus of the lateral lemniscus** as a relay station, to be continued to the posterior quadrigeminal and to the internal geniculate bodies and thence to the cortical auditory "centre" in the supertemporal gyre.

2. The **vestibular nerve** axones arise in the bipolar vestibular ganglion cells (G. of Scarpa), enter the brain stem, and bifurcate into ascending and descending rami, which terminate as follows: The ascending rami end in the **medial nucleus** (Schwalbe's); the descending rami end in the **spinal vestibular nucleus**, which extends down to the gracile and cuneate nuclear level; another group of axones ends in the **lateral nucleus** (*nucleus magnocellularis*) (Deiters'); while a fourth and last group ends in the **superior nucleus** (Bechterew's). From the cells of all these nuclei of termination axones proceed toward the cortex, dentate nucleus, and nucleus fastigii of the cerebellum, as part of the nucleocerebellar tract, to the nuclei of the abducent, trochlear, trigeminal, and oculomotor nerves by collaterals from axones in the medial longitudinal bundle, to the thalamus, and to the ventral horn nuclei of the spinal cord along the tractus vestibulospinalis. The far-reaching and complex connections of the vestibular nerve with the cerebellum and the centres for eye muscles and the spinal centres for bodily movements make this cranial nerve a most interesting subject for the active research now going on.

The Facial Nerve Nucleus.—The facial nerve proper is to be distinguished from its so-called **sensor root**, or *pars intermedia*, or *nervus intermedius*.

The axones of the **efferent facial nerve** arise from cells forming the **facial nucleus** in the ventrolateral region of the reticular formation, in line with the nucleus ambiguus or nidus pharyngei, a little over 4 mm. ($\frac{1}{8}$ inch) from the ventricular floor. These axones converge toward the ventricular floor to form a compact bundle which curves over the abducens nucleus from behind (caudad), overlying it like a horseshoe over a ball (*genu facialis internum*); not as a straight but as a bent horseshoe, bent so that its cephalic branch is directed more laterad than its caudal branch. After having encircled the abducens nucleus, the facial root passes ventrolaterad, passing its own nucleus ectad, and emerging in the *postpontile groove* (*recessus facialis*).¹

Pyramidal fibres from the precentral cortex place this nucleus under the influence of the will; it also receives fibres from the trigeminal and acoustic central systems.

The *nervus intermedius* is a mixed nerve, containing **afferent** (taste) fibres and **efferent** (excitoglandular or secretory) fibres. With respect to its afferent component it may be regarded as an aberrant portion of the glossopharyngeal nerve.

FIG. 649.—Terminal nuclei of the vestibular root of the auditory nerve, with their upper connections. (Schematic.) (Testut.)

1. **Afferent Portion.**—These axones arise from the cells of the **geniculate ganglion**, implanted upon the *genu facialis externum*, and terminate in a nuclear extension cephalad of the **nucleus tractus solitarii**. They probably convey gustatory sense impulses from the anterior two-thirds of the tongue and the pillars of the soft palate.

2. **Efferent Portion.**—A nucleus of origin for the excitoglandular elements has been described as a group of cells extending beneath the ventricular floor from the level of the facial nucleus to that of the motor trigeminal nerve, close to the *raphé*, and called the **nucleus salivatorius**.

Peripherally we shall study this nerve as the **chorda tympani**. The mixed nature of the *nervus intermedius* and of the geniculate ganglion makes it probable that they combine the elements of a sympathetic and a spinal ganglion; the nerve, at least, contains both vegetative and sensorial elements.

¹ The peculiar course of the deep root of the facial nerve has been shown by Streeter to be due to a wandering of the facial nucleus in the embryonic period.

The Abducent Nerve Nucleus.—The abducent nerve is a small motor nerve, supplying the External rectus muscle of the eyeball. Its nucleus of origin with large, multipolar cells, lies close to the median plane beneath the eminentia tere. The axones from these cells pass ventrad through the tegmentum and trapezium, and laterad of the pyramidal tract, to emerge in the postpontile groove. The nuclei are brought under the dominion of the cerebral cortex by pyramidal fibres of the opposite side. They are likewise brought into intimate relation with the trigeminal, acoustic, and opposite oculomotor nerve nuclei.

FIG. 650.—Terminal nuclei of the cochlear nerve, with their upper connections. (Schematic.) The vestibular root with its terminal nuclei and thin efferent fibres have been suppressed. On the other hand, in order not to obscure the trapezoid body, the efferent fibres of the terminal nuclei on the right side have been resected in a considerable portion of their extent. The trapezoid body, therefore, shows only one-half of its fibres—viz., those which come from the left. (Testut.)

The Trigeminal Nerve Nucleus.—The trigeminal is relatively enormous and has correspondingly extensive central connections, including nuclei in the mid-brain, pars dorsalis pontis and oblongata, and spinal cord. It is a mixed sensomotor nerve and the afferent and efferent divisions must be considered separately.

1. **Afferent Portion.**—The axones of the afferent or sensor root arise in the cells of the large **semilunar** (Gasserian) **ganglion**. As in the dorsal roots of the spinal nerves, these axones bifurcate, on entering the brain axis, into ascending and descending rami. These terminate in a cephalic nuclear extension of the gelatosi Rolandi of the cord; the ascending rami terminate in the so-called **sensor nucleus** of the trigeminus, the descending rami in the **nucleus of the spinal tract** of the trigeminus, which extends as far as the second cervical segment of the cord. The sensor nucleus, at the level of the entrance of the nerve, is quite massive, becoming attenuated cephalad. The spinal tract, in its descent, likewise decreases rapidly as it gives off its terminal axones to the nucleus of the tract. The cells of these terminal nuclei send out axones which cross the median plane, giving off collaterals to the facial nucleus, to join the medial lemniscus to reach the thalamus, and, *via* thalamus, the somesthetic cerebral cortex. Other axones are distributed (a) to the motor or efferent nucleus of the trigeminus and (b) to the motor or efferent cranial nerve nuclei.

2. **Efferent Portion.**—The efferent or motor component of the trigeminal nerve consists of axones arising from cells in two *nidi*: (a) the **principal nucleus** in the

dorsolateral part of the pontile tegmentum, dorsomesad of the sensor nucleus; (b) a small, slender, so-called **mesencephalic root nucleus** (*nucleus radialis ascendentes nervi trigemini*) extending cephalad of the region of the locus coeruleus to lie along the aqueduct in the mid-brain. The fibres from the principal nucleus supply the muscles of mastication. The distribution of the fibres from the mesencephalic root is not precisely known. Kölliker suggests that they may supply the Tensor veli palatini, Tensor tympani, Mylohyoid, and anterior belly of the Digastric.

Like other motor nuclei, these efferent divisions of the trigeminus are under the dominion of the cerebral cortex *via* pyramidal fibres.

The Cerebellum.—The cerebellum occupies the greater part of the posterior fossa or cerebellar part of the skull, and is the largest portion of the hind-brain. It is overlapped by the occipital poles of the cerebrum, being separated from these by the tentorium. It lies dorsad of the pons oblongata and partly embraces this portion of the brain stem. It is composed of a white central core with scattered gray masses and a surface layer of gray substance that is of darker hue than the cerebral cortex.

FIG. 651.—Upper surface of the cerebellum. (Schäfer.)

The cerebellum is convoluted on a plan entirely different from that of the cerebrum. Each primary fold is folded by secondary and these in turn by tertiary folds, so that on sagittal section a cypress-leaf appearance is noted, the *arbor vitae cerebelli*. The interior or medullary white substance follows all these branchings and sub-branchings, forming a skeleton of the minute folds which are called *folia*. These *folia* are demarcated on the surface by numerous curved and more or less parallel fissures of various depths.

The cerebellum is connected to the brain stem by three pairs of peduncles and by vestigial portions of the primitive dorsal wall of the brain tube. Among the latter the medullary vela or laminae are most important; they are the **superior medullary velum** (*valvula*), and the **inferior medullary velum** (*velum*) which enter into the formation of the "roof" of the fourth ventricle.

The rounded margin of the cerebellum demarcates two surfaces looking respectively "upward" and "downward," or cephalic and caudal surfaces. Both are convex, the inferior or caudal surface more so than the upper or cephalic. The inferior surface shows a deep median depression, the **vallecula**, into which the medulla oblongata is sunk. The ventral margin is widely notched to partly embrace the **brain stem** (tegmental part of the pons and corpora quadrigemina); a **dorsal notch** (*incisura cerebelli posterior*), which is smaller and narrower and

lodges the cerebellar falx. separates the hemispheres as these project beyond the inferior vermis.

The cerebellum is arbitrarily subdivided into a medial segment, the **vermis** or **worm**, from its annulated appearance, and two lateral portions, commonly called the cerebellar "**hemispheres**." The vermis may, according to the aspect in which it is viewed, be divided into the **superior vermis** or **prevermis** on the upper or cephalic surface, and the **inferior vermis** or **postvermis** on the inferior or caudal aspect. The superior vermis is hardly distinguished from the adjacent sloping surfaces of the hemispheres; occasionally a slight furrow exists on either side. Ordinarily the term is to be restricted to the high median elevation usually called the **monticulus cerebelli**. The inferior vermis is more distinctly bounded by a deep fissure, the **sulcus valliculae**, on each side, separating it from the corresponding lateral hemisphere.

Among the many fissures which traverse the surface of the cerebellum, one is particularly conspicuous as a deep cleft which may be traced along the dorso-lateral margin from the dorsal notch to the point of entrance of the cerebellar

FIG. 652.—Under surface of the cerebellum. (Schäfer.)

peduncles. This is the **peduncular sulcus** or **great horizontal sulcus** (*sulcus horizontalis cerebelli*), and it divides the cerebellum into a cephalic or upper and caudal or lower part. The sulcus is usually quite deep in the hemispherical portion, but it frequently fails to traverse the vermis. Other deep fissures demarcate the lobes or major subdivisions of the intricately convoluted surface of the cerebellum. Conventionally the lobes and fissures or sulci are described upon the "upper" and "lower" surfaces respectively, and this mode of description is partially adhered to here. A better idea of the topographical relations of the lobes and sulci in the vermis and the hemispheres may be gained from a study of the divisions of the cerebellum as if extended in one plane as well as on sagittal sections through the mesal and lateral planes.

Lobes and Fissures of the Cerebellum.—The surface of the cerebellum is traversed by eight more or less curved and deep fissures demarcating nine lobar subdivisions. Distinctive names are given to the portions of each lobe in the hemispheres as contrasted with that in the vermis, although often without warrant, as the two are quite continuous and merit no such distinction. This burdensome nomenclature seems so firmly rooted in descriptive anatomy that the various terms must be

repeated here. The arrangement of the fissures and lobes will be understood by reference to the following schema, in which structures are named from "before backward," or cephalocaudad:

	VERMIS.	HEMISPHERE.
	Lingula.	Vincula lingualae.
Superior vermis.	← Precentral Fissure. →	
	Lobulus centralis.	Ala lobuli centralis.
	← Postcentral Fissure. →	
	Culmen monticuli.	Anterior crescentic lobe. ¹
	← Preclival Fissure. →	
	Clivus monticuli.	Posterior crescentic lobe.
Inferior vermis.	← Postclival Fissure. →	
	Folium cacuminis.	Superior semilunar lobe.
	← Peduncular Fissure. →	
	Tuber vermis.	{ Inferior semilunar lobe. ← Postgracile fissure. → } Postero-inferior lobule. Gracile lobe.
	← Postpyramidal Fissure. →	
	Pyramis.	Biventral lobe.
	← Prepyramidal Fissure. →	
	Uvula.	Tonsilla (Amygdala).
	← Postnodular Fissure. →	
	Nodus.	Flocculus.

The **lingula** (*lingula cerebelli*) is a tongue-shaped process of the vermis lying in the ventral cerebellar notch, ventrad of the central lobe, and is partially or completely concealed by it. It consists of five, six, or seven lamellæ lying upon and connected with the dorsum of the *valvula*. At either side the lingula gradually shades off, being prolonged only for a short distance toward the region of the peduncles as the **vincula lingualae**.

The **central lobe** (*lobulus centralis*) is a small median mass situated in the ventral notch, dorsad of and overlapping the lingula. Its lateral, wing-like prolongation is called the **ala lobuli centralis**.

The **culminal lobe** is much larger than the two lobes just described, and constitutes, with the succeeding lobe (the clival lobe), the bulk of the superior vermis and "upper" surface of the cerebellum. It partly overlaps the central lobe. Its lateral extensions are also termed the **anterior crescentic lobes**.

The **clival lobe** is of considerable size, separated from the culminal lobe by the preclival fissure and from the cacuminal lobe by the postclival fissure. Its lateral extensions are also termed the **posterior crescentic lobes**.

The anterior and posterior crescentic lobes of either side have been described by some writers as the **pars anterior** and **pars posterior** of the **quadrate lobe** or **lobulus quadrangularis**.

The **cacuminal lobe** (*folium vermis; superior semilunar lobe*) is a short, narrow band at the dorsal margin of the vermis, which expands in either hemisphere into a lobe of considerable size, of semilunar shape, and bounded caudad by the peduncular fissure.

¹ The anterior and posterior crescentic lobes are often called the **pars anterior** and **pars posterior**, respectively, of the "lobulus quadrangularis."

The **tuberal lobe** is of small size in the region of the inferior vermis, but laterally spreads out into the large **inferior semilunar** (*lobulus semilunaris inferior*) and **gracile lobes** demarcated by the intervening postgracile fissure. These lobes comprise at least two-thirds of the "inferior" surface of the cerebellar hemispheres.

FIG. 653.—Diagram showing fissures on under surface of the cerebellum. F. Flocculus. N. Nodule. U. Uvula. Py. Pyramid. Am. Amygdala or Tonsilla. Bivent. Biventral lobe.

The **gracile lobe** is often divided by an intragracile fissure into pre- and post-gracile lobes.

The **pyramidal lobe** is a conical projection, forming the largest prominence of the inferior vermis. It is continued laterad into the hemisphere as the **biventral lobe** (*lobulus biventer*); the demarcation between the latter and the pyramis proper is accentuated by the deep sulcus valliculæ.

FIG. 654.—Sagittal section of the cerebellum, near the junction of the vermis with the hemisphere. (Schäfer.)

The **uvular lobe** (*uvula vermis*) occupies a considerable portion of the inferior vermis as the **uvula**, while its lateral extension in either hemisphere, the **amygdala** or **tonsilla** (*amygdaline nucleus*; *tonsilla cerebelli*), is a rounded mass lying in a deep fossa between the uvula and biventral lobe. (This fossa was termed by the

older anatomists the *nidus avis* or "bird's nest" [Reil and Vicq d'Azyr].) The junction of uvula and tonsilla is an attenuated isthmus marked by a few shallow furrows and termed the **furrowed band**.

The **nodular lobe** comprises the **nodulus** (*nodulus vermis*) (in the inferior vermis) and the **flocculus** (*flocculi secundarii*) of each side, connected by a delicate lamina of white substance, the **velum medullare posterius**. Each flocculus lies adjacent to the ventrolateral surface of the peduncular mass, extending into the ventral extremity of the peduncular fissure. The flocculi of the two sides are connected with each other by a band of white substance, termed the **posterior medullary velum** in its medial portion, while its lateral expansions toward the flocculi are termed the **peduncles of the flocculi**.

FIG. 655.—Diagram showing the origin and course of the fibres of the peduncles of the cerebellum. (Edinger.)

The Internal Structure of the Cerebellum.—In any section of the cerebellum we may recognize the interior white substance, **corpus medullare** (*medullary body*), and the peripheral gray cortex. The white substance in each lateral hemisphere is more bulky than in the median vermis, while the cortex is of more uniform thickness throughout. In a sagittal section in the mesal plane the central white core is seen to divide into two main branches—**anterior ramus** or **preramus** and **posterior ramus** or **postramus**; these main branches divide and subdivide into a series of

medullary laminae surmounted by the foliated cortex, and presenting the characteristic appearance known as the *arbor vitae cerebelli*.

Isolated Gray Masses or Nuclei of the Cerebellum.—Embedded in the white matter of the cerebellum are several gray masses. They are four in number on each side:

1. *Dentate nucleus* or *dentatum*.
2. *Nucleus emboliformis* or *embolus*.
3. *Nucleus globosus* or *globulus*.
4. *Nucleus fastigii* or *fastigiatum*.

The **nucleus dentatus** is the largest and best studied of the cerebellar nuclei. It is located in the mesal part of the corresponding cerebellar hemisphere, in the direct prolongation of the superior peduncle of the cerebellum, which appears to enter it. It consists of a folded lamina of gray substance convoluted like the similar nucleus of the olive, and opens cephalomesad where its **hilum** (*hilus nuclei dentati*) permits of the entrance and exit of fibres from various sources.

Fig. 656.—The peduncles of the cerebellum. On the left the three peduncles have been cut at their entrance into the cerebellum; on the right side they are shown penetrating the cerebellar hemisphere. (Poirier and Charpy.)

The **nucleus emboliformis** is a small mass of gray substance, elongated cephalocaudad, and placed entad of the dentate nucleus, partly covering its hilum.

The **nucleus globosus** consists of several small round or oval masses connected with each other and lying entad of the preceding.

The **nucleus fastigii** (nucleus of the "roof") is second in size to the dentate nucleus, situated close to the mesal plane directly dorsad of the fourth ventricle, or in the fastigium of the cerebellum, and within the inferior vermis. The nuclei of opposite sides approach each other so nearly as almost to fuse.

The Cerebellar Peduncles.—Three pairs of peduncles constitute the chief avenues for the entrance and emergence of the fibres composing the white substance of the cerebellum and connecting adjacent parts of the brain stem therewith. The peduncles are, on each side, the **superior**, **middle**, and **inferior peduncles**.

The **inferior peduncle** (*postpedunculus*; *corpus restiforme*) is the continuation of the restiform body of the medulla oblongata. It contains both afferent and efferent fibres, connecting the cerebellar cortex with structures situated caudad: (1) The **dorsal or direct spinocerebellar tract**, composed of axones arising in Clarke's column (spinal cord) and terminating in the cortex of the superior vermis on both sides of the median line, but chiefly on the opposite side. (2) The **olivocerebellar tract**, composed of axones arising in the (inferior) olivary nuclei—principally from the contralateral or opposite olive, and terminating in the cortex of the superior vermis and adjacent hemispherical portions, as well as in the dentate nucleus. (3) **External arcuate fibres** from the homolateral and contralateral nuclei of the gracile and cuneate funiculi. (4) The **nucleocerebellar tract**, composed of axones from the recipient nuclei of certain cranial nerves (*vestibular, trigeminal*). (5) The **cerebellospinal (descending) tract**, terminating in relation with the ventral horn cells at various levels of the spinal cord.

The **middle peduncles** (*medipedunculi*; *brachia pontis*) are the largest of the three pairs. They consist of a mass of curved fibres comprising the pons and entering either cerebellar hemisphere between the parted lips of the ventral end of the peduncular fissure, just ectad of the inferior peduncle. Each peduncle contains axones coursing in opposite directions and in large part may be considered as purely commissural fibres.

FIG. 657.—Semidiagram of the three cerebellar peduncles. (Testut.)

Some of the axones terminate, however, in the nuclei pontis to convey impulses to the cells therein; these in turn send their axones (*tractus pontocerebellares*) into the opposite middle peduncle, and therefore constitute interrupted commissural systems. A few fibre systems in the middle peduncles establish relations with certain other structures in the brain stem, notably the nuclei of the oculomotor, trochlear, and abducent cranial nerves.

The **superior peduncles** (*prepedunculi*; *brachia conjunctiva*) emerge cephalad from the cerebellum entad of the middle peduncles. As they extend cephalad they converge to form the lateral boundaries of the fourth ventricle and partly roof it in. On trans-section they appear of oval outline, somewhat concave toward the cavity of the ventricle. The **superior medullary velum** or **valvula**, a thin lamina of white substance, spans the interval between the converging superior peduncles, and thus completes the roofing-in of the cephalic portion of the fourth ventricle.

The superior peduncles consist almost wholly of axones arising from the cells of the dentate nucleus, the ectal part of the nucleus fastigii of the same side, and mesal part of the nucleus fastigii of the opposite side. In their course, converging cephalad, these bundles pass into the tegmentum of the mid-brain ventrad of the inferior corpora quadrigemina, and decussate almost wholly. The fibres of each peduncle terminate in the **red nucleus** of the opposite side, although a few continue to enter the thalamus.

This system of fibres is also called the **tractus cerebellotegmentalis**, and axones of inverse functional direction have been included therein.

The **ventral spinocerebellar tract** (*Gowers' tract*) is in relation with the superior peduncle and superior medullary velum. Unlike the dorsal or direct spinocere-

bellar tract, it does not enter the cerebellum along the inferior peduncle. Its fibres pass farther cephalad, through the reticular formation of the pars dorsalis pontis and medulla oblongata, to become reflected dorsocaudad at the level of the isthmus of the hind-brain, and entering the superior medullary velum, proceed with the superior peduncle into the cerebellum.

The **medullary vela** are two thin, relatively undeveloped laminae of white substance, representatives of the mid-dorsal wall of the brain tube adjacent to the cerebellar proton, and in the adult brain appear as prolongations of the white central core of the cerebellum. They are the **anterior or superior medullary velum** (*valvula*; or *valve of Vieussens*) and the **posterior or inferior medullary velum** (*velum*).

The **superior medullary velum** is a thin lamina of white substance spanning the interval between the converging superior peduncles, and with these assisting in the formation of the "roof" of the fourth ventricle. Caudad it is continuous with the white substance of the cerebellum, while on its dorsal surface lie the five to seven folia of the lingula. Cephalad it narrows as the corpora quadrigemina are approached, and a slight median ridge, the **frenulum**, descends upon the dorsal surface of its apical portion from between the posterior quadrigemina; on either side of the frenulum may be seen the superficial origin of the trochlear nerve. The majority of the fibres in the superior medullary velum are longitudinal; as already described (p. 842), the ventral spinocerebellar (Gowers') tract reaches the cerebellum along the superior medullary velum.

The **inferior medullary velum** is a still thinner lamina of white substance which bears the same relations to the nodulus that the superior medullary velum presents to the lingula. Laterad it extends to the flocculus of either side. The inferior medullary velum ends in a free crescentic edge and its ependymal and pial coverings continue as a fused, delicate membrane, the *tela choroidea ventriculi quarti*.

The superior and inferior medullary vela enter the cerebellum at an acute angle, forming the peaked roof (*fastigium*), while the tent-like recess is called the *recessus tecti*.

The Fibres Proper of the Cerebellum.—The *fibræ propriae* of the cerebellum are of two kinds: (1) **commissural fibres**, which cross the middle line to connect the opposite halves of the cerebellum, some at the anterior part and others at the posterior part of the vermis; (2) **association fibres**, which are homolateral fibres connecting adjacent laminae with each other.

Microscopic Appearance of the Cerebellar Cortex.—The cerebellar cortex, on section, presents two marked layers—an outer, of a pale gray color, the **molecular layer**, and an inner, of a rusty-brown tint, the **granular layer**. At the contact line of these two layers, but more within the molecular than the granular, are found the characteristic nerve elements of the cerebellum, the **flask-shaped Purkinjean nerve cells**.

The **molecular or ectal layer** consists of cells and delicate fibrillae embedded in a neuroglial network. The cells are small and are characterized by the course of their branching axones which run parallel with the surface of the folium, give off numerous collaterals which pass in a vertical direction toward the cell bodies of the Purkinjean elements and embrace these in a basket-like network. Hence these cells are called **basket cells** (Fig. 658).

The **Purkinjean cells** are flask-shaped, and form a stratum at the junction of the molecular and granular layers, their bases directed toward the latter. Each cell gives off an axone entad, while ectad it gives off numerous dichotomously branching dendrites covering a very large field of the molecular layer. The axone, after giving off several collaterals which pass toward different parts of the granular layer, becomes myelinic not far from the cell body and passes into the white

substance to establish connections with other folia within the cerebellum or with more distinct brain structures.

The **granular** or **ental layer** is characterized by containing numerous small nerve cells or granules of a reddish-brown color, together with many nerve fibrils. Most of the cells are nearly spherical and provided with short dendrites, which spread out in a spider-like manner in the granular layer. Their axones pass outward into the molecular layer, and, bifurcating at right angles, run horizontally for some distance. In the outer part of the granular layer are also to be observed some larger cells, of the type termed **Golgi cells** (Fig. 658). Their axones undergo frequent division as soon as they leave the nerve cells, and pass into the granular layer, while their dendrites ramify chiefly in the molecular layer.

FIG. 658.—Trans-section of a cerebellar folium. (Diagrammatic after Cajal and Kölliker.)

Finally, in the gray substance of the cerebellar cortex fibres are to be seen which come from the white centre and penetrate the cortex. The cell origin of these fibres is unknown, though it is believed that it is probably in the gray substance of the spinal cord. Some of these fibres end in the granular layer, by dividing into numerous branches, on which are to be seen peculiar moss-like appendages; hence they have been termed by Ramón y Cajal the **moss fibres** (Fig. 658); they form

an arborescence around the cells of the granular layer. Other fibres derived from the medullary centre can be traced into the molecular layer, where their branches cling around the dendrites of Purkinje's cells, and hence they have been named the **clinging** or **tendril fibres** (Fig. 658).

The cerebellum is an important sensomotor organ, transmuting sensor impressions into motor impulses under the dominance of the cerebral centres. Its connections with other brain portions and the spinal cord are established by the peduncular fibres. It is essentially an apparatus for the coördination of movements and the space-sense perceptions or orientation of the body and its parts in space. These functions depend principally upon the reception of sensor impulses from (1) the vestibular nerve (from the semicircular canals) and (2) the spinocerebellar (ascending) tracts conveying sensor impulses from the skin, muscles and joints. Motor impulses pass along (1) the cerebellospinal (descending) tracts to the ventral horn nuclei of the cervical cord; (2) the tractus rubrospinalis, which arises in the red nucleus—an intercalated ganglionic mass connected with the cerebellar cortex by the superior peduncles, or tractus cerebello-tegmentalis. The tractus rubrospinalis is a tract for voluntary motor impulses next in importance to the pyramidal tract.

Weight of the Cerebellum.—Its average weight in the male is 165 grams (5.8 ounces avoirdupois) and 155 grams (5.4 ounces avoirdupois) in the female. It attains its maximum between the twenty-fifth and thirty-fifth years, its increase in weight after the fourteenth year being relatively greater in the female than in the male. The proportion between the cerebellum and the cerebrum is as 1 to 7.5; among eminent men it is 1 to 8.5. In the newborn the ratio is as 1 to 20.

The Mid-brain (Mesencephalon).

The mid-brain is the short and constricted portion of the brain which lies in the opening of the tentorium cerebelli (*incisura tentorii*) and which connects the pons with the inter-brain and hemispheres, and hence it is frequently called the **isthmus cerebri**. It is developed from the second brain vesicle, the cavity of which becomes the aqueduct. It comprises the **crura cerebri**, the **corpora quadrigemina**, the **internal geniculate bodies**, and the **aqueduct**. Its two surfaces are ventral and dorsal. They are free, but concealed; the ventral surface by the apices of the temporal lobes which overlap it; the dorsal, by the overhanging cerebral hemispheres. The *ventral surface*, when exposed by drawing aside the temporal lobes, is seen to consist of two cylindrical bundles of white substance, which emerge from the pons and diverge as they pass forward and outward, to enter the inner and under part of either hemisphere. They are the **crura cerebri**, and between them is a triangular area, the **intercrural space**;¹ near the point of divergence of the crura cerebri the roots of the third nerve are seen to emerge in several bundles from a groove, the **sulcus oculomotorius** (*sulcus nervi oculomotorii*) (Fig. 619). The *dorsal surface* is not visible until a considerable portion of the cerebral hemispheres and other overlying structures have been removed. It then presents four rounded eminences placed in pairs, two cephalad and two caudad, and separated from one another by a crucial depression. These are termed the **corpora quadrigemina** (*tubercula quadrigemina*) (Fig. 659). The ventral and dorsal surfaces meet on the side of the mid-brain, and are separated from each other by a furrow, the **lateral groove** (*sulcus lateralis mesencephali*), which runs caudocephalad (Fig. 659).

External Morphology. Dorsal Surface.—The corpora quadrigemina are four rounded eminences placed in pairs separated by a shallow median groove and a

¹ Also called interpeduncular space, or posterior perforated space.

more sharply cut transverse furrow. The cephalic pair, the **superior quadrigeminal bodies** (*pregemina; superior colliculi*; the *nates* of older authors), are the larger, and the pineal body rests in the flattened depression between them. The superior quadrigeminal bodies are oval, their long diameter being directed, *cephalolaterad*, and are of a yellowish-gray color. The **inferior quadrigeminal bodies** (*postgemina; colliculi inferiores*; the *testes* of older authors) are hemispherical in form and lighter in color than the preceding. The lamina quadrigemina, comprising the whole of the dorsal wall of the mid-brain, extends from the root region (posterior commissure) of the pineal body to the cephalic end of the superior medullary velum.

FIG. 659.—The brain stem, showing medulla oblongata, pons, mid-brain, and part of the optic thalami.

Each superior and inferior quadrigeminal body is continued lateroventrad in prominent white bands, the *brachia*. The band from the superior quadrigeminal body is termed the **superior brachium** or **prebrachium**; that from the inferior quadrigeminal body is called the **inferior brachium** or **postbrachium**.

The **superior brachium** or **prebrachium** (*brachium quadrigeminum superius*) proceeds cephaloventrad between the overhanging pulvinar and a light-gray eminence, the internal geniculate body. In reality it is a continuation of a part of the optic tract. The **inferior brachium** or **postbrachium** (*brachium quadrigeminum inferius*) proceeds in a similar direction to disappear beneath the internal geniculate body.

Of the two geniculate bodies, on either side, the external geniculate body belongs rather to the thalamus (p. 906), while the internal geniculate body may properly be considered here among the structures of the mid-brain.

The **internal geniculate body** or **postgeniculum** (*corpus geniculatum mediale s. internale*) is a small oval eminence of the lateral surface of the mid-brain in which the mesal root of the optic tract appears to terminate. The inferior

brachium likewise appears to run into this body; as a matter of fact, so far as is known, the internal geniculate body is (1) a way-station for auditory impulses in their course toward the cerebrum; (2) the origin and terminus for the **arched commissure of Gudden** (*infracommissure; commissura inferior [Guddeni]*), by means of which circuitous path, through the optic chiasm, and along the mesal root of the optic tract, the internal geniculate bodies of the two sides are connected.

The **quadrigenal lamina** is continuous caudad with the superior peduncles of the cerebellum and the intervening superior medullary velum. A slight, median ridge-like projection, the **frenulum valvulae**, descends from between the inferior quadrigenal bodies onto the superior medullary velum; on either side of the frenulum emerge the slender trochlear nerves.

The **crura cerebri** constitute the bulk of this portion of the brain stem. Upon the ventral aspect of the brain they appear as two large, white, rope-like strands emerging from the pons and diverging to either cerebral hemisphere, becoming embraced by the optic tracts. Each crus is composed of a **dorsal tegmental part**—a continuation of the tegmentum of the hind-brain—and a ventral **crusta** or **pes**. These parts are demarcated from each other on the external surface by the **oculomotor sulcus** ventrad (which looks into the intercrural space) and the **sulcus lateralis mesencephali** on the lateral aspect. The lateral surface shows dorsally the superior cerebellar peduncle dipping into the substance of the mid-brain, while between it and the **crusta** is a small triangular field of oblique fibre strands, not always well defined, called the **trigonum lemnisci** because the lateral lemniscus tends to reach the surface of the brain stem at this situation (Fig. 659).

The surface of the **crura cerebri** shows a rope-like twist in the course of its fibre bundles. Oblique or transverse fasciculi are sometimes seen upon the surface, two of which are fairly constant. They are (1) the **taenia pontis**, and (2) **Gudden's tractus peduncularis transversus** (*cimbria*).

The **taenia pontis**, as Horsley has shown, takes origin contralaterally in the gray substance continuous with the "interpeduncular ganglion," but ventral to it. The taenia then passes over the lateral lemniscus and superior cerebellar peduncle to the dentate nucleus and nucleus fastigii.

The **tractus peduncularis transversus**, or *cimbria*,¹ may be traced from the superior quadrigenal body and internal geniculate body over the surface of the crus cerebri to near the ventromeson, disappearing from view in the oculomotor sulcus.

Internal Structures of the Mid-brain.—If a cross-section be made through the mesencephalon it will be seen that each lateral half is divided into two unequal portions by a lamina of deeply pigmented gray substance, named the **substantia nigra** (*intercalatum; ganglion of Soemmering*). The postero-superior portion of the crus is named the **tegmentum**, and the antero-inferior the **crusta** or **pes**. The substantia nigra is curved on section with its concavity upward, and extends from the lateral groove externally to the oculomotor sulcus internally. The two crustæ are in contact in front of the pons, from which point they diverge from each other, but the two halves of the tegmentum are joined to each other in the mesal plane by a forward prolongation of the raphé or median septum of the pons. Laterally the tegmenta are free, but dorsally they blend with the corpora quadrigena.

Traversing the mid-brain in the median plane and nearer the dorsal surface is the **aqueduct**, surrounded by the central tubular gray, which in this brain segment has retained the comparatively primitive arrangement of the embryonic brain tube.

The Aqueduct (mesocoele) and Central Aqueduct Gray.—The aqueduct is a narrow canal connecting the third with the fourth ventricle, and demarcating the

¹ In architecture, a band or fillet about a column. Also called *fasciculus arciformis pedis*.

lamina quadrigemina dorsad from the tegmental zone. Its shape on trans-section varies at different levels, being T-shaped caudad, oval or quadrangular along its middle, and triangular cephalad. It is lined by the ependyma (columnar ciliated epithelium) and surrounded by the central aqueduct gray. The **central gray** is separated dorsally from the corpora quadrigemina by the **stratum lemnisci**;

FIG. 660.—Trans-section of the mid-brain through the level of the superior quadrigeminal body.

ventrad near the median plane lie the medial longitudinal bundles. Within the gray substance lie certain well-defined cell clusters, the nuclei of origin of the oculomotor and trochlear nerves and the mesencephalic root of the trigeminal nerve. These will be described in detail later.

The **substantia nigra** or **intercalatum** is a crescentic layer of deeply pigmented gray substance interpolated between the crusta and the tegmentum. Mesad it nearly touches its fellow of the opposite side, being separated by the rudimentary

FIG. 661.—Trans-section of the mid-brain through the level of the inferior quadrigeminal body.

ganglionic gray (the *posterior perforated substance* or *postperforatum*) in the intercrural space. Its ventral face sends numerous ramifying prolongations among the fasciculi of the crusta. It extends from the cephalic border of the pons to the subthalamic region, while its lateral edge reaches the surface along the lateral sulcus. Its cells are medium-sized, multipolar, their bodies approaching the

fusiform or angular in outline. The cells are characterized by a pigment (marked only in man) which varies from a pale brown in the young to an absolute blackness in the very aged. The axones arising from the cells proceed in various directions toward the tegmentum and crusta, but their exact course is not known. Experimental excitation of this ganglionic mass elicits movements of deglutition accompanied by respiratory changes. Mellus has found in the monkey that a portion of the pyramidal tracts is interrupted in the substantia nigra.

The **corpora quadrigemina** are largely composed of gray substance, but the superior and inferior corpora quadrigemina differ distinctly in structure.

The superior corpora quadrigemina or **pregemina** present a true cortical type, which is more evident in the optic lobes of lower vertebrates. In man the thin, outermost white layer—the **stratum zonale**—is an expansion of the optic tract. Beneath this lies a gray nucleus, with numerous small cells—the **stratum cinereum**—a cup-like layer of crescentic outline on trans-section. The succeeding ental layer is a white stratum, also derived from the optic tract—the **stratum opticum**. Between this and the underlying stratum lemnisci is a second gray layer, less defined because of the diffuse interlacing of white fibres.

Each superior quadrigeminal body is one of a series of primary centres of vision related more to eye-muscle reflexes resulting from optic and auditory stimuli than to actual light and color perception. Fibres from the retina, for the most part, form the stratum zonale and end in the ganglionic gray; others enter into the formation of the **stratum opticum**. Return fibres from the occipital cortex also enter the stratum opticum. The retinal and occipital fibres determine the formation of the superior brachium. Other fibres reach the superior quadrigeminal body through the lateral and medial lemnisci—from both sides—to end in relation with the deeper cells of the stratum cinereum. The connections of the superior quadrigeminal body with the cochlear centres afforded by the lateral lemniscus establishes the so-called **optic-acoustic reflex path**.

The inferior corpora quadrigemina or **postgemina** are more homogeneous in texture, comprising a pair of compact ganglia which on trans-section have the shape of biconvex lenses, encapsulated by white substance. The cells are small, multipolar, and very numerous, embedded in a fine molecular groundwork. The white **stratum zonale** is principally derived from the fibres of the lateral lemniscus, which terminate in the central gray of the inferior quadrigeminal body as well as in the internal geniculate body. The axones of the cells in the inferior quadrigeminal body course cephalad in the inferior brachium, dip beneath the internal geniculate body into the tegmentum, and proceed to the thalamus. The inferior quadrigeminal bodies are important links in the chain of the auditory neurone system, and are special localities for the reflexion of auditory impulses.

The **tegmentum** of the mid-brain is continuous with the like formations in the hind-brain stem and consists of longitudinal fibre bundles intersected by transverse arched fibre systems with gray substance irregularly scattered in the interstices, composing the **formatio reticularis**. In its ventral portion, on either side, and at the level of the superior quadrigeminal body, lies a gray ganglionic mass, the **red nucleus**.

The **red nucleus** or **rubrum** (*nucleus tegmenti*; *nucleus ruber*), so termed from its reddish tinge in the fresh brain, which it owes to the pigmentation of its cells as well as to its great vascularity, is found subjacent to the superior quadrigeminal body in those section-levels where the substantia nigra has its greatest expansion. In trans-sections its outline is irregularly circular; in sagittal sections an elongated oval. The red nucleus is the end station for the majority of the decussated fibres of the superior peduncles of the cerebellum, for fibres from the cerebral cortex, and from the corpus striatum. These fibre bundles form for the nucleus a capsule which is thicker on its ectal surface. From the cells of each of the

nuclei arise axones which pass (1) to the thalamus and cerebral cortex (links in the cerebello-cortical neurone-chain), and (2) axones which descend into the spinal cord to form the **tractus rubrospinalis** (Monakow's)—a continuation of an indirect motor path from the cerebral cortex to the peripheral motor nerve. The tracts arising from the red nuclei of the two sides decussate with each other and descend in the tegmentum.

FIG. 662.—The medial longitudinal bundle. (The nuclei may be identified by comparison with Fig. 646.)

In the intercrural space lies a primitive gray ganglionic mass, the **posterior perforated substance** or **postperforatum**. In this posterior perforated substance, cephalad of the pons and in the median line, lies a cluster of cells, the **interpeduncular nucleus** (Gudden). The **fasciculus retroflexus** (Meynert), whose fibres arise in the habenal ganglion, descends to end in the interpeduncular ganglion.

The principal longitudinal fibre tracts in the tegmentum of the mid-brain are (1) the **medial longitudinal fasciculus**, (2) the **lateral lemniscus**, (3) the **medial lemniscus**,

(4) the decussating superior cerebellar peduncles, (5) the decussating rubrospinal tracts, and (6) the central tegmental tracts.

The **medial longitudinal bundle** lies on each side of the median plane, just ventrad of the central aqueduct gray in the mid-brain and continuous throughout the brain stem in its formatio reticularis. It is the continuation and the equivalent, but in a more differentiated form, of the ventral basis bundle of the spinal cord. It is formed by association neurones and acts as an associating agent with regard to many cranial and spinal nerve centres for the performance of certain definite functions. Its neurones receive impulses from afferent elements and transmit them to motor or efferent elements. It particularly brings into relation the sensor cranial nerve nuclei and the corpora quadrigemina with the motor nerves of the eye (III, IV, and VI), of the face (VII), and of the trunk. A special nucleus for the bundle is described as being situated in the gray floor of the third ventricle, at its junction with the aqueduct. The axones from the cells of this nucleus cross to the opposite side through the posterior commissure (Fig. 662).

The **lateral lemniscus**, we have learned, is a continuation of the auditory path in its course to the cerebral cortex. Its formation is described on page 883. In the mid-brain the fibres of the lateral lemniscus course through the lateral part of the tegmentum, near the surface, and most of them end in the gray nucleus of the inferior corpora quadrigemina and in the internal geniculate body. A few fibres are carried into the superior quadrigeminal body.

The **medial lemniscus**, or principal conduction path for sensor impulses from the trunk and extremities, and already discussed in the preceding (p. 878), ascends in the tegmentum of the mid-brain in the contact zone with the crista. In its ascent it is deflected slightly dorsolaterad by the red nucleus. The lateral border of the ribbon-like bundle is in contact with the lateral lemniscus, and forms an angle with it, as seen on trans-section (Figs. 660 and 661).

Many of the fibres of the medial lemniscus terminate in the superior quadrigeminal body; the remainder proceed to the thalamus.

The **superior peduncles** or **prepeduncles of the cerebellum** sink into the mid-brain tegmentum in a cephaloventral direction, the two superior peduncles converging and their fibres undergoing a complete decussation (*Wernicke's commissure*) subjacent to the inferior quadrigeminal body. The crossed fibres end, for the most part, in the red nucleus of each side; others circumvent the nucleus, forming a white capsule for it which is thicker on its ental surface, and proceed to the thalamus.

The **tractus rubrospinalis** (Monakow's) is composed of axones arising in the red nucleus, decussating with those of the opposite tract, and descending in the tegmentum to the lateral intermedial fasciculus of the cord, to terminate in relation with ventral-horn cells.

The **central tegmental tract** (*olivary fasciculus*) probably arises in the inferior olivary nucleus and ascends in the tegmentum. In the pars dorsalis pontis it is best seen in trans-sections as a compact longitudinal bundle along the dorsomesal aspect of the superior olive. Cephalad it is said to end in the lenticular nucleus.

Fountain Decussation.¹—A dense decussation may be found in the space between the two red nuclei. The fibres composing the decussating bundles arise from cells in the superior corpora quadrigemina and central aqueduct gray. After having crossed the middle line they descend as the **tectospinal tract**, join the medial longitudinal fasciculus, and give off collaterals to, or terminate in the nuclei of, the eye muscle nerves, as well as to spinal centres for movements of the head and neck.

¹ *Decussatio fontinalis*, so called because of the resemblance of the scattering strands to the jets of a fountain.

The **crusta** or **pes** is somewhat crescentic in outline on section and is composed of longitudinal fibre bundles—the continuation of the internal capsule—divisible into three sectors. The middle sector comprises three-fifths of the cross-section area of the crusta, and comprises the **pyramidal tract** on its way from the cerebral cortex (motor area) to cranial and spinal centres below. The ectal sector, or lateral one-fifth, comprises the **temporopontile tract**;¹ its axones arise from the cortical cells in the temporal lobe and end in fine terminal arborizations in relation with cells of the nuclei pontis. The ental sector, or mesal one-fifth of the crusta, comprises the **frontopontile tract**; its axones arise from cells in the cortex of the frontal lobe and terminate in the nuclei pontis.

The **pyramidal tract** is a *direct* voluntary motor tract; the two corticopontile tracts enumerated above are links in a chain of neurones which constitute an indirect motor tract. The series of neurones in the chain of the *indirect motor tract* may be shown in the following order: **Corticopontile tract**; **nuclei pontis**; **cerebello cortex**; **dentate nucleus**; **superior cerebellar peduncle**; **red nucleus**; **tractus rubrospinalis**; **spinal gray**; **spinal nerve**; **muscle**.

Summary of the Gray Masses in the Mid-brain:

*Central aqueduct gray.

(a) Oculomotor n. nucleus.

(b) Trochlear n. nucleus.

Nucleus radialis descendens n. trigemini.

*Nucleus of medial longitudinal bundle and postcommissure.

*Formatio reticularis.

*Substantia nigra (intercalatum).

*Red nucleus (rubrum).

*Stratum cinereum of superior corpora quadrigemina.

*Nucleus of inferior corpora quadrigemina.

*"Interpeduncular" ganglion.

Structures marked with an asterisk have been considered in the preceding description. The central connections of the oculomotor, trochlear, and trigeminal nerves may now be described.

Deep Origin of Cranial Nerves Arising in the Mid-brain.—The mesencephalic root of the trigeminal nerve has been described on page 886.

The Trochlear Nerve Nucleus.—The trochlear nerve nucleus is situated in the level of the cephalic half of the inferior quadrigeminal body. It is a small oval mass of gray substance in the ventral part of the central aqueduct gray. The cells are large, sometimes stellate in appearance. The root fibres pursue a peculiar course; they accumulate in the lateroventral angle of the aqueduct gray, run caudad, gradually rising dorsad, and suddenly turn mesad to undergo a complete decussation with the root of the opposite side of the superior medullary velum, emerging laterad of the frenulum, or at the inner border of the superior peduncle.

The nucleus is placed under the dominion of the cerebral cortex by pyramidal fibres, and it is associated with other nuclei in the brain stem by the medial longitudinal bundle.

The Oculomotor Nerve Nucleus.—The oculomotor nerve nucleus is a group of cell clusters in the ventral portion of the aqueduct gray, subjacent to the superior quadrigeminal body, and extending cephalad to become lost in the gray wall of the third ventricle at the slope formed by the opening out of the aqueduct. Its nerve elements are arranged in definite groups. The most cephalic of these is composed of smaller elements, closely crowded and embedded in deeply staining

¹ Türk's bundle; not to be confused with Türk's column in the cord.

molecular ground substance. In a flat-wise section of the brain stem the outline of this nucleus resembles an inverted L or the tip of a boat hook; the axones from the cells of this nucleus (of Edinger and Westphal) supply the Ciliary muscle and Sphincter iridis (pupillary motion). The main nucleus, composed of several sub-groups, lies caudolaterad of the preceding, and is composed of larger cell elements.

The root fibre bundles from this nuclear group pass ventrad, breaking through the medial longitudinal fasciculus, separating like the strands of a horse's tail by the interference of the red nucleus, to become gathered into more compact bundles between the mesal edge of the substantia nigra and intercrural region, and emerging by eight to twelve fascicles which compose the trunk of the oculomotor nerve.

FIG. 663.—Showing the different groups of cells, which constitute, according to Perlia, the nucleus of origin of the oculomotor nerve. (Testut.)

The origin of each nerve is not limited to the nuclei of its side; a part is decussated and the decussated origin is related to the innervation of the Internal rectus. By means of association neurones in the medial longitudinal fasciculus the oculomotor and abducens nuclei of one side are brought into relation, affording an organic basis for the synergism existing between the Internal and External recti muscles in the conjugated lateral eye movements.

The paradox of the facial nerve supplying muscles under the reflex dominion of the retina (*Orbicularis oculi*) instead of the oculomotor may be explained by the assumed existence of fibres emerging from the oculomotor nucleus, entering the medial longitudinal fasciculus and joining the root of the facial.

Parts Derived from the Fore-brain.

The fore-brain or prosencephalon includes those portions of the brain which are derived from the cephalic one of the three primary brain vesicles. It includes, according to prevailing schemas, a thalamic portion (the thalamencephalon or diencephalon) and the telencephalon. The two divisions constitute a structural continuity and exhibit a mutual dependency so close that the arbitrary distinction

now in vogue tends to mislead. The relations of "diencephalon" and "telencephalon" are further complicated by the intimate fusion of the sides of the former (thalami) with the floors of the latter; this caudatohalamic fusion, in the adult brain, gives rise to some difficulty in distinguishing the two segments. The internal capsule which intervenes between thalamus and lenticular nucleus also intervenes between lenticular nucleus and caudate nucleus, both telencephalic parts.

External Morphology.—The diencephalon or thalamencephalon comprises the thalami, the pineal body or epiphysis and habenulæ, the external geniculate bodies, and the pars mammillaris hypothalami. (Other classifications include also the pars optica, with tuber cinereum, infundibulum, optic chiasm, and pituitary body or hypophysis. It is also defined as so much of the fore-brain as does not enter into

FIG. 664.—Mesal aspect of a brain sectioned in the median sagittal plane.

the formation of the cerebral hemispheres.) Caudad it is continuous with the mid-brain, cephalad with the cerebral hemispheres. Its primitive cavity becomes metamorphosed in the adult into the third ventricle or diacele as the lateral walls hypertrophy to form the thalami. Its ventral surface is the relatively insignificant gray lamina in the intercrustral space. Its dorsal surface is concealed from view by the massive hemispheres and their great commissure, the **corpus callosum**, and by the **fornix**. Its actual roof, separating it from the overlapping cerebral parts, is a delicate membranous fold, the **velum interpositum** or **diatela**.

The Thalami.¹—The thalami constitute the bulk of this portion of the brain. They are large ovoid masses of gray substance so named by the ancients after their resemblance to a pair of couches. Each thalamus is smaller frontad than caudad and the caudal ends are more widely separated from each other. The **mesal** or

¹ *Thalamos*, bed or couch; bed-chamber.

ventricular surface is largely free, except for an area, of variable size, by which the two thalami are fused in 90 per cent. of brains. This **thalamic fusion** is also called the **middle commissure** or **medicommisure**. This surface is covered by **ependyma** and of smooth contour. Its dorsal limit is marked by an **ependymal ridge**, usually torn through in dissection, the **taenia thalami** or *ripa*¹ fortified by a subjacent narrow band of fibres called the **stria medullaris**, which may be traced to the **habenular nucleus** and **habenular commissure** (or "stalk" of the pineal body). Caudad lies a depressed triangular area—the **trigonum habenulae**, situated cephalad of the superior quadrigeminal body.

FIG. 665.—Dissection showing the two thalami, the two caudate nuclei, and adjacent parts.

The **dorsal surface** is usually described as being free, but only a narrow ectal portion can be so described, the **ependyma** of the lateral ventricle being slightly reflected upon it (the *lamina affixa*) before entering into the formation of the plexus of the lateral ventricle. The rest of the dorsal surface is not lined by **ependyma**, but is in contact with the pial fold called the **velum interpositum**.

¹ The line formed by the rupture of the **ependyma** along the lines of its reflection from **entocerlian** (ventricular) surfaces.

This surface is of a whitish color owing to a thin layer of white fibres, the **stratum zonale**. A faint oblique groove crosses this surface in a caudolateral direction, corresponding to the ectal edge of the fornix. Laterad it is demarcated from the caudate nucleus by a groove which is occupied by a slender band of fibres and the striatal vein, called the **taenia semicircularis** or **stria terminalis**. The surface is not of even contour throughout, usually showing three eminences (in addition to the pulvinar) corresponding to the main nuclear aggregations within the thalamus—viz.:

Tuberculum anterius.
Tuberculum medialis.
Tuberculum lateralis.

The **tuberculum anterius** forms a marked bulging frontal extremity, which helps to form the boundary of the **foramen of Monro** or aperture of communication between lateral and third ventricles.

The caudal extremity of the thalamus is a prominent bolster-like projection which overhangs the brachia of the corpora quadrigemina and is called the **pulvinar**. A smaller oval prominence, situated ventrolaterad of the pulvinar, is termed the **external geniculate body** or **pregeniculum** (*corpus geniculatum laterale*)—a partial end station for the optic tract.

The **lateral surface** of the thalamus is in contact with the internal capsule—that great concentration of fibre tracts coursing to and from cerebral centres and forming the **crusta** below. To this white stratum the thalamus itself contributes fibres destined to reach the cortex, and in turn it receives fibres from the cortex. These thalamocortical and corticothalamic sets of fibres constitute the **thalamic radiation**, forming a more or less distinct reticulated capsular zone (*external medullary lamina; stratum reticulatum*) for the thalamus.

The **ventral or inferior surface** is continuous with the subthalamie tegmental substance and with the central gray substance of the third ventricle lining its sides and floor.

Internal Structure of the Thalamus.—The thalamus is composed of gray substance, with large multipolar cells, which is subdivided into a number of distinct nuclei; twenty such have been described; three are universally recognized. They are separated from each other by a white layer (*lamina medullaris interna*) which runs parallel to the wall of the third ventricle for its greater length; caudally it runs mesad, overlapped by the ectal nucleus, and numerous sub-laminae run into it. Frontad the internal medullary lamina subdivides into two branches, thus permitting the intrusion of the **nucleus anterius** between the two main nuclei (*medial and lateral*).

The **nucleus anterius** lies frontodorsad; in it terminate the axones of the **fasciculus thalamomammillaris** (*fasciculus albicantiothalami*—*bundle of Vicq d'Azyr*). The **nucleus medialis** is lined mesad by the central gray of the third ventricle and is usually fused with its fellow of the opposite side (middle commissure). A special spheroidal cell cluster in this nucleus is called the **centrum medianum** (Luys). The **nucleus lateralis** is the largest of the three, extending the entire length of the thalamus and including the pulvinar. A special semilunar cluster of cells in the ventral portion of this nucleus is called the **nucleus semilunaris** (Flechsig).

The Connections of the Thalamus.—The thalamus is a ganglion interposed between the sensor tracts in the tegmentum and the cerebral cortex, as well as an important link in the optic path. It also gives rise to motor tracts concerned with instinctive movements of an emotional nature. It is a relay station for the various tracts which convey sensations of touch, temperature, and pain from the body, extremities, head and neck, of muscle sense, and of the special senses. It transmits these impulses to, and, reciprocally, receives impulses from the

cerebral cortex. As an "emotional" centre it is also under the inhibitory influence of the cerebral cortex, which, if the emotion be not too strong, prevents its external manifestation.

The **thalamocortical** and **corticthalamic fibres**, with the **internal capsule**, enter into the **corona radiata** or fan-like formation of the white substance of the cerebral hemisphere. Although there is no anatomic subdivision into distinct groups of these fibres as they stream to and from the thalamus, it is customary to distinguish a **frontal**, a **parietal**, an **occipital**, and a **ventral stalk**. The frontal and parietal stalks, as their names indicate, pass between the thalamus and frontoparietal cortex, as well as to the lenticular nucleus and caudate nucleus. The occipital stalk is composed of fibres passing in both directions between the pulvinar and occipital cortex, constituting the so-called **optic radiation**. The ventral stalk comprises the **ansa lenticularis** (*thalamolenticular*) and the **ansa peduncularis** (*thalamotemporal and thalamoinsular*). They will be described in detail farther on.

The **external geniculate body**, or **pregeniculum**, is an intercalar ganglion proper to the optic nerve, derived from the thalamus. On section it is seen to be characterized by the regular alternation of deeply gray and white laminae. The latter are thicker and composed of fibres which enter the lateral geniculate body from the optic tract and optic radiation. The nerve cells in the gray substance are large, multipolar, and pigmented.

[NOTE.—The external geniculate body and the more isolated internal geniculate body are generally included under the head of *metathalamus*.]

The **hypothalamic tegmental substance**, continuous with the mid-brain tegmentum, is interpolated between the ventral face of the thalamus, the red nucleus, and a continuation of the substantia nigra known as the **corpus hypothalamicus** or **body of Luys**. Through the hypothalamic tegmentum stream the fibres of the **medial lemniscus**, of the **superior peduncle** of the cerebellum, and from the red nucleus, to end in relation with thalamic cells. The corpus hypothalamicus is a grayish-brown, lentiform mass which lies in the ideal continuation frontad of the lateral part of the substantia nigra, and, like it, situated between pes and tegmentum. It is made up of fine myelinated fibres crowded in great profusion and confusion, with numerous delicate, coiled capillaries and sparse, multipolar, more or less pigmented, nerve elements of moderate size. The outline of the body is defined by a white capsule, some of the fibres of which are seen to decussate in the floor of the third ventricle with those of the opposite side, dorsocaudad of the corpora albicantia.

The **Pineal Body** (*epiphysis; corpus pineale*) (Figs. 664 and 665).—The pineal body (from its shape resembling a fir-cone—*pinus*) is a small, reddish-gray body placed between the caudad ends of the thalami and occupying the depression between the two superior quadrigeminal bodies. It is covered by the velum interpositum, which intervenes between it and the splenium of the corpus callosum. It is an outgrowth which is not regarded as an important neural ingredient of the human brain and is generally believed to be a rudimentary relic, representing a cyclopean eye¹ of some extinct ancestral vertebrate, homologous with the parietal organ, resembling a molluscan eye of a living species of lizard (the *Hatteria* of Australia). Its attached base is a hollow peduncle divisible into a dorsal and ventral part by the intrusion of the **epiphyseal recess** (*recessus pinealis*) of the third ventricle. The **dorsal stalk** continues on either side and upon each thalamus as the **stria medullaris**; it is reinforced by commissural fibres joining the **habenulae** of the two sides; hence another name for the dorsal stalk is the **habenular com-**

¹ Although most vertebrates show a single pineal body or parietal organ, it is double in the lamprey and certain reptiles; the two bodies lie one in front of the other—not side by side (although probably paired organs originally). The frontal organ sends its fibres into the habenular nucleus; the caudal organ to the region of the posterior commissure (tectum opticum).

missure (*supracommissure* of Osborn). The **ventral stalk** is folded over another commissural band—the **posterior commissure**.

Structure.—The pineal body consists of a number of follicles, lined by epithelium and connected by ingrowths of connective tissue. The follicles contain a transparent viscid fluid and a quantity of sabulous matter named **brain sand** (*acervus cerebri*), composed of phosphate and carbonate of lime, phosphate of magnesia and ammonia, with a little animal matter. These concretions are almost constant in their existence, and are present at all periods of life.

In the interval between the pineal body and the caudal end of the **thalamus** lies a small triangular depression (sometimes an elevation) known as the **trigonum habenulae**, marking the position of the **nidus**, or **ganglion habenulae**, a group of small angular cells. The axones from these cells are collected ventrad into the **fasciculus retroflexus** (Meynert), which courses through the tegmentum mesad of the red nucleus to end in the **interpeduncular ganglion** (Gudden) in the posterior perforated substance. In addition to this fasciculus, the habenula is the reunion point for two other sets of fibres: (1) the **stria medullaris** and (2) **habenular proper**, or **habenular commissure**. The stria medullaris (p. 905) is made up of axones arising from two sources: (1) cells in the hippocampus (*via fornix*) and (2) cells in the ganglion opticum basale. These join near the anterior pillar of fornix (fornicolumn) and run caudad on the mesal thalamic surface, to end in the habenular ganglion of the same side and, by crossing in the dorsal stalk of the epiphysis from the habenular commissure, ending in the corresponding **nidus habenulae** of the opposite side.

The **posterior commissure** is a round band of white fibres crossing from side to side in the ventral stalk of the pineal body bridging the aqueduct at its continuation into the third ventricle. The posterior commissure shares relation with both fore-brain and mid-brain structures and is formed of decussating fibres which may be enumerated in the following systems: (a) fibres arising in the special nucleus (described on p. 901) for the **medial longitudinal bundle**; (b) fibres connecting the two **thalami**; (c) fibres connecting the **habenular nidi**; (d) fibres connecting the **superior quadrigemina**.

[NOTE.—The habenulae, pineal body, and posterior commissure are generally included under the head of *epithalamus*.]

The **posterior perforated substance** or **postperforatum** (*locus perforatus posticus*) has been described on page 900. It marks the situation of the "interpeduncular ganglion," which is small in man, but very large in rodent brains. From the cells in this primitive gray lamina arise the fibre tracts already described as the **taenia pontis** (p. 897), and often visible at the point of emergence from the gray substance of the intercrural space.

The **corpora albicantia** (Fig. 669), or **corpora mammillaria**, are two symmetrical, small, round, white protuberances situated side by side in the intercrural space cephalad of the posterior perforated substance, at a point where the floor of the third ventricle rapidly decreases in thickness to form the tuber cinereum. The color of each corpus albicans is white, owing to a superficial stratum of fibres derived from the fornix. Within lie three nuclear masses—two medial, constituting the main mass, and a smaller lateral nucleus applied against the former, so as to represent a crescent on cross-section.

The fibres of the fornix terminate in the corpus albicans. From its cells arise two fasciculi which have a common neurone origin. Cajal discovered, and Kölliker confirmed the fact, that the axones from the medial nucleus cells bifurcate; one set of limbs passes fronto-dorsad to form the **fasciculus thalamomammillaris** (*bundle of Vicq d'Azyr*), which ends in the nucleus antierius of the thalamus, while the other set of limbs of the primary axones passes caudad to form the **fasciculus**

pedunculomammillaris in the mid-brain tegmentum; its destination is doubtful. The axones from the lateral nucleus join the latter bundle.

[NOTE.—The posterior perforated substance and the corpora albicantia are generally included under the head of the *Pars Mammillaris Hypothalami*.]

Third Ventricle (*ventriculus tertius*) (Fig. 664).—The third ventricle is the adult representative of the cavity of the primary fore-brain vesicle, but only so much of it as is not carried laterad, on either side, in the rapidly growing, eventually huge cerebral hemisphere buds to form the lateral ventricles. It is a narrow, cleft-like interval between the two thalami and hypothalamic gray, limited frontad by the *terma*, continuous caudad with the aqueduct and laterad, through the foramina of Monro, with the lateral ventricles. Its roof is destitute of nerve tissue and is formed by a delicate, fused ependymal and pial layer, invaginated on either side of the median plane by the plexuses of the lateral ventricle. The pial layer is one of the constituents of the fold known as the *velum interpositum*. The *floor* of the ventricle is formed by structures already described on the basal

FIG. 666.—Coronal section of lateral and third ventricles. (Diagrammatic.)

aspect in the intercrural space—viz., the tuber cinereum, corpora albicantia, and posterior perforated substance, as well as the optic chiasm and a portion of the tegmentum of the crura cerebri. Much of the floor, it may be noted, is formed by the primitive, undifferentiated central gray; and although the optic vesicle develops from its ventrocephalic portion, the caudal shifting of central optic connections to thalamus and mid-brain has made this portion of the neural tube wall comparatively insignificant. The lateral walls are formed in part by the thalami, in part by the hypothalamic gray ventral extension. The fornix may be seen, shining through a thin lamina of gray substance and the ependyma, coursing caudoventrad to the corpus albicans. A slight furrow, the *sulcus* or *sulcus of Monro*, may sometimes be traced from the aqueduct to the foramen of Monro, curving ventrad of a bridge-like fusion of the two thalami—the *middle commissure* (*medicommisure*). (The term commissure is inappropriate, as no commissural fibres appear to pass from one thalamus to the other in this “thalamic fusion;” it is absent in about 10 per cent. of brains examined.)

The cephalic wall is formed by the *lamina terminalis* or *terma*, the rudimentary median cephalic wall of the neural tube. The *terma* is attached to the dorsum of the optic chiasm; dorsally it is reinforced by the anterior commissure.

As seen in mesal section or as shown by a cast of the ventricle (Fig. 664) it is seen to be of irregular outline. Frontad is the optic recess, dorsad of the

optic chiasm; caudad thereof is the infundibular recess in the tuber. The epiphyseal recess is seen between the habenular commissure and the posterior commissure. Dorsad of the pineal body is a diverticular recess of variable extent (*recessus suprapinealis*).

If the segmentation of the fore-brain into two divisions be adopted ultimately, it will be necessary to allot one portion of the third ventricle (between the thalami) to the diencephalon (hence *diacele*), and the rest to the telencephalon (the medial cavity of which is termed the *aula* by Wilder).

In anticipation of the description of the cerebral hemispheres we may consider here the remaining structures in the floor of the third ventricle, usually included under the head of the *pars optica hypothalami* of the telencephalon, in order to lead up to a description of the cerebral connections of the optic tract.

External Morphology of the Optic Portion of the Hypothalamus.—This includes the *tuber cinereum* and *pituitary body* or *hypophysis*, the *lamina terminalis*, the *optic chiasm*, and the *optic tracts*.

FIG. 667.—The pituitary body, or hypophysis, in position. Shown in median sagittal section. (Testut.)

The *tuber cinereum* (Fig. 664) is a thin-walled conical projection in the intercrural space cephalad of the corpora albicantia. Its apical portion is attenuated to form the stalk of the pituitary body; this is generally termed the *infundibulum*, while the cavity of the funnel-shaped diverticulum is called the *infundibular recess of the third ventricle*. The gray lamina composing the tuber is continuous with the central ventricular gray, and therefore with the *lamina terminalis*.

The *pituitary body* or *hypophysis* is a structure of twofold origin, giving rise to a division into a *prehypophysis* and a *posthypophysis*. The *posthypophysis* alone is of neural origin, developing as a ventral diverticulum from the primitive neural tube. The *prehypophysis* or *epithelial lobe*, develops from the stomodeum, or buccal cavity, as a tubular diverticulum (Rathke's), which eventually loses its connection¹ with the oral tissues to become included within the cranial cavity and intimately attached to the neural bud. Both pre- and posthypophysis are therefore of ectodermal origin and have developed from a conjunction of surface tissues which have migrated from opposed (ventral and dorsal) parts through the head! The *prehypophysis* is much the larger and somewhat embraces the *posthypophysis*; the two are inseparable, however, and together occupy the *fossa hypophyseos* of the sphenoid.

¹ Occasionally the channel persists as the *craniopharyngeal canal*.

The two parts of the pituitary body are as distinct in structure as they are in embryonic origin. The posthypophysis consists of a mass of nerve cells, neuroglia, connective tissue, and bloodvessels; the structure of the prehypophysis is distinctly glandular, resembling that of the parathyroid bodies. It is surmised that the latter is the functional part of the pituitary body—concerned with the internal secretions, and usually involved in the pathological form of giantism called *acromegaly*.

The *lamina terminalis* or *terma* (*lamina terminalis s. cinerea*) (Fig. 664) is a thin, easily torn lamina between the optic chiasm and the anterior commissure, limited laterally by the closely approximated cerebral hemispheres and constituting the primitive, undifferentiated cephalic boundary of the original neural tube.

The Optic Tract and its Central Connections.—In the section on the development of the brain it was learned that the optic nerve is not a peripheral nerve; it is rather a central brain tract extruded from the neural tube. Evidence is at hand that in ancestral vertebrates the general cutaneous sensor system was also capable of light perception. With the recession of the neural tube from the surface and in company with the morphological differentiation of the head end, a light-perceiving pair of organs arose as a special development. The distal end of the optic brain vesicle becomes the retina, in structure like the brain wall, whose cell axones carry afferent impulses to the brain. Although the optic fibres enter the ventral wall of the brain, the retina is originally derived from the dorsolateral (sensor) wall of the second neuromere (Fig. 627). The parietal organs, also light-perceiving, likewise developed as paired dorsal buds farther caudad, eventually to atrophy, as the more frontal optic organs better subserved the purposes of the organism.

The remarkable and as yet unexplained fact regarding the optic apparatus is that the afferent fibres from the retinal cells pass into the ventral wall to cross to the opposite side, forming a decussation which is total, or nearly so, in vertebrates below the mammals; the more laterally placed the eyes are the more nearly total is the decussation.¹

Although the optic vesicle is a diverticulum of the fore-brain in its cephalic portion, the optic tract in its central connections becomes intimately related with the external geniculate body and pulvinar, with the superior quadrigeminal body of the mid-brain, and with the occipital cortex of the cerebrum. Some of these central structures are way-stations in reflex paths; the occipital cortex alone is the actual visual centre, though visual perceptions are here brought into association with tactile, auditory, and other impulses.

Optic Chiasm.—From the retina of each eye the so-called optic nerves converge to partially decussate at the base of the brain to form the **optic chiasm**, a white quadrangular plate which presses in the primitive central gray floor of the third ventricle, as previously described. Approximately one-third of the fibres of each optic nerve do not cross to the opposite side. The optic chiasm is further reinforced by the *infracommissure* (of Gudden) and other lesser fibre tracts (*commissura superior* [*Meynerti*] and *commissura ansata* [*Kölliker*]). The fibres in the chiasm are so complexly interwoven that only through exhaustive experimental, developmental, and pathological studies has it been possible to understand its structure. Broadly stated, the fibres from the medial (or nasal) halves of the retinae decussate *in toto*, while those from the lateral (or temporal) halves do not cross. Leaving the optic chiasm, the crossed medial and uncrossed lateral fibres form the slightly flattened **optic tracts** coursing caudolaterad, embracing the *crura cerebri* and dividing in the neighborhood of the lateral geniculate body into two "roots," a mesal and a lateral root. The **mesal root** is in reality not a part of the

¹ Possibly the reflex contraction of the muscles on one side of the body in the ancestral vertebrate followed the perception of a menacing object by the eye of the opposite side; hence the advantage of a decussation.

true optic path; it is a separate fascicular representation of the **infracommissure of Gudden**, composed of fibres forming a reciprocal bond of union (commissural) between the internal geniculate bodies of the two sides and coursing through the chiasm (Fig. 668). The **lateral root of the optic tract** is the true visual path, composed of (a) the uncrossed fibres from the lateral half of the retina of the same side and (b) the crossed fibres from the mesal half of the retina of the opposite side. The fibres of the lateral root are distributed to the **primary or lower optic centres** as follows: (1) Most fibres end in the external geniculate body; (2) a less number end in the pulvinar; (3) the remainder end in the nucleus of the superior quadrigeminal body.

FIG. 668.—Scheme showing central connections of the optic nerve and optic tract.

The **lateral geniculate body** and **pulvinar** are ganglionic way-stations or inter-nodes in which visual impulses are reflected, in large part, to the visual cortex in the occipital lobe; the superior quadrigeminal body, on the other hand, plays no part in the conduction of impulses perceived as light or color; it presides rather over the eye-muscle reflexes to visual¹ stimuli, and in its turn is under the dominion of the higher cortical centre. Reflex impulses are sent to the oblongata and spinal centres along axones entering into the formation of the medial longitudinal bundle.

¹ And auditory stimuli as well (see p. 899).

The axones of corticifugal neurones proceed to the nucleus of the superior quadrigeminal body along the optic radiation.¹

Some fibres are detached from the optic tract and course through the crus cerebri to the oculomotor nucleus. These fibres are small, and are believed to be afferent branches for the Sphincter pupillæ and Ciliary muscles.

The connections of the external geniculate body and pulvinar with the higher cortical centre of vision are established by neurones, the cells of which lie in the two ganglia just mentioned, and whose axones stream in an arched, more or less compact bundle in the white substance of the cerebral hemisphere toward the occipital cortex. Another system of neurones, whose cells lie in the cortex, sends its axones in the reverse direction (corticifugal) to the two lower centres. The cerebral tract thus formed between primary and secondary (cortical) centres is called the **optic radiation**, to be studied more fully in the sequel. The components of the optic path are delineated schematically in Fig. 668.

The Cerebral Hemispheres.

External Morphology.—Of all the component parts of the brain, the cerebral hemispheres form the largest part, and their preponderance and remarkable specialization underlie the extraordinary manifestations of the intellect so highly amplified in man.

FIG. 669.—Mesal aspect of a brain sectioned in the median sagittal plane.

The term **cerebrum**, often employed loosely as embracing several brain parts, is here intended to include the brain mantle and the olfactory lobe—equivalent to the *telencephalon* of His, with the exception of the *pars optica hypothalami*. As

¹ Centrifugal fibres ending in the retina, and probably arising from cells in the superior quadrigeminal body, have been discovered in the optic tracts.

already indicated in the section on brain development, there has occurred, in the evolutionary history of man's vertebrate ancestry, a progressive increase of the secondary fore-brain, with concomitant reduction of the *rhinencephalon*, or *smell brain*—the most archaic portion because of the important relations of the smell sense to the life history of the earliest vertebrates.¹

In a mesal view of a hemisected brain (Fig. 669) may be seen the various parts of the brain stem and the cerebellum overlapped by the preponderatingly greater cerebrum. Among the many notable features exposed to view in this brain

FIG. 670.—The cerebral hemispheres viewed from above. (Spalteholz.)

section are certain fibre masses, **commissures**, extending across the meson, and therefore divided by the knife in this preparation. Of the commissures pertaining to the cerebrum one is conspicuous for its size and firm consistency. This great fore-brain commissure is the **corpus callosum** already mentioned as being demonstrable in the depths of the intercerebral cleft on divaricating the lips of this fissure. The corpus callosum constitutes a massive system of association fibres for the bilateral coördination of corresponding cortical parts. It is thickened caudally, forming the **splenium of the corpus callosum**; frontad it bends on itself

¹ For a more thorough discussion on the natural subdivision of the fore-brain, based upon comparative morphology, see the paper by G. Elliott Smith, *Journal of Anatomy and Physiology*, 1901.

ventrocaudad to form the **genu** ("knee"), including an interval, between the two limbs, which is flanked on both sides by a thin lamina (hemiseptum) and bounded ventrad by the fornix, constituting a closed cavity, the **pseudocoele**. The recurved ventral part of the genu tapers into a thinner, beak-shaped part, the **rostrum**. The rostrum is joined to the lamina terminalis, frontad of the anterior commissure, by a thin lamina, the **copula** (*lamina rostralis*; *lamina baseos alba*).

An arched structure composed of longitudinal fibre bundles comes to view in front of and below the junction of the splenium with the body of the corpus callosum, proceeds frontoventrad with its convexity frontad, to sink from view in the substance of the hypothalamic gray at a point just caudad of the anterior commissure. This white arched bundle is the **fornix**. Between it and the corpus callosum, rostrum, and copula stretches a thin, translucent lamina of nerve tissue—the **hemiseptum**. The hemisepta of the two sides together have usually been termed the **septum pellucidum**, while the enclosed narrow cavity is called the **pseudocoele** or **fifth ventricle**. The subjacent parts revealed in this section have already been described; the morphology and internal relations of the corpus callosum, fornix, and hemiseptum will be described at a later stage.

FIG. 671.—Principal fissures and lobes of the cerebrum viewed laterally.

The cerebral hemispheres together, as viewed from above or dorsally, appear as two symmetrical masses in close apposition, conforming in outline to that of the cranial cavity, which they so nearly fill. The frontal extremities or poles are massive and rounded, preponderatingly so in comparison with the brains of any related primate species. The occipital poles are each more pointed but expand frontad into the widest part of the cerebrum—the **parietal lobes**. The cerebral hemispheres or, briefly, the **hemicerebra** are partially separated from each other by the **intercerebral cleft** or **great longitudinal fissure** (*fissura longitudinalis cerebri*), into which fits a fold of the dura—the **falx cerebri**. By means of a large commissural band of white fibres—the **corpus callosum**—the cerebral halves are joined together in the depths of the intercerebral cleft. All adjacent parts of the brain are overlapped by the ponderous cerebrum so as to entirely conceal the thalamic portion and the mid-brain, while the occipital lobes overlap the cerebellum with

the intervening tentorium—another fold of the dura. Further description will be restricted to each cerebral hemisphere.

Configuration of Each Cerebral Hemisphere.—Each cerebral hemisphere presents an *outer convex surface* (*facies convexa cerebri*), applied to the corresponding half of the cranial vault; a *mesal flattened surface* (*facies medialis cerebri*), which lies in a sagittal plane, applied to the corresponding surface of the opposite cerebral hemisphere, with the great longitudinal fissure intervening, and for the most part in contact with the falx cerebri; and a *basal or ventral surface*, of irregular form, resting frontad upon the floors of the anterior and middle cranial fossæ, and caudad upon the tentorium cerebelli.

Prominent in the lateral and ventral views is the blunt projection of the temporal pole, while at the ventrolateral border, nearer the occipital pole, is a slightly marked indentation usually called the **preoccipital notch**. The deep vallecular depression between the orbital surface and the temporal pole accommodates the greater wing of the sphenoid.

More or less distinct borders demarcate the surfaces. The arched *dorsimesal border* intervenes between the mesal and the convex surfaces; a straight *mesorbital border* intervenes between the orbital and mesal surfaces of the frontal lobe; a *ventrolateral border* separates the tentorial surface from the lateral, convex surface of the occipital and temporal lobes; while an obtuse border—the *mesoventral or internal occipital border*—separates the tentorial from the mesal surfaces.

Cerebral Fissures and Gyres.—The surface of each cerebral hemisphere presents alternating depressions or **fissures** which demarcate gyrus elevations—the **convolutions or gyres**.¹ The fissures vary in depth from that of a mere shallow groove to as much as 30 mm., and may attain a length of 15 cm. They are more or less sinuous and ramified. They mark the surface with fairly approximate uniformity, that is, one rarely finds an unfissured surface more than 15 to 20 mm. ($\frac{3}{8}$ inch to $\frac{1}{2}$ inch) in width. Numerous functional and mechanical influences must be credited with bringing about the complex foldings of the cerebral surface, principally (a) resistance of the cranium to the expanding brain or “mechanical packing;” (b) differences of growth rate in different parts of the cortical surface; (c) differences of growth rate of different fibre bundles retarding cortical expansion along the fissure lines and elongating to help in the formation of the gyres. The obvious result, whatever the influences may be, is an expansion of the cerebral cortex to an enormous degree, so that, instead of having a surface area of only 60,000 sq. mm. (if unconvoluted), the average adult cerebrum has a cortical area of 200,000 sq. mm. or more. Furthermore, the vascular pia, closely investing the surface and dipping into every fissure, is expanded in a like manner, affording an ample and uniform supply of blood for the entire cerebral cortex.

The cerebral vesicle of the fetal brain presents a smooth surface during the first half of intrauterine life,² except for the depressed fossa at the site of the future island of Reil—destined to become buried in the depths of the sylvian cleft formed by the apposition of the more energetically growing contiguous parts of the cerebral mantle. Some of the cerebral fissures develop early as infoldings of the comparatively thin wall of the vesicle, and hence produce corresponding projections into the cerebral cavity; these are termed the **total or complete fissures**. The remaining fissures are only linear depressions of the surface not involving the entire thickness of the wall—the **partial or incomplete fissures**. The complete fissures and their correlative projections into the cerebral cavity (lateral ventricle) are:

¹ Consistent with the use of the English *lobe* and *lobes* (for *lobus* and *lobi*), the English *gyre* and *gyres* are preferable to *gyrus* and *gyri*. The term *fissure* is here uniformly employed for all anfractuosities of the surface, though *sulcus* (pl. *sulci*) is quite as generally used; sometimes both terms are indiscriminately mixed in other works on this subject.

² The so-called *transitory fissures* of older descriptions may be neglected, since the researches of Retzius, Hochstetter, and Mall have shown these to be in reality artefacts due to postmortem swelling.

Among the remaining cerebral fissures, of which over fifty have been recognized and named, some are constant in representation in all normal brains, while others are of variable occurrence in different individual specimens. The constant fissures are those which regularly exist as interlobar and intergyral boundary lines forming a common pattern for all normal brains, but these, like all cerebral fissures, are subject to many individual variations as to course, depth, length, mode of branching, and anastomosis with neighboring fissures or manner of interruption by gyral isthmuses. The range of individual variations is so great that no two brains can be said to be exactly alike; in fact, one may find numberless stages of complexity in the cerebral surface configuration from the simply fissured brains of mentally inferior individuals and races to the complexly fissured and more highly organized brains of vigorous thinkers and talented geniuses among the highly intellectual races of man.

FIG. 672.—Cerebral fissures and gyres viewed dorsally

Cerebral Lobes and Fissures.—The cerebral surface is divided into five principal areas, called **lobes**, demarcated by certain constant fissures which are more or less conspicuous, and were therefore selected by the older anatomists as arbitrary boundary lines; these are termed the **interlobar fissures**.

The lobes are: (1) the **frontal**; (2) the **parietal**; (3) the **temporal**; (4) the **occipital**; (5) the **island of Reil** or **insula**. The **interlobar fissures** are: (1) the **sylvian**; (2) the **central**; (3) the **occipital**; (4) the **calcarine**; (5) the **circuminsular**. A series of fissures demarcating the rhinencephalon from the pallium or cerebral mantle proper will be considered at a later stage.

The Interlobar Fissures. The Sylvian Fissure and Its Rami (*fissura cerebri lateralis* [*Sylvii*]).—This fissure is a well-marked cleft on the base and side of the cerebral hemisphere. Traced laterad from the region of the anterior perforated substance, it begins as a deep depression between the orbital surface of the frontal lobe and the temporal pole, corresponding to the bony ridge formed by the lesser wing of the sphenoid and extending to the convex surface. This portion of the fissure is termed the **basisylvian fissure** or **vallecula sylvii**, as far as the **sylvian point**.¹ The sylvian point marks the conjunction of the main portion of the sylvian fissure with its basisylvian part as well as one or two rami. These rami are (1) the **presylvian ramus** and (2) the **subsylvian ramus**.

The **presylvian ramus**² usually proceeds dorsad, slightly inclined frontad, for a distance of 2 to 3 cm. into the subfrontal gyre.

The **subsylvian ramus** (*anterior horizontal limb*) extends frontad for a distance of 1.5 to 2 cm., parallel to the orbitofrontal (superciliary) margin.

These two rami often spring as shorter branches from a common stem, and both may be replaced by a single unbranched limb.

The sylvian fissure proper is the most conspicuous part. It extends from the sylvian point in a caudal direction, inclined slightly dorsad,³ on the lateral surface of the cerebrum for a distance averaging 6 cm. (2½ inches). It separates the temporal lobe wholly from the frontal and partly from the parietal lobe. It usually ends in an upturned manner, in the parietal lobe, the change of direction being oftener abrupt than gradual; this terminal piece receives the name of **episylvian ramus**. Occasionally a short ramus is sent ventrad into the supertemporal gyre and is called the **hyposylvian ramus**.

The sylvian fissure ranges in depth from 15 mm. or less at the presylvian point to 25 or 30 mm. (1 inch to 1½ inches) at the postsylvian point, correlative with the contour of the island of Reil, which lies in its depths. If the lips of the sylvian fissure be divaricated, the island of Reil is revealed as a cortical district, of tetrahedral form, which is normally completely concealed by overlapping portions of the cerebral hemisphere called the **opercula**. These are four in number: (1) the **operculum proper**, (2) the **preoperculum**, (3) the **suboperculum**, and (4) the **postoperculum**.

The **operculum** (*frontoparietal operculum*) is composed of the adjacent portions of the ventral border of the frontal and parietal lobes, the sylvian fissure intervening between it and the **postoperculum**, which is the overlapping part of the temporal lobe. The **preoperculum** is a small triangular portion embraced by the presylvian and subsylvian rami, and is also called the **pars triangularis** or **Broca's cap**. The **suboperculum** (*orbital operculum*) is small, demarcated by the subsylvian ramus, and, for the most part, on the orbital face of the frontal lobe, projecting slightly over the frontal part of the island of Reil, with its margin separated from the temporal pole by the basisylvian cleft.

The overlapping opercula are demarcated from the island of Reil by the **circuminsular fissure** (*sulcus circularis Reilii*).

Development of the Island of Reil and the Sylvian Cleft.—The insular cortical district is topographically correlative with the great gray ganglia of the cerebral

¹ So called in cranial topography.

² Also called the *anterior ascending limb*. In BNA terms the name for this fissural branch is *Ramus anterior ascendens fissurae cerebri lateralis*.

³ Its inclination to the horizontal plane is called the *sylvian angle*, approximately 15 degrees.

hemisphere, particularly the lenticular nucleus, from whose ectal surface the insular cortex is but little removed. As will be learned at a later stage, few if any projection fibres pass to and from the island of Reil; its function is almost wholly associative for adjacent parts of the cerebral mantle. The island of Reil therefore becomes buried beneath the more energetically growing and bulging parts immediately around it. There is at first a slight fossa (observable in the tenth to twelfth week) which, as development proceeds, and as the overhanging opercula encroach upon the island of Reil, becomes more deeply situated as a cleft-like depression until at birth the fossa has become a fissure, with the island of Reil perhaps slightly exposed near its cephalic extremity, where the incomplete apposition of the opercula leaves a triangular space. This space is usually obliterated in childhood, but is commonly met with in certain races (negro, Australian) and in brains showing developmental defects or arrest. The mechanics of the formation of the surface outline of the sylvian fissure by the apposition of the growing and plastic opercula may be understood by a reference to Fig. 678.

FIG. 673.—Central fissure fully opened up, so as to exhibit the interlocking gyres.

The **central fissure** (*fissure of Rolando* [*sulcus centralis*]) is situated at about the middle of the convex surface, and, coursing obliquely laterofrontad, divides this surface into approximately equal parts, intervening between the frontal and parietal lobes. It may be traced from a point at or near the dorsimesal border, about 1 cm. ($\frac{2}{5}$ inch) caudad of the mid-point of the occipitofrontal arc. It then runs sinuously laterofrontad to within a short distance of the sylvian fissure, about 2 cm. ($\frac{1}{2}$ inch) caudad of the sylvian point; its line of general direction makes an angle of about 70 degrees with the median line (**Rolandic angle**). If measured along its sinuosities, its length averages 10.5 cm. (4 inches). Its curved course may be analyzed into five alternate curves (sometimes more or less), of which three are convex frontad and two caudad. It is rarely very much branched and does not often anastomose with neighboring fissures. Its dorsal end bears a constant relation to the caudal limb of the paracentral, frontad of which it can be found as a hook-like curve (Fig. 675). If the lips of the central fissure be divaricated, interdigitating sub-gyres are commonly seen in its depths (Fig. 673). These interlocking gyres are often fused to a greater or less degree, and a total interruption of the fissure has, in rare instances, been observed. The central fissure develops at about the end of the fifth month of intrauterine life, not as a single integer, but as the result of the union of two segments—a short dorsal and a longer ventral segment. As development proceeds these segments eventually

unite end to end, and at the site of this union a vadium (or shallow uprising of the floor of the fissure) or even a complete isthmus may be demonstrated in the adult brain. Only three cases of *bilateral* interruption are on record.

The **occipital fissure** (*fissura occipitalis*) is a deep cleft across the dorsimesal border transsecting the occipitofrontal arc at about 5 cm. (2 inches) from the occipital pole, and extending upon both the mesal and the convex surfaces. On the meson it attains a length of 3 to 3.5 cm. ($1\frac{1}{2}$ to $1\frac{3}{4}$ inches) (to its junction with the calcarine fissure) while its lateral extent is shorter (2 to 2.5 cm., $\frac{4}{5}$ to 1 inch). It is quite deep throughout and usually shows a number of interdigitating subgyres.

The **calcarine fissure** (*fissura calcarina*) is a slightly arched fissure which is usually joined with the occipital fissure at the apex of the cuneus and extends caudad to the occipital pole, ending in a bifurcation. The fissure is composed of two integers which may be partially or completely separated (by a vadium or an isthmus); the caudal segment may then be distinguished as the **postcalcarine fissure**.

The occipital and calcarine fissures join to form a Y-shaped junction; the two limbs of the Y embrace the cuneus, while the stem is continued as the **occipitocalcarine stem** for a distance of about 3 cm. This fissural stem is allotted to the occipital fissure by some and to the calcarine fissure by other authors. As there is no greater frequency of confluence with one as against the other, so far as present statistics go, it is preferable to assign no special relationship for this stem to one or the other principal fissure.

I. Frontal Lobe. FISSURES OF THE FRONTAL LOBE.—1. The *lateral surface* is bounded by the dorsimesal arched border, by the fronto-orbital (or superciliary) border, by the sylvian fissure (in part), and by the central fissure. The principal fissures marking this surface demarcate four gyres: (1) the **precentral**, (2) **superfrontal**, (3) **medifrontal**, and (4) **subfrontal gyres**. The fissures are (1) the **precentral**, (2) **superfrontal**, and (3) **subfrontal fissures**. In addition must be described certain fissures which are intragyral and of more or less constant occurrence.

The **Precentral Fissural Complex** (*sulcus praecentralis*).—Two fissural integers which are sometimes joined extend more or less parallel with the central fissure. The mesally situated piece is usually of zygal (*yoke-shaped*) shape or triradiate, and usually anastomoses with the superfrontal fissure. From its position it is termed the **supercentral** or **superior precentral fissure** (*sulcus praecentralis superior*). The laterally situated piece is of longer extent, sometimes straight or slightly sinuous, sometimes arched like an inverted L, or T-shaped. It usually anastomoses with the subfrontal fissure. The two precentral segments demarcate the precentral gyre from the remaining three gyres of the lateral surface of the frontal lobe.

The **superfrontal fissure** (*sulcus frontalis superior*) usually springs from the supercentral and pursues a sinuous course frontad, to become lost, as a rule, in the zigzag or transverse ramifications of the prefrontal region. It is usually quite ramified and often anastomoses with other fissures. It demarcates the superfrontal from the medifrontal gyre.

The **subfrontal fissure** (*sulcus frontalis inferior*) is most often confluent with the precentral, less often with the supercentral fissure. It proceeds frontad in an arched course, to end either in a bifurcation or by anastomosing with other fissures (radiate fissure, orbitofrontal fissure, or medifrontal fissure). The subfrontal fissure demarcates the medifrontal from the subfrontal gyre.

Both the superfrontal and medifrontal gyres are characterized by a more or less pronounced longitudinal subdivision by less constant fissural segments. They are: (1) the **paramesal fissure** (*sulcus paramedialis*) occupying an intermediate position between the superfrontal fissure and the dorsimesal border, in the superfrontal gyre, more often composed of a series of short segments which become lost

in the more complex configuration of the prefrontal region; (2) the **medifrontal fissure** (*sulcus frontalis medius*) situated in the prefrontal part of the medifrontal gyre, rarely extending throughout, and usually ending cephalad in a widely spread bifurcation which constitutes the **orbitofrontal fissure** when independent. The medifrontal fissure is usually very much ramified and frequently anastomoses with neighboring fissures. The fissure is a characteristic of human and anthropoid brains only.

By the occurrence of either or both paramesal and medifrontal fissures, the ordinary three-tier type of frontal lobe is converted into a four-tier and five-tier type; the latter more often in the brains of the more highly intellectual—a feature which is concomitant with the comparatively late phyletic and embryonic development of the two secondary fissures described.

FIG. 674.—Fissures and gyres of the lateral surface of the left hemisphere.

Other, less important, fissures are: (1) the **inflected fissure** (*fissura inflexa*), incising the dorsimesal border between the central fissure and the cephalic limb of the paracentral; (2) the **radiate fissure**, near the lateral orbitofrontal border; (3) the **transprecentral**, a short oblique piece ventrad of the central and usually dipping into the sylvian cleft; and (4) the **diagonal fissure** between the presylvian ramus and the ventral end of the central, and often confluent with the precentral (Fig. 674).

2. The *mesal surface* of the frontal lobe is bounded by the dorsimesal border, the mesorbital border, and the callosal fissure. An arcuate fissure or system of fissures intermediate between the dorsimesal margin and the supercallosal fissure divides this surface into the **superfrontal gyre**, **mesal aspect**, and the **callosal gyre**. The name "callosomarginal" was usually applied to this fissure, but an examination of many brains reveals a certain integrality of fissural parts, which are not always connected. One constant segment from its relations with the central fissure is called the **paracentral fissure**, composed of a main stem with a cephalic and a caudal limb, embracing the paracentral gyre. Frontad thereof extends the supercallosal fissure, often in two segments, running a concentric course between the arched dorsimesal border and the genu of the callosum. The supercallosal may be confluent with the paracentral. The supercallosal is,

2. *Mesal Surface*.—On the mesal surface of the frontal lobe and embracing the dorsal end of the central fissure lies an oval lobule or gyre called the **paracentral gyre** (*lobulus paracentralis*), limited by the paracentral fissure with its caudal and cephalic limbs. Frontad thereof extends the large arched mesal surface of the **superfrontal gyre** (*gyrus frontalis superior*), limited by the supercallosal fissure. Between the latter fissure and the callosal fissure, concentrically situated with respect to the superfrontal, lies the **callosal gyre** (the “*gyrus fornicatus*” of other authors).

Frontad these two gyres arch around the genu of the corpus callosum, to become merged through the disappearance of the intervening supercallosal fissure, and the rostral fissures alone mark this surface.

FIG. 676.—Fissures and gyres of the basal surface of the cerebrum.

3. *Orbital Surface*.—The olfactory fissure and the mesorbital border bound the **mesorbital gyre** (*gyrus rectus*). The remaining orbital surface is not regularly divisible on account of the great variability of the orbital fissures; when the trans-orbital fissure is pronounced, a pre- and postorbital gyre may be distinguished.

The **postorbital limbus** is a formation occasionally met with on the orbital surface. It consists of a curved, welt-shaped eminence demarcated by an incisure created by the lesser wing of the sphenoid, and due, apparently, to the intrusion of the postorbital portion into the middle fossa of the skull.

II. **Parietal Lobe** (*lobus parietalis*). **FISSURES OF THE PARIETAL LOBE**.—1. The *lateral surface* is bounded by the dorsimesal border, by the central fissure, and by a part of the sylvian fissure; it is only partially demarcated from the occipital lobe by the occipital fissure, and merges gradually into the temporal lobe.

The principal fissures marking its surface consist of a group of integral segments showing various degrees of confluence in different individuals and formerly known in the aggregate as the **intraparietal sulcus of Turner** (*sulcus intraparietalis*). Two of the fissural segments present much the same parallelism to the central fissure which was noted for the precentral group, and hence these are termed the **postcentral fissural complex**.

The **postcentral fissural complex** (*sulcus postcentralis*) comprises a longer mesal and a shorter lateral (and ventral) segment, which are confluent in about 75 per cent. of brains and then very much resemble in length, continuity, and course the central fissure. This appearance has given rise to reports of alleged duplication of the central; an analysis of the relations of the dorsal ends of the fissures in question with the caudal limb of the paracentral removes all doubt.

The **postcentral fissure** (proper) is the longer mesal (and dorsal) segment. Its dorsal end is frequently bifurcated and sometimes embraces the dorsal extension of the caudal limb of the paracentral. The **subcentral fissure** constitutes the shorter lateroventral segment.

The **parietal fissure** is usually a slightly arched fissure inclining mesocaudad, sometimes independent but more often confluent, with one or both of the postcentral segments just described. It demarcates the parietal gyre from the subparietal district.

The **paroccipital fissure**, in whole or in part, probably represents a part of the simian exoccipital or "Affenspalte," isolated by the upgrowth of gyral protons which are totally submerged in the ape brain, but rose to the surface concomitant with the rise in functional dignity of cortical areas so important in the human brain. The fissure is almost invariably of zygal shape, its stem directed sagittally, its ends bifurcated. Its confluence with the parietal fissure seems to be subject to some morphologic law; continuity is the rule on the left side (77 per cent.), and occurs less often on the right. The combination of continuity on the right and separation on the left is a rare one (6 per cent.).

Less constant fissures are the **transparietal**, in the parietal lobe, and the **intermedial** (Fig. 674). In the subparietal district terminate the upturned ends of the sylvian (*i. e.*, episylvian ramus) of the supertemporal and the mediotemporal fissures.

2. The **mesal surface** of the parietal lobe is equivalent to the quadrangular **precuneus**, limited by the paracentral and occipital fissures, while ventrad it is imperfectly separated from the callosal gyre by the **precuneal fissure** (*postlimbic sulcus*), usually of zygal or triradiate form and occasionally confluent with the paracentral.

GYRES OF THE PARIETAL LOBE. 1. *Lateral Surface.*—The **postcentral gyre** (*gyrus centralis posterior*) is one of the chief somesthetic areas of the cortex. It is a long, more or less sinuous convolution extending obliquely from the dorsimesal border to the sylvian fissure and demarcated by the central and the postcentral + subcentral fissures.

The **parietal gyre** (*gyrus parietalis*) lies between the dorsimesal border and the parietal fissure, bounded cephalad by the postcentral, caudad partly by the occipital fissure, the transition to the occipital lobe being maintained by the arched **paroccipital gyre**.

The **subparietal district** or **lobule** (*lobulus parietalis inferior*) is divided into three convolutions which arch around the upturned ends of the sylvian, supertemporal, and mediotemporal, and merge insensibly with the adjacent temporo-occipital gyres. The **marginal** (*supramarginal*) **gyre** arches over the extremity of the episylvian ramus and is connected frontad with the postcentral gyre, ventrad with the supertemporal gyre. The **angular gyre** (*gyrus angularis*) arches over the upturned extremity of the supertemporal fissure, and its limbs fuse with the

supertemporal and mediotemporal gyres. The **postparietal gyre** is not always clearly defined; it arches around the upturned end of the mediotemporal or its representative segment; mesally it is bounded by the paroccipital fissure. Variable **intermedial fissures** sometimes help to define the angular gyre from its two neighbors.

2. The **mesal surface** of the parietal lobe has already been described as equivalent to the **precuneus**, from its position in "front" of the **cuneus** or **quadrate lobe** from its general shape. It is sometimes marked by a mesal extension of the **transparietal fissure** or by **intraprecuneal fissures**.

III. Occipital Lobe (*lobus occipitalis*). FISSURES OF THE OCCIPITAL LOBE.—

1. The **lateral surface** of the occipital lobe is imperfectly demarcated from the adjacent parietal and temporal lobes in most brains. The sharply defined **exoccipital fissure** or "Affenspalte" of other primates has, in the ancestry of man, been reduced to a series of fissural segments by the upgrowth of submerged cortical parts. The paroccipital fissure, we have already learned, probably represents one of the gaps in the series; another may be the **sulcus lunatus** (Elliott Smith), usually termed the **lateral occipital** by the authors; lastly, a fissure sometimes called the **inferior occipital** (*suboccipital*), and usually embraced, on the occipital pole, by the bifurcate limbs of the postcalcarine, may complete the series. Further researches are necessary to elucidate the morphology of this region.

2. The **mesal surface** is equivalent to the wedge-shaped region embraced by the occipital and calcarine fissures, and called the **cuneus**. A fairly constant **cuneal fissure** traverses its surface parallel to the calcarine.

If it is ever determined that the morphological boundary of the occipital lobe is as outlined above, the lobe is practically excluded from the basal surface of the hemiserebrum.

IV. Temporal Lobe (*lobus temporalis*). FISSURES OF THE TEMPORAL LOBE.—1.

The **lateral surface** of the temporal lobe is bounded by the basisylvian and sylvian fissures and by the ventrolateral border; caudally it merges into the adjacent parietal and occipital lobes.

The **supertemporal fissure** (*sulcus temporalis superior*) is a deep, long (10 to 12 cm.), and usually continuous fissure which begins near the temporal pole, proceeds ventrad of but parallel with the sylvian, to become upturned in the parietal lobe and embraced by the arched angular gyre.

The **mediotemporal fissure** (*sulcus temporalis medius*) is rarely continuous; more often it is represented by a series of segments, two, three, or four in number, the caudal segment running more vertically into the parietal lobe to be embraced by the postparietal gyre. The mediotemporal fissural segments run nearly parallel with the supertemporal and demarcate the mediotemporal from the subtemporal gyre.

2. **Tentorial or Ventral Surface**.—Close to the ventrolateral margin and more or less parallel with it runs the **subtemporal fissure** (*sulcus temporalis inferior*), extending from near the temporal to near the occipital pole. It is rarely continuous, being usually broken up into two or more segments. It demarcates the subtemporal from the subcollateral gyre.

The **collateral fissure** (*fissura collateralis*) is a well-marked, long (8 to 12 cm.), and deep fissure extending from near the occipital to near the temporal pole. Caudally it demarcates the subcalcarine gyre from the subcollateral; frontad it intervenes between the latter gyre and the hippocampal gyre. Its middle part is correlative with the collateral eminence. On the ventromesal aspect of the temporal lobe and near its pole, cephalad of the uncus, is a moderately marked fissure or groove, called, because of its topographic relation to the amygdaline nucleus—a gray, ganglionic mass—the **amygdaline fissure** (*fissura ectorhinalis s. postrhinalis*), or **incisura temporalis**.

3. The *dorsal* or *opercular surface* of the temporal lobe enters into the formation of the sylvian cleft. It is but slightly marked by a few oblique or transverse furrows (**transtemporal fissures**) demarcating slightly elevated **transtemporal gyres**.

GYRES OF THE TEMPORAL LOBE.—The five principal fissures named subdivide the lobe into five gyres. On the lateral surface lie the **supertemporal**, **medietemporal**, and **subtemporal gyres** (*gg. temporalis superior, medius et inferior*); on the tentorial surface are the **subcalcarine** (*gyrus lingualis*), **subcollateral** (*gyrus fusiformis*; *g. occipitotemporalis*) and part of the **subtemporal**.

The **hippocampal gyre** (*gyrus hippocampi*), formerly included in the "limbic lobe," but morphologically belonging to the neopallium, occupies the dorsomesal part of the ventral surface of the temporal lobe. The longer or shorter extension of the occipitocalcarine stem partially (forming the **isthmus gyri hippocampi**) interrupts its continuity with the callosal gyre. It is demarcated by the collateral fissure (in part) and the hippocampal fissure, broadens out toward the temporal pole, and appears to become bent upon itself dorsally to form the **uncinate gyre** (*uncus*). As will be learned in the sequel, the hippocampal gyre is demarcated from the uncus proper by the intervention of the frenulum *Giacomini*—an extension of the narrow, gray, dentate gyre.

FIG. 677.—Brain of a six-months' human embryo, natural size, right side. (Kölliker.)

FIG. 678.—Cerebrum of an eight-months' human embryo, left side. The insula is nearly covered in. (Testut.)

Near the temporal pole it is demarcated from the subcollateral gyre by the **fissura rhinica**,¹ or **postrhinal fissure**; this fissure is not infrequently confluent with the collateral.

The surface of the hippocampal gyre, particularly in the zone along the hippocampal fissure, is of a more whitish color than is characteristic of other cerebral gyres; this is due to a white reticular stratum of fibres, the **substantia reticularis alba** (Arnold). The convex, broader part of the gyre is marked by numerous small, wart-like eminences, resembling the skin of an amphibian, and called by Retzius the **verrucae gyri hippocampi**. Just ventrad of the uncinat portion, or the terminus of the hippocampal fissure, lies a groove marking the impression of the free edge of the tentorium cerebelli.

The Island of Reil (*central lobe* or *insula*) (Figs. 678, 679).—The island of Reil lies deeply in the sylvian cleft and can only be seen when the lips of that cleft are widely separated, since it is overlapped by the opercula already described. With the opercula removed, the island of Reil presents a tetrahedral shape with its **apex** or **pole** directed ventrocephalad. Its borders are sharply outlined by the **circuminsular fissure** except in the depths of the basisylvian cleft, where the insular cortex is continuous with the gray substance of the anterior perforated substance—

¹ Called by Wilder, on account of its correlation with the amygdaline nucleus, the *amygdaline fissure*. Schwalbe calls it (in part) the *incisura temporalis*.

the threshold or *limen insulae* (belonging to the rhinencephalon). An oblique **transinsular** or **central insular fissure** divides this district into a larger **preinsular** and a smaller **postinsula**. The postinsula is usually a single long gyre (*gyrus longus insulae*), while the preinsula is subdivided by shallow fissures into three, four, or five shorter **preinsular gyres** built upon a radiate plan, converging in the region of the insular pole. As already hinted, the island of Reil represents an area of the brain mantle whose growth did not keep pace with that of the surrounding parts; hence its submergence by them. The close apposition of the insular region to the subjacent basal ganglia, and the failure of development of great masses of projection fibres so prominent elsewhere, were doubtlessly factors therein. The insular cortex is uninterruptedly continuous with the rest of the cortex, but it has become specialized into the purest association centre in the cerebrum, and we shall learn of its intimate relations to the faculty of speech at a later stage.

FIG. 679.—The left island of Reil schematically represented in a supposedly transparent cerebral hemisphere, showing how it is concealed from view by the opercula.

The Rhinencephalon, or Olfactory Lobe (*lobus olfactorius*) (Figs. 680, 681).—The grouping of the parts constituting the central olfactory structures under the term “rhinencephalon” as distinguished from the rest of the fore-brain (*pallium*) was first clearly made by Turner and proved by His to be embryologically well founded and by Edinger to agree with phylogenetic development. More light has been thrown upon the subject recently by Retzius and Elliott Smith. The sense of smell, while highly useful in the quest for food in earlier and lower forms of vertebrates, is relatively little used in the mental life of man. The enormous preponderance of the cerebral mantle and the concomitant atrophy of the rhinencephalon in the human brain afford one of the most striking contrasts in brain morphology. This relatively feeble development in bulk of the olfactory apparatus in the human brain by no means renders its description simple. In fact, not until its development in lower macrosmatic animals was studied could anatomists form even an approximately clear conception of the seemingly disjointed remnants in the human brain of an olfactory apparatus so relatively huge in lower animals. The great expansion of the cerebral hemispheres and of the great commissure

which connects them (the corpus callosum) has been an important factor in widely displacing primitively connected parts. The developmental history must be sought for in the writings of Edinger, Retzius, and Elliott Smith.

The Rhinencephalon comprises:

1. Peripheral parts.
2. Central or Cortical parts.

A comprehensive term for the peripheral part is *lobus olfactorius*, divisible into *pre-* and *postolfactory* parts.

- | | | |
|--------------------|---|--|
| Preolfactory lobe | { | 1. <i>Bulbus olfactorius</i> . |

| | | 9. <i>Gyrus subcallosus</i> and <i>Broca's diagonal band</i> . |

FIG. 680.—Schematic representation of the rhinencephalon, basal aspect.

THE PREOLFACTORY DIVISION.—The olfactory bulb and tract form a long and slender band with a bulbous extremity situated on the basal aspect of the frontal lobe and constituting a rudimentary remnant of a relatively large diverticulum, developed from the sensor ectoderm close to the border of the neural plate before it becomes converted into the neural tube and situated on either side of the neuropore at the extreme frontal end. Although hollow at first, the cavity (rhinocele) soon becomes obliterated.

The **olfactory bulb** (*bulbus olfactorius*) is an oval mass of reddish-gray color, which rests on the cribriform plate of the ethmoid and is received in the olfactory fissure on the orbital surface of the frontal lobe. It receives the numerous

olfactory nerves (*fila olfactoria*) from the nasal mucous membrane. The **olfactory tract** (*tractus olfactorius*) is a band of white substance, of prismatic outline on section, its apical ridge fitting into the olfactory fissure. Toward its root region it is somewhat narrowed.

The medial and lateral olfactory gyres are also termed the medial and lateral roots of the tract, and diverge in the region of the trigonum. The **olfactory tubercle** (*tuberculum olfactorium*) is best seen if the bulb and tract be lifted away from the olfactory fissure; the tubercle appears as a small pyramidal elevation, its apex buried in the olfactory fissure, its irregularly triangular base forming the **trigonum olfactorium**, a small gray area frontad of the anterior perforated substance. This area is marked by ridge-like elevations which appear like radiating roots of the tract, and named, according to their position, the **medial, intermediate, and lateral roots, striæ or gyres**. The **lateral olfactory stria or gyre** is continuous with the **limen insulæ** in the depths of the basisylvian cleft, and thence passes to the uncus to end in the **gyrus ambiens** and **gyrus semilunaris**. The sharp turn made at the limen insulæ is called the **angulus lateralis**. The **medial olfactory stria or gyre**, a narrow gyral band, proceeds mesad and merges with the adjacent cerebral surface; its extension on the mesal surface is known as the **parolfactory area** (Broca) limited frontad by the **anterior parolfactory sulcus** (*sulcus parolfactorius anterior*) and separated from the subcallosal gyre by the **posterior parolfactory sulcus** (*sulcus parolfactorius posterior*).

The **intermediate stria** is not always very distinct; when present it may be traced from the proximal end of the olfactory tract for a short distance over the gray field of the trigonum, to plunge into the gray of the anterior perforated substance.

POSTOLFACTORY DIVISION.—The **anterior perforated substance or space** (*preperforatum*) occupies an irregular quadrate field between the olfactory trigone and the optic chiasm and tract. A more or less marked groove (*sulcus parolfactorius posterior*), which is identical with the *fissura prima* (His) of the embryo, separates the trigonum from the anterior perforated substance. Its frontal part, much perforated, is of a darker color than the hind portion; the latter is distinguished by the name of **Broca's diagonal band**. This courses obliquely laterad along the optic tract toward the uncus; mesally the bands of the two sides converge, frontad of the lamina terminalis, and proceed toward the rostrum of the corpus callosum as narrow fields which taper to curve around the genu and continue in the indusium of the corpus callosum as the **striæ longitudinales**. The narrow field seen on the mesal aspect frontad of the lamina terminalis and anterior commissure is known as the **gyrus subcallosus** (*formerly peduncle of the corpus callosum*). The continuity of the various parts may be understood by reference to Figs. 680 and 681.

The cortical and central part of the rhinencephalon comprise:

- | | | |
|----------|---|--|
| Cortical | { | 1. The hippocampus. ¹ |
| | | 2. The uncus. |

¹ Not to be confounded with the *hippocampal gyre* of the pallium.

CENTRAL OR CORTICAL PARTS OF THE RHINENCEPHALON.—Following the suggestion made by Broca in 1878, it has been customary to designate these various parts by the comprehensive term **limbic lobe**. Broca's notion of the limbic lobe in man was founded upon attempts to homologize the human cerebral configurations with those found in lower animals. More recent researches have proved that Broca's "limbic lobe" included parts belonging to the neopallium and not to the rhinencephalon. The term is therefore inappropriate in a morphologic sense.

The **hippocampus** is the submerged, peculiarly folded margin of the cerebral hemisphere produced by the hippocampal fissure. Its architecture can best be understood by referring to a frontal section (Fig. 682). It is seen that the whole cerebral marginal wall is pushed into the ventricular cavity (middle cornu) as a fold caused by the intrusion of the hippocampal fissure. A secondary fold not produced by a fissure, however—constitutes the **gyrus dentatus**. Superimposed lies a prominent white band—the **fimbria**—composed of axones from

FIG. 681.—Schematic representation of the rhinencephalon, mesal aspect.

the hippocampal cells, assisting in the formation of a white lamina, subjacent to the ependyma of the ventricle, and called the **alveus**. The whole formation is characteristic of this region, and from its fancied resemblance to a ram's horn—a symbol used on the temple of Jupiter Ammon—the name of **cornu ammonis**¹ has been given; the name **hippocampus** was applied because of a fancied resemblance to the marine animal of the same name. The ventricular relations and internal structure of the hippocampus will be given farther on (p. 943).

The **uncus**, with the atrophied lateral olfactory stria, is all that remains in the human brain of the relatively large pyriform lobe of lower forms. It appears to be a hook-like retroflexion of the hippocampal gyre which is partially encircled by the gyrus dentatus. Morphologically speaking, it is only the apical portion, or that which lies caudad of the dentate gyre which is the true uncus (the *gyrus intralimbicus* of Retzius); the remainder is neopallial and a part of the hippocampal gyre. The uncinate or intralimbic gyre may be traced caudad in the

¹ Frequently, but incorrectly, given as *Ammon's Horn*.

The **indusium** (*gyrus epiccallosus s. supracallosus*), considered to be a vestige of the hippocampus, is a thin strip of gray substance superimposed upon the corpus callosum and raised into two paired ridges by longitudinal fibre bundles which constitute the **mesal** and **lateral longitudinal striæ**.¹ The indusium and its striæ are continued cephalad into the gyrus subcallosus; perhaps, also, into the parolfactory area (Fig. 681).

The central connections of the rhinencephalon will be considered in the description of the internal configuration of the hemisphere. (See Fornix, Anterior Commissure, etc.)

Internal Configuration.—Each cerebral hemisphere contains a cavity, the **lateral ventricle** (*paracele*), an extension of the primitive neural cavity carried outward, its contours modified by the developmental changes in the growth history of the secondary fore-brain vesicle. This central cavity is surrounded by the thick, convoluted walls of nerve tissue which make up the bulky cerebral hemispheres. The cerebral tissue, as elsewhere in the central axis, is made up of gray and white

FIG. 683.—Mesal view of a partly dissected cerebral hemisphere, to show the relations of fimbria, fasciola cinerea, dentate gyre, and uncus.

substances. Two well-marked types of gray substance are recognizable: (a) the **cortical**, so named because its situation upon an interior white centre invites comparison with the rind (cortex) of a fruit; (b) the massive **ganglionic** or nugget-like masses not dissimilar from the thalamus already described, comprising, in this division of the brain, the **caudate**, **lenticular**, and **amygdaline nuclei**. The **white substance** fills out the entire space intervening between the cortex, the cavity of the lateral ventricle, and the great basal ganglia, and is composed of myelinic axones which connect the elements of the cortex with other parts of the nerve system, or with other regions of the cortex of the same or the opposite cerebral hemisphere.

If a brain, resting upon its basal surface, be sliced by successive horizontal sections from above, the peripheral gray and internal white are brought into view.

¹ The mesal striæ are also called *Striæ Lancietii*; the lateral striæ, *Teniae lectae*.

The more superficial sections reveal relatively more gray than white substance; deeper sections show a reverse condition, and a section immediately dorsad of the corpus callosum reveals, in each cerebral hemisphere, a very extensive semioval field of white substance, the **centrum semiovale**, surrounded on all sides by a narrow, convoluted margin of gray substance, the **cortex**. A close examination of the cut surface, in a fresh and normal brain, shows it to be studded with numerous minute red dots (*puncta vasculosa*) produced by the escape of blood from divided blood-vessels.

The Cortex.—The cortex, as revealed in such a section, is not of uniform thickness throughout; different regions show different cortical thicknesses. In general, the cortex is somewhat thicker at the summit of a gyre than in the depths of an adjoining fissure, and it is thicker upon the convex than upon the mesal or basal surfaces. The maximum thickness is observed in the cortex of the central gyres

FIG. 684.—Corpus callosum. (From above.)

and the insula; the minimum at the frontal and occipital poles, notably the latter. Not only is the cortex not of uniform thickness, but it is not of homogeneous structure as seen with the naked eye. An alternation of gray and white stripes is discernible, particularly in the occipital cortex, where a white band runs parallel with the cortical surface between two gray strata; this white stripe, first described by Gennari and usually bearing his name, is also called the **band of Vicq d'Azyr**.

The preponderance of white substance over gray substance in the cerebrum is a human characteristic concomitant with the relative increase of the association cortex, in turn demanding a more intricate interconnection of the many nerve cells by a multitude of association neurones. These

coördinating fibre systems are as truly representative of the complexity of man's thought apparatus as the number of interconnecting wires within a telephone "central" station is indicative of the amplitude of connections possible in that system. The proportions of gray and white substances are expressed in the following tabulation:

Gray substance	{ Cortex	33 per cent.
	{ Ganglia	6 per cent.
White substance	61 per cent.

The removal, by successive slices, of the dorsal parts of the cerebrum soon brings into view the large expanse of transverse myelinic fibres, the **corpus callosum**, which connects the two hemispheres.

The Corpus Callosum (*trabs cerebri; commissura maxima*).—The corpus callosum is a thick stratum of transversely directed nerve fibres, by which almost every part of one cerebral hemisphere is connected with the corresponding part of the other cerebral hemisphere (Figs. 685 and 686). The axones composing it arise from the

FIG. 685.—Diagram of coronal section of cerebrum to show course of fibres of corpus callosum. (Testut.)

FIG. 686.—Diagram of horizontal section of cerebrum to show course of fibres of corpus callosum. (Testut.)

small pyramidal or the polymorphous cells of the cerebral cortex, or they may be collaterals from the long association or even the projection neurones. They pass in both directions and within the **centrum semiovale** radiate in various directions (**radiatio callosi**) between the fibres of the corona radiata to terminate in the layer of small pyramidal cells of the cortex, thus forming a great transverse commissural system, and at the same time roofing in the greater part of the lateral ventricle in each half. A portion of the dorsal surface is free for a width of about 1 cm. on either side of the mesal plane, partly covered by the indusium and overlapped by the callosal gyres of the two sides, a fold of pia intervening.

The mass of radiating fibres may, for convenience of description, be subdivided into a **pars frontalis**, a **pars parietalis**, and a **pars occipitotemporalis**. The frontal and occipitotemporal portions are compressed or thickened mesally because the fibres cannot pass directly across, but curve, respectively, frontad and caudad in each hemiserebrum to form two tong-like bundles, the **forceps anterior s. minor** (*preforceps*), and **forceps posterior s. major** (*postforceps*). The pars parietalis constitutes the greater part of the "body" of the corpus callosum. The fibres traversing the **body** (*truncus corporis callosi*) and the adjacent part of the splenium curve around the posterior cornu and trigonum ventriculi of the lateral ventricle, to form a thin but definite white stratum, the **tapetum**, in the roof and ectal wall of these parts of the cavity.

The transverse direction of the fibres is rendered apparent in a dorsal view of the exposed corpus callosum in the form of the **striae transversae**. These are

but little obscured by a thin, gray lamina—the **indusium**—which is thickened longitudinally by two symmetrically situated fibre strands, the **mesal** (*striae Lancisii*) and **lateral longitudinal striae** (*teniae tectae*), already mentioned as rudiments of the rhinencephalon.

The best conception of the size and form of the corpus callosum is obtained from a view of a mesal section. It is then seen to be a long, thick, somewhat flattened arch which bends sharply upon itself frontad to form the **genu** (*genu corporis callosi*), while its caudal end is rounded and somewhat folded closely upon itself to form the **splenium**. The corpus callosum ranges in length from 7 to 10 cm., its cross-section area from 5 to 10 sq. cm., being longer and larger in heavier brains and in those of the highly intellectual as compared with smaller and less highly efficient brains. It extends to within 4 cm. of the frontal pole and to within 6 cm. of the occipital pole. The thickness of the “body” averages 5 mm.; of the splenium, 9 mm. or more, while the maximum thickness of the genu is about 13 to 15 mm. The reflected portion or **rostrum** (*rostrum corporis callosi*) gradually tapers into a very thin lamina, the **copula** (*lamina baseos alba*), which in turn joins the lamina terminalis frontad of the anterior commissure.

The **splenium** (*splenium corporis callosi*) projects as a rounded welt over the mid-brain, but is separated from it by a pial fold—the **velum interpositum**. Farther frontad the fornix becomes fused to the ventral surface of the corpus callosum for a short distance, to again leave it in its more arched course toward the corpus albicans. Two thin laminae, one on either side of the median plane, but closely applied to each other and frequently partially fused, occupy the interval between corpus callosum and the fornix of each side. The laminae together are termed the **septum lucidum** of the authors, each one being called a **hemiseptum**; the enclosed cavity is called the **fifth ventricle** or **pseudocoel**, though not derived from the original neural cavity.

FIG. 687.—Schemata showing the development of the corpus callosum and its relations to hippocampus, fornix, and anterior commissure. Lamina terminalis (terma) in heavy black, corpus callosum dotted. * Represents the attenuated indusium and longitudinal striae already described.

Development.—The corpus callosum develops as a mass of commissural fibres which grow from side to side in the lamina terminalis (terma). The lamina terminalis serves as a matrix for several commissural systems—viz., the hippocampal commissure and the anterior commissure, in addition to the corpus callosum. The last develops rapidly in higher mammalian brains, thrusts aside the hippocampal margin of the pallium so that it atrophies in large part, and stretches out within its sharply bent arch a portion of the precommissural wall of each cerebral vesicle. It thus withdraws a part of the intercerebral cleft, eventually enclosing it entirely as the fifth ventricle. The stages of development are shown schematically in Fig. 687 and its development in the human embryo is shown in Fig. 688. The corpus callosum is most fully developed in man and does not appear below the marsupials. Its growth kept pace with the preponderatingly greater development of the neopallium in higher forms, and it may be looked upon as an index of the elaboration of at least one division of the association systems—those concerned with bilateral coördinations.

FIG. 688.—Brains of human embryos; mesal aspects of median sagittal section show the development of the corpus callosum: *A*. Fourth month. *B*. Fifth month. *C*. Sixth month. *D*. Seventh month.

The Lateral Ventricles.—An incision through the corpus callosum, on either side of the median plane, will expose two large, irregular, symmetrically situated cavities, the **lateral ventricles** (*paraceles*), extending through a great part of each cerebral hemisphere. Each lateral ventricle communicates with the third ventricle through a small opening, the **foramen of Monro**, situated between the fornix (anterior pillar of fornix) and frontal end of thalamus. The cavity is lined throughout by ependyma; it is narrow in some and wide in other localities, and contains cerebrospinal fluid.

The shape of the ventricle is best understood by reference to a cast of its interior, and its location within the cerebrum may be appreciated by a study of Figs. 689 and 690. Conventionally the lateral ventricle or paracele is described as being composed of a **body** or **cella** and three horn-like extensions or **cornua**. Viewed laterally its contour corresponds to that of the cerebral hemisphere and its cornua project toward the three poles—viz., frontal, occipital, and temporal.

FIG. 689.—Showing the ventricular system of the brain as a solid cast as if seen through a transparent brain.

The **body** (*pars centralis ventriculi lateralis*) or **cella** of the lateral ventricle is defined as that portion which extends from the foramen of Monro to the region of the splenium. Its frontal prolongation is called the **anterior horn** or **precornu**. Near the splenium the cavity may be traced ventrolaterad into a capacious part (*trigonum ventriculi*), from which the **posterior horn** (*postcornu*) and **middle horn** (*medicornu*) are prolonged, respectively, toward the occipital and temporal poles.

The **anterior horn** or **precornu** (*cornu anterius*) passes frontad, inclined slightly ventrolaterad. Its **floor** is the head (*caput*) of the caudate nucleus, forming a rounded incline sloping mesad toward a trench-like recess floored by the rostrum of the corpus callosum. Its **roof** is the anterior forceps of the corpus callosum. Its **mesal wall** is formed by a portion of the hemiseptum of the septum lucidum. *Laterally* it is limited by the apposition, at an acute angle, of corpus callosum and caudate nucleus. Its **apex** reaches the ventricular surface of the genu of

FIG. 688.—Brains of human embryos; mesal aspects of median sagittal section show the development of the corpus callosum: *A*. Fourth month. *B*. Fifth month. *C*. Sixth month. *D*. Seventh month.

The Lateral Ventricles.—An incision through the corpus callosum, on either side of the median plane, will expose two large, irregular, symmetrically situated cavities, the **lateral ventricles** (*paraceles*), extending through a great part of each cerebral hemisphere. Each lateral ventricle communicates with the third ventricle through a small opening, the **foramen of Monro**, situated between the fornix (anterior pillar of fornix) and frontal end of thalamus. The cavity is lined throughout by ependyma; it is narrow in some and wide in other localities, and contains cerebrospinal fluid.

The shape of the ventricle is best understood by reference to a cast of its interior, and its location within the cerebrum may be appreciated by a study of Figs. 689 and 690. Conventionally the lateral ventricle or paracele is described as being composed of a **body** or **cella** and three horn-like extensions or **cornua**. Viewed laterally its contour corresponds to that of the cerebral hemisphere and its cornua project toward the three poles—viz., frontal, occipital, and temporal.

FIG. 689.—Showing the ventricular system of the brain as a solid cast as if seen through a transparent brain.

The **body** (*pars centralis ventriculi lateralis*) or **cella** of the lateral ventricle is defined as that portion which extends from the foramen of Monro to the region of the splenium. Its frontal prolongation is called the **anterior horn** or **precornu**. Near the splenium the cavity may be traced ventrolaterad into a capacious part (*trigonum ventriculi*), from which the **posterior horn** (*postcornu*) and **middle horn** (*medicornu*) are prolonged, respectively, toward the occipital and temporal poles.

The **anterior horn** or **precornu** (*cornu anterius*) passes frontad, inclined slightly ventrolaterad. Its **floor** is the head (*caput*) of the caudate nucleus, forming a rounded incline sloping mesad toward a trench-like recess floored by the rostrum of the corpus callosum. Its **roof** is the anterior forceps of the corpus callosum. Its **mesal wall** is formed by a portion of the hemiseptum of the septum lucidum. *Laterally* it is limited by the apposition, at an acute angle, of corpus callosum and caudate nucleus. Its **apex** reaches the ventricular surface of the genu of

the corpus callosum. The general outline of this part of the ventricle, in a frontal section, is triangular (Fig. 700).

The **body** of the cavity is curved with its convexity dorsad; its outline in trans-sections varies from the triangular to a mere slit which slopes slightly meso-ventrad. It is wholly *roofed* in by the corpus callosum (*pars frontoparietalis*). Its *floor* is formed by the following structures named in order from its *ectal* toward

FIG. 690.—Dissection showing the left lateral ventricle (paracele) exposed.

its ental limit: (1) **caudate nucleus** or **caudatum**; (2) a groove which marks the line of coalescence of caudate nucleus and thalamus and lodges the *taenia vein* and a narrow fibre strand—the *taenia semicircularis*, beneath the ependyma; (3) a reflexion of the ependyma onto a narrow area of the thalamus; (4) the **choroid plexus of the lateral ventricle** (*paraplexus*); (5) the thin, sharp (fimbriated) edge of the **fornix**. The caudate nucleus narrows rapidly as it passes caudad.

The **taenia semicircularis**, lying along the ental border of the ventricular surface of the **caudate nucleus**, is a small band of white fibres arching from the amygdaline nucleus (near the temporal pole) to the anterior perforated substance. The entrance of a part of the thalamus into the formation of the floor of the lateral ventricle is apparent enough, but morphologically it should be strictly excluded therefrom. The thalamus is in no way formed from the parietes of the secondary fore-brain vesicles (telencephalon), for it is, in fact, excluded by a layer of ependyma (*lamina affixa*) reflected onto, and often separable from, the surface of the thalamus, so that it *appears* as a constituent of the floor because of the transparency of the ependymal sheet. The choroid plexus of the lateral ventricle is a richly vascular invagination over which the ependyma is continuous to again become reflected onto the fornix along its sharp edge. A reference to Fig. 666, showing the topographical relations of these structures in a frontal section, may be of assistance.

The cavity is thence continued ventrolaterad in a bold sweep to become expanded as an obliquely pyramidal space of a somewhat triangular outline on section, and placed subjacent to the parietal lobe—the **trigonum ventriculi**. A conspicuous feature in its floor is the **collateral eminence**, correlated with the collateral fissure. From the trigonum, the most capacious part of the lateral ventricle, the cavity is prolonged in opposite directions as the middle and posterior cornua.

FIG. 691.—Coronal section of descending horn of the lateral ventricle. (Diagrammatic.)

The **middle horn** or **medicornu** (*cornu inferius*) is a prolongation of the ventricular cavity, from its trigone toward the temporal pole, which pursues a curved course with its convexity directed ventrolaterad (Figs. 689 and 690), corresponding to the curved contour of the temporal lobe, and situated at a depth of about 3 cm. from its lateral surface as well as from the temporal pole. The **roof** is formed by (a) the **tapetum of the corpus callosum**; (b) the **cauda** (tail) of the **caudate nucleus**; (c) the **taenia semicircularis**. The **medial wall** is principally composed of the **hippocampus**, a prominent welt-like eminence bulging into the cavity, largely filling it, and produced by the hippocampal fissure. The hippocampus nearly conceals from view the actual **floor**, which is of variable extent in different brains and usually marked by an extension of the collateral eminence previously described. Surmounting the corrugated hippocampal formation and projecting slightly into the cavity, is the **fimbria**, and from its sharp edge the ventricular ependyma

is reflected upon the invaginated choroid plexus of the lateral ventricle. The choroid plexus of the middle cornu is more voluminous than that of the body of the ventricle, and must be lifted in order to expose the whole of the ventricular aspect of the hippocampus.

At the *apex* of the middle cornu the roof presents a more or less pronounced bulging, the **amygdaloid tubercle**, due to the presence of the amygdaline nucleus, a small mass of ganglionic gray from which the taenia semicircularis arises and in which the caudate nucleus apparently ends.

The **posterior cornu** or **postcornu** is a shorter diverticulum which passes toward the occipital pole in a gently curved course, with its convexity directed laterad. It is not very capacious, usually slit-like on section, and tapers to a point within 2 or 3 cm. of the occipital pole. Its *roof*, slanting lateroventrad, is formed by the

FIG. 692. —Diagram showing the topography of the lateral ventricle, middle meningeal artery, and cerebrum within the cranium.

tapetum of the corpus callosum. On the inner or *mesal wall* two elongated bulgings may be observed. The upper or dorsal elevation, called the **occipital bulb** or **bulb of the cornu** (*bulbus cornu posterioris*, *callosal eminence* [Wilder]), is formed by the compact arched posterior forceps of the corpus callosum as it curves around the very deep occipital fissure. The occipital bulb is not always well marked. Ventrad of it lies a more constant limbus or welt-like elevation, the **calcar** (*calcar avis*; *hippocampus minor*), a projection produced by the infolding of the cerebral wall along the calcarine fissure. The choroid plexus does not enter the posterior cornu.

The **choroid fissure** or **rima** (*rima transversa cerebri magna*; *fissure of Bichat*) is not a true fissure, and only becomes one when the choroid plexus of the lateral ventricle is torn from its connections. The choroid fissure is nevertheless a gap between the diencephalic part and the overlapping and recurved telencephalon produced by the extension of the secondary fore-brain vesicles in an arcuate manner.

It is along this arcuate and fissure-like gap (Fig. 693) that the richly vascular (pial) choroid plexus invaginates the atrophied parietes of the secondary fore-brain to form the choroid plexus which is everywhere covered by ependyma. The choroid fissure extends from the foramen of Monro to near the tip of the middle cornu in an arcuate course, and ependymal reflections everywhere close in this gap except at the foramen of Monro. The manner in which this is accomplished may best be understood by a study of a trans-section showing the ependymal reflections from the ventricular wall onto the invaginated choroid plexus (Fig. 666). The caudatothalamic fusion and the intrusion of the great fibre masses constituting the cerebral crura play their parts in complicating the relations in brains of higher type.

FIG. 693.—Diagram showing the choroid fissure.

The Choroid Plexus of the Lateral Ventricle (*paraplexus*) and Velum Interpositum.

—The choroid plexus is a highly vascular, fringe-like structure composed of pia which is invaginated into the lateral ventricle along the choroid fissure, or gap between cerebral hemisphere and diencephalon. The portion of the choroid plexus protruding into the “body” of the lateral ventricle is the fringed vascular border—a triangular fold of pia—the *velum interpositum* (*tela choroidea superior*), which, as its name implies, is interposed between the relatively small primary fore-brain and the enormous overlapping secondary fore-brain, and is produced by the overgrowth of the latter onto the former. Inasmuch as the nerve tissue in the roof of the third ventricle atrophies totally, the ventral fold of the pia comes into contact with the ependyma of that ventricle and here permits a similar vascular invagination in the form of two parallel fringes hanging into the cavity (*diaplexus* or *choroid plexuses of the third ventricle*). The dorsal leaf of the pial fold is in contact with the ventral face of the body of the fornix. Frontad, the velum interpositum tapers toward the region of the two foramina of Monro, where the choroid plexuses of the two sides are continuous with each other. The ventricular surface of the choroid plexuses is everywhere covered by ependyma which is reflected from it to the fimbriated edge of the fornix on the one hand and to the line of the taenia semicircularis (over the thalamus by the lamina affixa) on the other. Its vascular components, in addition to undefined lymphatic channels, are the *anterior choroid artery*, a branch of the internal carotid, entering the plexus of the middle cornu; and the *posterior choroid artery* from the posterior cerebral artery reaching the choroid plexus in the neighborhood of the splenium. The venules of the plexus join to form a tortuous *middle cornual vein* which terminates frontad by joining one of the *velar veins*.

FIG. 694.—Diagram showing the mode of formation of the velum interpositum.

FIG. 695.—The fornix, velum interpositum, and middle cornu of the lateral ventricle.

The **velar veins** (*veins of Galen*), one on either side close to the median line, running in the fold of the velum interpositum, are formed by the union of the **tenial**, **striatal**, and **middle cornual veins**. The two velar veins unite to form a common trunk which empties into the straight sinus.

The Hippocampus and Fornix.—The hippocampus and the fornix merit special description. The **hippocampus**, as seen in the middle cornu, is a white eminence about 5 cm. (2 inches) in length, of a curved elongated form, enlarging cephalad and tapering caudad as the hippocampal fissure decreases in depth. The enlarged extremity is marked by alternate elevations and depressions, usually three in number, the **hippocampal digitations**; because of its resemblance to a lion's paw it is sometimes called the **pes leonis** or **pes hippocampi**. The white appearance of the ventricular aspect of the hippocampus is due to a stratum of white substance, the **alveus**, made up of myelinic axones from hippocampal cells and continued into the fimbria. The fimbria is folded so that its sharp margin is directed

FIG. 696.—Posterior and descending cornua of left lateral ventricle exposed from the side.

toward the cavity of the middle cornu; eventually its fibres will be seen to enter into the formation of the fornix. The formation of the hippocampus is best observed in a coronal section (Fig. 682). In this view it is seen to be a peculiarly folded margin of the cerebral cortex, corrugated by the intrusion of the hippocampal and fimbriodentate fissures. Morphologically it is a vestigial submerged portion of the rhinencephalon, as a part of which it has already been described (p. 930).

The **fornix** (Figs. 697, 698) is really a paired structure consisting of bilaterally symmetrical halves composed of longitudinally directed fibres which arch on each side from the region of the uncus to the corpus albicans. The two lateral parts join each other in the mesal plane along the summit of the arch to form the **body of the fornix** (*corpus fornicis*). Frontad they diverge slightly as they proceed toward the corpus albicans; caudad they diverge more widely. The paired diverging portions are called respectively the **anterior** and **posterior pillars of the fornix**. The fibres of each half fornix arise from the pyramidal cells in the hippo-

campus, and their course will be traced from this source to the ending in the corpus albicans. Beginning at first as a stratum of white substance (*alveus*) constituting the ectal surface of the ventricular bulge of the hippocampus, the fibres

FIG. 697.—The fornix, hippocampal commissure, splenium, and dentate gyrus seen from the basal aspect.

become collected along its medial border in a narrow but distinct folded band, the *fimbria*. This increases in diameter as increments are added to it along its course, until, at the apical region of the trigonum ventriculi, it leaves the dwindling hippocampus to ascend in a curved course (dorsimesad) toward the

FIG. 698.—Diagram of the fornix.

subsplenial callosal surface as a thick, flattened band. Once free from the hippocampus on each side, the two converging bands of opposite sides are called the *posterior pillars* or *crura fornicis*. The majority of the fibres continue frontad

in each half fornix, but a number course transversely to enter the crus fornix of the opposite side to end in the hippocampal formation. These fibres, of transverse course, form a thin lamina filling in the small triangular space in the subsplenial region between the converging crura fornix and constituting the **hippocampal commissure** (*lyra*; *psalterium*). Occasionally a small recess called **Verga's ventricle** is formed between the corpus callosum and the hippocampal commissure.

The two half fornices now become joined in the mesal plane and, leaving the subsplenial surface of the corpus callosum, dip frontoventrad in an arch—the **body of the fornix**. Its caudal part is broad and each half is of triangular outline (on section) with a sharp edge directed laterad. Where it is not in contact with the corpus callosum it affords attachment, on each side of the mesal plane, to the hemiseptum of the septum lucidum. Laterad of these lines of attachment the dorsal surface of each fornix enters into the formation of the floor of the lateral

FIG. 699.—A frontal section of the brain slightly caudad of the genu of the corpus callosum.

ventricle and is covered by ependyma (Fig. 690). The ventral surface rests upon the velum interpositum, which separates it from the third ventricle and the dorsal surface of the thalamus (Fig. 666).

Near the region of the anterior commissure the fornix again divides into its constituent lateral halves, separating as rounded strands called the **anterior pillars** (*fornicolumns*). These curve ventrad to form the frontal boundary of the foramen of Monro and thence plunge into the hypothalamic gray, inclined slightly caudad, to end in the corpus albicans. The terminals of the fornix fibres come into relation with the cells of the nucleus of the corpus albicans, which, in turn, give off the bifurcating Y-shaped axone bundles already described (p. 908).

In rare instances each anterior pillar has been seen to divide on approaching the anterior commissure, a part passing frontad thereof as an anomalous pre-commissural pillar of the fornix. The fornix, in its course from hippocampus to corpus albicans, gives off, in addition to those described as hippocampal commissural fibres, axones (a) to the opposite half fornix, decussating in the fused portion (body), (b) to the hemiseptum of the septum lucidum, and (c) to

the gray tissues of the anterior perforated substance (Fig. 681). It constitutes an *inner* olfactory arc as distinguished from the epicallosal or outer arc, represented by the atrophied indusium and its longitudinal striæ.

FIG. 700.—A frontal section through the brain in the plane of the junction of caudate and lenticular nuclei.

FIG. 701.—A frontal section of the brain in the plane of the anterior commissure.

The Septum Lucidum (*septum pellucidum*).—The so-called septum lucidum really consists of two vertically placed **laminae** or **hemisepta**. Between them lies a narrow, enclosed space, the **cavum septi pellucidi** (*pseudocoele*; *fifth ventricle*),

roofed in by the corpus callosum, while the floor consists of the fused fornices and the rostrum. Each hemiseptum bounds a part of the anterior cornu and body of the lateral ventricle in its mesal wall, and in a lateral view is of triangular outline. The hemisepta represent the thin, undeveloped parts of the mesal walls of the cerebral vesicles, which were enclosed within the rapidly developing arch of the corpus callosum. The *cavum septi pellucidi* is therefore a closed-off part of the original intercerebral cleft and not a part of the neural cavity, as its older name, "fifth ventricle," seems to imply.

The Anterior Commissure.—The anterior commissure, or *precommissure*, is a bundle of white fibres, of oval outline in a sagittal section, which crosses the midline as a localized reinforcement of the lamina terminalis, slightly bulging into the frontal part (aula) of the third ventricle and clothed by its ependyma. It is a comparatively insignificant intercerebral commissure in the human brain, having become diminished as the corpus callosum increased in mammalian development. It courses from side to side frontad of the anterior pillars of the fornix, ventrad of the head of the caudate nucleus, and passes, in part, through the frontal end of the lenticular nucleus (Fig. 701). Its fibres radiate chiefly to the cortex of the temporal lobe and to certain parts of the rhinencephalon.

The bundle is slightly twisted in each lateral, buried part. Two divisions are distinguishable: (1) The *pars anterior* or *frontal part* (in the median plane) contains two groups of fibres belonging to the olfactory apparatus—(a) fibres arising from the mitral cells in the olfactory bulb of one side to the same layer in the opposite bulb; (b) fibres which associate the uncus of one side with that of the other. (2) The *pars posterior* contains the fibres passing between the cortices of the two temporal lobes.

Gray Masses in the Cerebral Hemisphere.—Aside from the cortex, the cerebral hemisphere contains certain gray ganglionic masses in its interior, more or less embedded in the white centrum, and called, because of their proximity to the base of the cerebrum, the *basal ganglia*. These comprise the *caudate*, the *lenticular*, and the *amygdaline nuclei*. It is usual to include the *claustrum* among the basal ganglia, but morphologically this structure belongs rather to the insular cortex of the island of Reil.

Conventionally the caudate nucleus and lenticular nucleus together are described as the *corpus striatum* (*striatum*), a ganglionic mass which in earlier vertebrate brains bore intimate relations with the olfactory apparatus, but later, with the rise in functional dignity and growth of the neopallium, underwent specialization and differentiation concomitant with the reduction of the rhinencephalon. The intrusion of great projection fibre masses, thrusting the cortical gray outward, has not been everywhere uniform, and we still find, in the human brain, a common ground in which the neopallial cortical gray, the corpus striatum, rhinencephalon, and amygdaline nucleus meet—the site of fusion being in the gray substance of the anterior perforated substance. To the cortical mantle they are regarded as bearing the relation of subordinate (subcortical) centres. In the human brain the *corpus striatum*—so called because of its striated appearance in sections—is composed of two masses, the *caudate* and *lenticular nuclei*, directly continuous with each other at their frontal ends (Fig. 703). The connecting gray bridge becomes broken up into numerous small bands of gray substance as the fibre masses of the internal capsule insinuate themselves between the two nuclei (Fig. 700).

The *caudate nucleus* (*caudatum*; *nucleus caudatus*) (Figs. 702, 703) presents a ventricular and a capsular surface; the ventricular surface, covered by ependyma, forms part of the floor of the body and anterior cornu, while in the middle cornu it is a constituent of its roof, owing to its arched contour in correspondence with the sweeping curve of the ventricle itself. It is of a pyriform shape with a very

much attenuated tail. The large, thick head projects into the **anterior cornu**, while its thinner tail is prolonged caudolaterad, separated from the **thalamus** by the narrow **taenia semicircularis**. Following the curved contour of the ventricle it is prolonged as a narrow gray band in the roof of the middle cornu, where it joins the **amygdaline nucleus**. The nonventricular or capsular surface is embedded in the white substance of the cerebral hemisphere, and is chiefly related to the **internal capsule**

FIG. 702.—The basal ganglia and thalamus schematically represented in a supposedly transparent brain (right side); on the left is shown the outline of the lateral ventricle.

The ventricular surface shows, in microscopic sections, a dense ependymal lining. The capsular face is not sharply outlined, numerous strands of fibres, to and from the internal capsule, entering it obliquely so as to appear as streaks which extend to about the middle of the ganglion, there separating into finer and finer strands which become lost to the naked eye.

The **lenticular nucleus** (*lenticula*) (Figs. 701 and 702) is wholly embedded in the white substance, and must be studied in sections. In its shape it resembles an irregular triangular pyramid with its convex base directed laterad and parallel with and near to the cortical expanse of the island of Reil and of about the same extent. Its ental, apical portion is directed toward the interval between caudate nucleus

(head) and thalamus. The contour and slope of the surfaces of the ental pyramidal face may be judged from the model pictured in Fig. 703. Its outline, as revealed in sections passing in different planes, is shown in Figs. 701 and 704.

Sections of the lenticular nucleus show it to be composed of three¹ concentric segments separated by two white medullary laminae. The segments are known as **artificuli**; the ectal one is designated the **putamen**; the two ental zones constitute the **globus pallidus** (*pallidum*). The **putamen** is the larger and of a deeper reddish-gray tint; the two mesal divisions are lighter in color owing to a greater proportion of radiating streaks of white fibres passing to and from the internal capsule. The ectal outline of the putamen is sharply defined against a white lamina, the **external capsule**.

The **amygdaline nucleus** (*amygdala*) is usually regarded as an hypertrophied aggregation of the temporal cortex which has become nearly isolated from its cortical connection by intruding white substance. It is a rounded, gray, striated mass situated in the fore part of the middle cornu at its apex, where it produces the bulging called the **amygdaloid tubercle**. Caudad it is joined by the tail of the caudate nucleus; frontad it is continuous with the putamen. Except for the marked streaking shown in sections, its structure is like that of the cortex. Its cells apparently give rise to the narrow band of fibres—the **taenia semicircularis**—which courses along the mesal margin of the ventricular surface of the caudate and ends in the gray of the anterior perforated substance, so that it nearly completes a circle.

The **claustrum** is a thin plate of gray substance embedded in the white substance which intervenes between the putamen and the cortex of the island of Reil, and corresponds in extent to these. Its dorsal edge is very much attenuated; traced ventrad it thickens considerably and becomes continuous with the surface gray at the anterior perforated substance. Its ectal surface presents alternate ridges and depressions which correspond to the corrugations of the cortex of the island of Reil. The “external capsule” intervenes between its ental face and the putamen of the lenticular nucleus. From the cortex of the island of Reil proper it is separated by a white lamina which may be termed the **periclastral lamina** or **capsula extrema**. Apparently the claustrum is the thickened and isolated spindle-cell stratum of the cortex of the island of Reil, a feature which may be of significance in relation to the preponderatingly associative function of the insular region.

Internal Capsule² (Fig. 704).—Between the lenticular nucleus on the one hand and the caudate nucleus and thalamus on the other lies the **internal capsule**, a broad

FIG. 703.—Two views of a model of the striatum: A. Lateral view aspect. B. Mesal view aspect.

¹ Four and even five have been observed.

² The terms *internal capsule* and *external capsule* owe their derivation to the fact that the lenticular nucleus is almost completely enveloped by white substance in the form of a capsule, of which the internal or mesal portion is relatively massive, while the external or lateral portion is thin.

band of white fibres which, as a leg is bent on the thigh, or caudatolenticular division of the caudate nucleus and of the lenticular nucleus, the limb lies between the frontal limb constituting the capsule mass.

ANT

COR

E

FIG. 706.—The motor tract. (Modified from Poirier.)

The **external capsule** (Fig. 704) is a thin lamina of white substance interposed between the ectal face of the lenticular nucleus and the claustrum. Dorsally, frontad and caudad, at the corresponding borders of the lenticular nucleus, it joins the internal capsule mass, while ventrally it is continuous with the white centrum of the temporal lobe. Its comparatively few projection fibres course to and from the ventral parts of the thalamus; its chief constituents are association axones for the circuminsular cortical areas.

Intimate Structure of the Cerebral Cortex and its Special Types in Different Regions (Fig. 707).—A section of the cerebral cortex reveals a tendency on the part of its constituent cells to arrange themselves in layers which alternate with zones less rich in cellular elements. Among the cells course the axones arising from them or terminating in their neighborhood. The axones are chiefly amyelinic, though some are myelinic for a part of their intracortical

last-mentioned system traverses the internal capsule to a greater or less extent, but does not continue into the crusta. These various systems are summarized on page 957. It may here be mentioned that the internal capsule, topographically, exhibits a functional dissociation in that its frontal or lenticulocaudate limb is composed of preponderatingly corticopetal fibres, while corticifugal fibres form the major portion of the thalamolenticular limb (Fig. 705). In the frontal limb are the **thalamofrontal** and **thalamostriate** fibres, the former ending in the cortex of the frontal lobe, the latter in the caudate and lenticular nuclei. The chief corticifugal components are the **frontopontile tract**, and fewer **frontothalamic** and **striatothalamic** fibres. The frontopontile tract arises in the cortex of the prefrontal region, traverses the frontal limb of the internal capsule, forms the ental sector (one-fifth) of the crusta, and ends in the nuclei pontis.

In the genu and the thalamolenticular limb of the internal capsule course several important fibre tracts which are chiefly corticifugal.

The **pyramidal (motor) tract**, in its course from the precentral cortex to the lower motor centres, occupies the frontal half of this limb. The portion in the genu, often designated the **geniculate tract**, comprises the pyramidal fibres which are destined to go to the facial and hypoglossal nerve nuclei; farther caudad lie, in succession, the fibres going to the motor centres for the upper and the lower extremity. The most caudal segment (also called the **retrolenticular part**) of the internal capsule contains (a) the **optic radiation**, composed of fibres coursing in both directions between the occipital cortex and the pulvinar, external geniculate and superior quadrigeminal bodies; (b) the **auditory radiation**, composed of

fibres passing in both directions between the cortex of the temporal lobe (auditory centre) and the posterior quadrigeminal and internal geniculate bodies; (c) the **occipitopontile** and **temporopontile tracts** from the occipital and part of the temporal cortex, coursing through the caudal segment of the internal capsule, constituting the ectal (one-fifth) sector of the crusta and ending in the nuclei pontis. In addition there are scattered fibre bundles which arise from the ventral portion of the thalamus, enter the internal capsule to pass toward the cortex, in part through

FIG. 705.—Diagram of the tracts in the internal capsule. Motor tract red. The sensor tract (blue) is not direct, but formed of neurones receiving impulses from below in the thalamus and transmitting them to the cortex. The optic radiation (occipitothalamic) is shown in violet.

the lenticular nucleus, in part in the sublenticular zone, to form the **ansa lenticularis**. The reinforcement of this sublenticular white-fibre tract by cortico-thalamic fibres from the temporal lobe to thalamus forms the **ansa peduncularis**. The topographic relations of the various tract masses as seen in a flatwise section is schematically shown in Fig. 706; on the whole, they correspond to the cortical areas with which they are connected.

FIG. 706.—The motor tract. (Modified from Poirier.)

The **external capsule** (Fig. 704) is a thin lamina of white substance interposed between the ectal face of the lenticular nucleus and the claustrum. Dorsally, frontad and caudad, at the corresponding borders of the lenticular nucleus, it joins the internal capsule mass, while ventrally it is continuous with the white centrum of the temporal lobe. Its comparatively few projection fibres course to and from the ventral parts of the thalamus; its chief constituents are association axones for the circuminsular cortical areas.

Intimate Structure of the Cerebral Cortex and its Special Types in Different Regions (Fig. 707).—A section of the cerebral cortex reveals a tendency on the part of its constituent cells to arrange themselves in layers which alternate with zones less rich in cellular elements. Among the cells course the axones arising from them or terminating in their neighborhood. The axones are chiefly amyelinic, though some are myelinic for a part of their intracortical

course. The cells, of various sizes and shapes, together with their dendrites and axones, are embedded in a matrix of neuroglia.

The nerve cells in a typical section of the cortex are arranged in five tangential layers, as follows: (1) the **molecular layer**; (2) the **ectal polymorphous cell layer**; (3) the **layer of small pyramidal cells**; (4) the **layer of large pyramidal cells**; (5) the **ental polymorphous cell layer**.

The **molecular layer** (*neuroglia layer*) lies immediately subjacent to the pia, and is chiefly made up of glia cells and fibres, among which the dendrites of the subjacent layer of cells intrude.

The **ectal polymorphous layer cells** are polygonal, triangular, and fusiform in shape, and tend to gather in groups in certain cortical regions. The fusiform cells are placed with their long axes parallel (*i. e.*, tangential) to the gyral surface and are presumably associative in function.

The Layer of Small and the Layer of Large Pyramidal Cells.—The cells in the second and third layers may be studied together, since, with the exception of the difference in size and the more superficial position of the smaller cells, they resemble each other. The body of each cell is pyramidal in shape, its base being directed to the deeper parts and its apex toward the surface. It contains granular pigment, and stains deeply with ordinary reagents. The nucleus is nucleolated, of large size, and round or oval in shape. The base of the cell gives off the axone, and this passes into the central white substance, giving off collaterals in its course to be distributed as a projection, commissural, or association fibre. Both the apical and basal parts of the cell give off dendrites. The apical dendrite is directed toward the surface, and ends in the molecular layer by dividing into numerous branches, all of which may be seen to be studded with projecting bristle-like processes when prepared by the silver or methylene-blue method. The larger pyramidal cells, especially in the precentral gyre, may exceed $50\ \mu$ in length and $40\ \mu$ in breadth, and are termed **giant cells**. The chief function of the small pyramidal cells is commissural and associative. The chief function of the large pyramidal cells in the precentral and paracentral cortex is motor, but they have also commissural and associative functions.

Layer of Ental Polymorphous Cells.—The cells in this layer, as their name implies, vary greatly in contour, the commonest varieties being of a spindle, star, oval, or triangular shape. Their dendrites are directed outward, toward, but do not reach, the molecular layer; their axones pass into the subjacent white substance. From this layer come commissural fibres, long association fibres, and some projection fibres.

There are two other kinds of cells in the cerebral cortex, but their axones pass in a direction opposite to that of the pyramidal and polymorphous cells, among which they lie. They are: (a) the **cells of Golgi**, the axones of which do not become myelinated, but divide immediately after their origin into a large number of branches, which are directed toward the surface of the cortex; (b) the **cells of Martinotti**, which are chiefly found in the polymorphous layer. Their dendrites are short, and may have an ascending or descending course, while their axones pass out into the molecular layer and form an extensive horizontal arborization.

Nerve Fibres in the Cortex.—These fill up a large part of the intervals between the cells. Some of these fibres form fasciculi; some are isolated, and others are arranged in plexuses. They may be myelinic or amyelinic, the latter comprising the axones of the smallest pyramidal cells and the cells of Golgi. In their direction the fibres may be either transverse, the **transverse**

FIG. 707.—Typical arrangement of the cell layers in the cerebral cortex.

tangential or horizontal fibres, or vertical, the **vertical or radial fibres**. The **tangential fibres** run parallel to the surface of the hemisphere, intersecting the vertical fibres at a right angle. They consist of several strata, of which the following are the most important: (1) A **stratum of white fibres** covering the superficial aspect of the molecular layer; (2) the **band of Bechterew**, found in certain parts of the superficial portion of the layer of the smaller pyramidal cells; (3) the **external or outer band of Baillarger** or the **band of Gennari**, which runs through the layer of large pyramidal cells; (4) the **internal band of Baillarger**, which intervenes between the layer of large pyramidal cells and the polymorphous layer. According to Cajal, the **tangential fibres** consist of (a) the collaterals of the pyramidal and polymorphous cells and of the cells of Martinotti; (b) the arborizations of the axones of Golgi's cells; (c) the collaterals and terminal arborizations of the projection, commissural, or association fibres. The **vertical fibres**: Some of these—viz., the axones of the pyramidal and polymorphous cells—are directed toward the central white substance, while others—the terminations of the commissural, projection, or association fibres—pass outward to end in the cortex. The axones of the cells of Martinotti are also ascending fibres.

In certain parts of the cortex this typical structure is departed from. The chief of these regions are (1) the **occipital lobe**, (2) the **transtemporal gyres**, (3) the **hippocampus**, (4) the **dentate gyre**, and (5) the **olfactory bulb**.

Special Types of Gray Substance. 1. **The Occipital Lobe.**—In the cuneus and the calcarine fissure of the occipital lobe Cajal has recently described as many as nine layers. Here the inner band of Baillarger is absent; the outer band of Baillarger or band of Gennari is, on the other hand, of considerable thickness. If a section be examined microscopically, an additional layer is seen to be interpolated between the molecular layer and the layer of small pyramidal cells. This extra layer consists of two or three strata of fusiform cells, the long axes of which are at right angles to the surface. Each cell gives off two dendrites, external and internal, from the latter of which the axone arises and passes into the white central substance. In the layer of small pyramidal cells, fusiform cells, identical with the above, are seen, as well as ovoid or star-like elements with ascending axones, the **cells of Martinotti**. This area of the cortex forms the visual centre, and it has been shown by Dr. J. S. Bolton¹ that in old-standing cases of optic atrophy the thickness of Gennari's band is reduced by nearly 50 per cent.

2. **The Transtemporal Gyres** are distinguished by a reduction of thickness of the pyramidal cell layer with closer approximation of the giant cells to each other, while the fusiform cell layer is more deeply situated than elsewhere. This cortical formation is the end station for cochlear nerve projections.

3. In the **Hippocampus** the molecular layer is very thick and contains a large number of Golgi cells. It has been divided into three strata: (a) **S. convolutum** or **S. granulosum**, containing many tangential fibres; (b) **S. lacunosum**, presenting numerous lymphatic or vascular spaces; (c) **S. radiatum**, exhibiting a rich plexus of fibrils. The two layers of pyramidal cells are condensed into one, and these are mostly of large size. The axones of the cells in the polymorphous layer may run in an ascending, descending, or horizontal direction. Between the polymorphous layer and the ventricular ependyma is the white substance of the alveus (Fig. 930).

4. **The Dentate Gyre.**—In the rudimentary dentate convolution the molecular layer contains some pyramidal cells, while the pyramidal layer is almost entirely represented by small ovoid elements.

5. **The Olfactory Bulb.**—In many of the lower animals this contains a cavity which communicates through the hollow olfactory stalk with the cavity of the lateral ventricle. In man the original cavity is filled by neuroglia and its wall becomes thickened, but much more so on its ventral than on its dorsal aspect. Its dorsal part contains a small amount of gray and white substance, but this is scanty and ill defined. A section through the ventral part shows it to consist of the following layers from without inward: (1) A layer of **olfactory nerve fibres**, which are the myelinated axones prolonged from the olfactory cells of the nose, and which reach the bulb by passing through the cribriform plate of the ethmoid bone. At first they cover the bulb, and then penetrate it to end by forming synapses with the dendrites of the mitral cells, presently to be described. (2) **Glomerular layer (stratum glomerulosum)**: This contains numerous spheroidal reticulated enlargements, termed **glomeruli**, which are produced by the branching and arborization of the processes of the olfactory nerve fibres with the descending dendrites of the mitral cells. (3) **Molecular layer**: This layer is formed of a matrix of neuroglia, embedded in which are the **mitral cells**. These cells are pyramidal in shape, and the basal part of each gives off a thick dendrite which descends into the glomerular layer, where it arborizes as above, or, on the other hand, interlaces with similar dendrites of neighboring mitral cells. The axones pass through the next layer into the white substance of the bulb, from which, after becoming bent on themselves at a right angle, they are continued into the olfactory tract. (4) **Nerve fibre layer**: This lies next the central core of neuroglia, and its fibres consist of the axones or afferent processes of the mitral cells which are passing on their way to the brain; some efferent fibres are, however,

¹ Phil. Trans. of Royal Society, Series B, vol. xciii, p. 165.

also present, and terminate in the molecular layer and presumably come *via* the anterior commissure from the mitral cells of the opposite bulb.

The **claustrum**, although usually enumerated among the basal ganglia, is probably the thickened and isolated deepest layer of fusiform cells belonging to the cortex of the island of Reil. The white lamina¹ intervening between it and the cortex proper consists of association axones of longer and shorter course.

Summary of the Cerebral Fibre Systems.—The white substance of the cerebrum consists of myelinic fibres intricately interwoven but permitting of classification into three systems arranged according to the course they take. These systems comprise: (1) **association fibres**, which connect neighboring or distant parts within the same cerebral hemisphere; (2) **commissural fibres**, which unite allied parts in the two cerebral halves and come transversely across the midline to form the commissures; (3) **projection fibres**, which connect the cerebral cortex with lower centres in the brain and spinal cord, and, conversely, those fibres which connect lower centres with the cerebral cortex.

FIG. 708.—Coronal section of olfactory bulb. (Schwalbe.)

1. The **association fibres** (Fig. 709) connect different structures in the same hemispheres, and are in or near to the cortex. They take origin from the small pyramidal and polymorphous cells of the deep layer of the cortex. Their direction is parallel to the surface of the hemisphere, and in their course they cross the projection and commissural fibres. They are of two kinds: (1) Those which unite adjacent convolutions, **short association fibres**; (2) those which pass between more distant parts in the same hemisphere, **long association fibres**.

The **short association fibres** are situated immediately beneath the gray cortex of the hemispheres, and connect adjacent convolutions. They constitute subcortical tracts and are divided into **arcuate fibres** and **tangential fibres**. Thus, some of these fibres connect the "visual sensor area with the visual memory area, and the auditory sensor with the auditory memory area."

The **long association fibres** associate cerebral centres which are far apart. They are gathered into bundles and dip down deep into the centrum ovale. They include the following: (a) the **uncinate fasciculus**; (b) the **superior longitudinal fasciculus**; (c) the **inferior longitudinal fasciculus** (doubtful); (d) the **cingulum**; and (e) the **fasciculus rectus**.

¹ Previously described as the *periclastral lamina* or *capsula extrema* (p. 949).

(a) The **uncinate fasciculus** (*f. uncinatus*) passes between the uncinate gyre and the orbital portion of the frontal lobe; in its course it curves beneath the depths of the basisylvian fissure (Fig. 709).

(b) The **superior longitudinal fasciculus** (*f. longitudinalis superior*) (Fig. 709) is beneath the convex surface of the hemisphere arching over the lenticular nucleus. It joins the frontal cortex with the parietal and temporal cortex and brings into relation the motor speech centres and the centres of auditory and visual memories.

(c) The **inferior longitudinal fasciculus** (*f. longitudinalis inferior*) is usually described as a tract associating the centres of auditory and visual memory. Such association fibres undoubtedly exist, but it is doubtful whether they are collected into a distinct fasciculus. The bundle which is usually designated by this term

FIG. 709.—Diagram showing the principal systems of associating fibres in the cerebrum.

has been proved to be in part the projection system between the occipital cortex and the thalamus and external geniculate body (E. Redlich) and in part also the fibres from the temporal cortex (meditemporal and subtemporal gyre) to the crusta.

(d) The **cingulum**, also called the *fornix periphericus*, is a band of white fibres that course in the white substance of the callosal gyre and runs excentrically to the corpus callosum. Its fibres may be traced frontad into the mesal olfactory stria and the anterior perforated substance, while caudad they radiate into the hippocampus. It may be regarded as an association tract of the rhinencephalon akin to the fornix.

(e) The **fasciculus rectus** or **perpendicular fasciculus** runs dorsoventrad in the occipitoparietal transition and associates the subparietal gyres with the medi- and subtemporal gyres; a part of the fasciculus associates the dorsal occipital region with its ventral part and with the subcollateral gyre (Fig. 709).

The **fornix**, previously described, may be enumerated among the long association tracts; it belongs exclusively to the olfactory apparatus.

2. The **commissural fibres** are grouped under the following heads: (a) the **corpus callosum**, described on page 934; (b) the **anterior commissure**, described on page 947; and (c) the **hippocampal commissure**, described on page 945.

3. The **projection fibres** connect the cerebral cortex with lower brain centres (caudate and lenticular nuclei, thalamus, hypothalamic region, corpora quadrigemina, pons, medulla oblongata), and with the spinal cord centres. They either project impulses from the cortex to the periphery or bring in impressions from without. Their radiations to and from the cortex, together with the radiations of the callosal fibres, give rise to the characteristic appearance of the **corona radiata**. We may distinguish the projection tracts of long course from those of short course, and, in the functional sense, those that are centrifugal, descending, or motor, from those that are centripetal, ascending, or sensor. The last mode of classification is more desirable.

FIG. 710.—The projection tracts joining the cortex with lower nerve centres. Sagittal section showing the arrangements of tracts in the internal capsule: A. Tract from the frontal lobe to the frontal half of the capsule, thence in part to the optic thalamus, A^1 , and in part to the pons, and thus to the cerebellar hemisphere of the opposite side. B. Motor tract from the precentral convolution to the facial nucleus in the pons and to the spinal cord. C. Sensor tract from dorsal columns of the cord, through the dorsal part of the medulla oblongata, pons, crus, and capsule to the parietal lobe. D. Visual tract from the thalamus (OT) to the occipital lobe. E. Auditory tract from the internal geniculate body (to which a tract passes from the VIII N. nucleus) to the temporal lobe. F. Superior peduncle. G. Middle peduncle. H. Inferior peduncle. CN. Caudate nucleus. CQ. Corpora quadrigemina. The numerals refer to the cranial nerves. (Starr.)

1. **Descending (corticifugal) tracts** are composed of axones arising from the cortical pyramidal cells.

(a) The **pyramidal or motor tract** from the "motor area," comprising the precentral gyre and paracentral gyre, courses through the genu and frontal two-thirds of the thalamolenticular limb of the internal capsule, forms the middle (three-fifths) sector of the crura, and passes through the pons into the medulla oblongata and spinal cord. The tract may be subdivided into a **corticobulbar** and a **corticospinal** division.

The **corticobulbar division** is the pyramidal tract to the efferent cranial nerve nuclei. Only those fibres which are destined to go to the facial and hypoglossal can be traced throughout. They originate in the ventral part of the precentral gyre (face and tongue centre), course through the genu of the internal capsule,

and end, contralaterally, in relation with the facial and hypoglossal nerve nuclei (also called the **emissary speech tract**).

The **corticospinal division** arises from the remainder of the motor area, courses through the frontal two-thirds of the internal capsule, through crusta, pons, and medulla oblongata, to form the pyramids, and, undergoing partial decussation, forms the direct and the crossed pyramidal tracts described in the spinal cord.

(b) The **frontopontile tract** (*Arnold's bundle*) arises in the midfrontal cortex, courses through the internal capsule (caudal part of frontal limb), forms the mesal sector (one-fifth) of the crusta, and ends in the nuclei pontis.

(c) The **temporopontile tract** (*Türk's bundle*) arises in the cortex of the temporal lobe, descends through the internal capsule (caudal segment), forms the ectal (one-fifth) sector of the crusta, and ends in the nuclei pontis. The existence of occipitopontile fibres is denied by Archambault in a recent contribution (1906).

(d) The **occipitomesencephalic tract** arises in the visual area (cuneus and calcarine formation), courses through the retrolenticular part of the internal capsule, to end in the superior quadrigeminal body and in relation with the nuclei for movements of the eyeball.

(e) Part of the fibres composing the **optic radiation** are corticipetal, arising in the occipital cortex and ending in the pulvinar of the thalamus and the external geniculate body.

FIG. 711.—Schema of the olfactory bulb and tract neurones.

2. **Ascending (corticipetal) tracts** arise mostly from the nuclei of the thalamus and hypothalamus, mid-brain, and cerebellum.

(a) The terminal or cerebral part of the **general sensor pathway of the body** comprises the axones arising in the cells of the lateral nucleus of the thalamus and the hypothalamic nucleus—interposed way-stations which transfer the impressions carried along the medial lemniscus from the nuclei of the gracile and cuneate fasciculi in the myeloblongata transition. They convey sensor impressions from the body periphery to the somesthetic area of the cortex—chiefly the postcentral and parietal gyres.

(b) The **terminal or cerebral part of the general sensor pathway of the head and neck** comprises the axones which arise from the afferent cranial nerve nuclei (excepting the auditory) and course along the medial lemniscus to the thalamus and hypothalamic nucleus, to be thence projected to the somesthetic cerebral cortex.

(c) The **terminal or cerebral part of the auditory pathway** from the inferior quadrigeminal body, internal geniculate body, and the interposed nucleus of the lateral lemniscus, ending in the auditory sphere of the cerebral cortex.

(d) The **terminal part of the visual pathway**, described on page 911.

(c) The **terminal (ascending) cerebellocortical pathway**, arising as the fibres of the superior peduncles of the cerebellum, decussating and ending in the red nucleus and lateral nucleus of thalamus, is thence directly projected by new axones to the somesthetic cortical area, or indirectly projected *via* thalamus (lateral nucleus).

Connections of the Corpus Striatum.—The connections of the caudate and lenticular nuclei with each other and with the cortex may be summarized as follows:

(a) Fibres from the cortex to the caudate and lenticular nuclei, entering into the formation of the **corona radiata**.

(b) Fibres from the caudate nucleus and putamen of the lenticular nucleus coursing to the thalamus and hypothalamic region. Those from the caudate nucleus pass through the internal capsule to traverse the globus pallidus, are joined by the fibres from the putamen to again traverse the internal capsule and end in the thalamus, forming the **striothalamic radiation**.

(c) Fibres coursing ventrad in the medullary laminae of the lenticular nucleus, and reinforced by additional fibres from the globus pallidus, course mesad to the hypothalamic region to form the **subthalamic radiation** or **ansa lenticularis** (described on p. 952). This radiation is further reinforced by the ventral stalk of the thalamocortical radiation to form the **ansa peduncularis** (described on p. 952).

The Olfactory Pathways. 1. **Peripheral Pathway.**—Impressions from the upper portion of the Schneiderian mucous membrane pass along the olfactory fila (central processes of the intraepithelial bipolar olfactory cells) to the **glomeruli olfactorii** in the olfactory bulb (Fig. 711).

2. **Central Pathway.**—In the glomeruli the impression is transmitted to the brush-like, dendritic endings of the mitral cells and brush cells; the axones of these cells carry the impression centrad to the gray masses of the olfactory tract, trigonum olfactorium, anterior perforated substance, and adjacent parts (Fig. 706). These constitute the primary centres.

The primary centres are connected with secondary or cortical centres (hippocampus, gyrus dentatus, uncus) by the following tracts: (1) Lateral olfactory striae, from the olfactory trigone to the uncus, ending in the gyrus ambiens and gyrus semilunaris (p. 929). (2) Axones from cells in the olfactory trigonal gray through the fornix to hippocampus. (3) Striae medialis (Lancisii) from the trigone into gyrus subcallosus around the corpus callosum to gyrus dentatus and hippocampus.

The amygdaline nucleus is by some regarded as a cortical centre to which impressions are carried by the taenia semicircularis.

The fornix fibres arise from the pyramidal cells in the hippocampus and the polymorphous cells of the dentate gyre. Some fibres traverse the median plane as the hippocampal commissure to the opposite hippocampus; the remainder end in the corpus albicans, gray nucleus, or, in small part, are retroflexed as the stria medullaris thalami to the habenular ganglion. In the corpus albicans impressions are transmitted to the cells of two nuclear masses; from the medial nucleus arise axones constituting the fasciculus albicantis princeps, each axone bifurcating and the diverging bundles forming, respectively, the albicantiothalamic and the albicantiotegmental fasciculi (p. 908).

The stria medullaris thalami consists of the following bundles ending in the habenular ganglion: (a) Axones from hippocampus *via* fornix—the cortico-habenular tract; (b) axones from the hemiseptum of the septum lucidum and olfactory gray—the olfactohabenular tract; (c) axones from the thalamus to the habenular ganglion—the thalamohabenular tract. In the habenular ganglion axones arise which pass as a distinct bundle ventrad through the tegmentum to the gray of the posterior perforated substance (*ganglion interpedunculare* [intercrurale] of Gudden)—the *fasciculus retroflexus* of Meynert.

The primary olfactory centres of the two sides are connected by the *pars*

olfactoria of the anterior *commissure*, a bundle of fibres passing from side to side to end in the tract, granular stratum, and glomerular layer of the bulb. Further connections are established with the tuber cinereum, mid-brain, and even spinal centres; one division has been named the *olfactomesencephalic tract* (Wallenberg).

The *cingulum* or *fornix periphericus* is an arcuate association bundle, or rather an arcuate series of short bundles which establishes the connections of the rhinencephalon with the adjacent cortical areas (p. 956).

Weight of the Brain.—The average weight of the brain in the adult male is 1400 grams (49.5 ounces avoirdupois); that of the female, 1250 grams (44 ounces avoirdupois). Among 1500 brains of males the brain weights ranged from 960 grams to over 1900 grams; the great majority of this series ranged from 1250 grams to 1500 grams. The average weight in the newborn is 400 grams (14.1 ounces avoirdupois) in the male and 380 grams (13.4 ounces avoirdupois) in the female. The weight is doubled at the end of the first, and trebled at the end of the fourth or fifth year, the female brain growing less rapidly than the male brain. Brain growth generally ceases in the eighteenth or twentieth year, earlier in the female than the male. After the sixtieth year the brain loses weight, at first slowly, but more rapidly in advanced senescence. Other factors, besides age and sex, which influence brain weight are stature, body weight, cranial form, and race. Persons of large stature average heavier brains than those of short stature in absolute figures, but not relatively. Brachycephalic persons average heavier brains than the dolichocephalic. A most profound influence upon brain weight appears to be exerted by racial differences. Representatives of the white race have heavier brains than those of the other races, although data are not sufficient to make a positive statement. Thus, the few Eskimo brains that have been secured so far are notable for their size and weight. The following table gives approximately accurate averages based upon greater or less numbers of brain weights:

		Males.	Females.
White race	Germans	1425	1260
	Bohemians	1420	1290
	Scots	1420	1260
	Swedes	1415	1260
	Russians	1395	1260
	English	1380	1255
	Italians	1375	1240
	French	1360	1250
Japanese		1365	1215
Chinese		1360	
Negroes (various races)		1390-1200	
Hawaiians		1330	
Papuans		1250	
Australians		1185	

The intellectual status is in some way reflected in the mass and weight of the brain. The average brain weight of 100 men eminent in the professions, arts, and sciences, with an average age of sixty-two years, was 1470 grams (nearly 52 ounces avoirdupois), exceeding the average weight of the ordinary population of about the same age by more than 100 grams (nearly 4 ounces avoirdupois). A further analysis shows that the brains of men devoted to the higher intellectual occupations, such as the mathematical sciences, involving the most complex mechanisms of the mind, those of men who have devised original lines of research, and those of forceful character are among the heaviest of all.

The brains of microcephalic idiots are far under the minimal size necessary

for mental integrity, which is about 1000 grams (35 ounces avoirdupois) in the male and 900 grams (31.7 ounces avoirdupois) in the female. Certain idiotic individuals possess brains of normal size or even abnormally large brains, but structural defects underlie these forms of idiocy.

The whale, porpoise, dolphin, and elephant possess larger brains than man, but relative to the size and weight of the body the human brain is proportionately larger.

CORTICAL LOCALIZATION OF FUNCTION.

Patient researches conducted along clinicopathological, experimental, physiological, and developmental lines have furnished us with a topographic map of the somesthetic and sense areas, and, inferentially, of the association areas of the cerebral cortex. The somesthetic and sense areas constitute less than one-third of the cortical area, while the remainder is presumed to be devoted to the elaboration of the higher mental activities manifested by abstract thought, ideation, reasoning, and language. The acquisition of these specifically human mental attributes has been the chief factor in bringing about the superior structure of the human brain, and those cortical regions which were subjected to increased associations rose in functional dignity and increased in size. With over nine billion functional nerve cells in the human cerebral cortex devoted to the mental processes, and less than one-third of these concerned with emissary and receptive functions, the intricacy and capacity of the human brain for the manifold registration of sensations and the numerous transformations that characterize man's mental process far exceed that of any other animal.

FIG. 712.—Mesal view of left cerebral hemisphere, showing localisation of functions. The schema of the fissures and gyres is the same as in Fig. 636.

The delineation of areas called **motor**, **visual**, **auditory**, etc., is not to be deemed as mathematically accurate or sharply defined as the boundaries of a State, county, or township. The areas rather shade off in a diffuse manner, and the arbitrary demarcations employed in the appended figures merely show the maximum concentration of those cortical parts which most distinctly appertain to the function alleged for them.

The principal areas that are known to be functionally differentiated are the following:

1. **Motor Area.**—The motor area comprises the precentral gyre and parts of the frontal gyres adjacent thereto, together with the paracentral gyre and the adjacent portion of the superfrontal gyre on its mesal face. Stimulation of various parts of this area causes movement, while their destruction impairs or abolishes voluntary movements. Within this motor area may be defined districts which are cortical projections of the muscular systems of the body. Thus, movements of the lower limb seem to be controlled by the dorsal part of the precentral and the paracentral gyre; the trunk musculature by the area lying frontad both on the mesal aspect and in the dorsal

superfrontal; the upper limb seems to be controlled by the midportion of the precentral; while the facial musculature is projected in the ventral part. The motor regions for the tongue, larynx, muscles of mastication, and pharynx lie in the frontal opercular part; and the movements of the head and eye are dominated by the medifrontal gyre, adjacent to the precentral. Recalling the fact that the pyramidal (motor) tract decussates in its course to the primary motor centres, it follows that the motor centres in one cerebral hemisphere control the movements of the opposite side of the body. As elsewhere in the cortex, these motor areas gradually pass one into the other and the boundaries are indeterminate. The localization of motor function is rather for coördinated groups of muscles than for individual muscles; as a rule, the most powerful articulation, as the thigh and the shoulder, is localizable frontad in the respective limb centres, while the smaller articulations and those differentiated as regards motility (digits, etc.) are localizable more posteriorly.

2. **Sensor Areas.**—(a) The area for tactile and temperature impressions is more intensely localized in the postcentral gyre and in corresponding order with its neighboring precentral motor areas; that is to say, there is the most intimate intercommunication between the sensor and the motor regions which preside over corresponding parts of the body. So closely coupled are the related sensor and motor cells in the highest category of the reflex arc system represented in the cerebral cortex that both sensor and motor areas are included under the term of **somesthetic** or **sensomotor area**, devoted to the registration of cutaneous impressions, impressions

FIG. 713.—Lateral view of left cerebral hemisphere, showing localization of functions. The schema of the fissures and gyres is the same as in Fig. 635.

from the muscles, tendons, and joints; in short, the sense of movement. The cortical area embraced by the parietal gyre, together with its extension in the precuneus on the mesal aspect, appears to be devoted to the concrete perception of the form and solidity of objects, and is therefore termed the **stereognostic sense area**.

(b) The **auditory area** is localized in the middle third of the supertemporal gyre and in the adjacent transtemporal gyres in the sylvian cleft.

(c) The **visual area** is most intensely localizable in the region of the calcarine fissure as well as in the cuneus as a whole. There seems to be an interrelation between the visual function and the special type of cortex already described, and chiefly characterized by the stripe of Gennari.

(d) The **olfactory area** comprises the uncus, frontal part of hippocampus, indusium, subcallosal gyre, parolfactory area, and anterior perforated substance.

(e) The **gustatory area** has not yet been accurately localized; presumably it lies in the neighborhood of the olfactory area in the temporal lobe (uncinate and hippocampal gyre?).

3. **The Language Areas.**—The cortical zone of language comprises certain specialized areas which take part in the intimate relations of speech to thought expression, to memory, in its reading form to sight, in writing to manual muscular innervation, and in "word understanding" to hearing.

(a) The **emissive (articular) centre for speech** is localized in the region of the junction of the subfrontal gyre with the precentral gyre—a region known to be intimately related to the control

of the muscles used in speech (larynx, tongue, jaw muscles). Destruction of this region at least causes a loss or disturbance of articulation of words.

(b) The **auditory receptive centre**, clinically known as the centre of "word deafness," is localized in the marginal gyre and adjacent parts of the super- and mediotemporal gyres, especially the latter. A patient suffering with a lesion of this area may clearly hear but not understand the spoken word. This division of the centre might also be called the *lalognostic* (word-understanding) centre.

(c) The **visual receptive centre**, clinically known as the centre of "word blindness," is localized in the angular gyre. Lesion of this area renders the patient incapable of understanding the significance of the words and objects which he sees.

(d) An **emissive "writing" centre**, not positively proved to exist, has been localized in the medifrontal gyre, frontad of the motor area for the upper limb.

(e) Of not a little importance with reference to the intellectual control of the faculty of language is the **island of Reil**, purely an association centre, serving to connect the various receptive sense areas relating to the understanding of the written and spoken word with the somesthetic emissary centre related to articulate speech and writing.

FIG. 714.—Diagram showing the language zone. The opercula are divaricated to expose the island of Reil.

The union of the various centres enumerated above forms the **cortical zone of language**, and is most intensely, if not exclusively, localized, or at least, active, in the left cerebral hemisphere in right-handed persons, and *vice versa* in left-handed persons.

4. **The Association Areas.**—The remaining area of the cerebral cortex is presumably the organic substratum for the higher psychic activities. At the present time not much is known about them, but broadly stated the **frontal association area** is concerned rather with the powers of thought in the abstract—creative, constructive, and philosophic. The **parieto-occipito-temporal association area**, on the other hand, seems to be more concerned with the powers of conception of the concrete, for the comprehension of analogies, comparing, generalizing, and systematizing things heard, observed, and felt.

The great extent of the association areas in the human brain is a somatic expression of man's possession of an associative memory or ability to register and compare sensations far greater than that of the highest ape. The pattern of the fissures and gyres in the brains of the higher anthropoids and man presents the same general features in all these types. In the course of evolution, however, the regions known as association areas assumed a greater energy of growth and expanded in proportion to the rise in functional dignity of these areas. They are regions of "unstable equilibrium" which afford greater and more complex associations as mental development goes on in the species, and concomitant with this great cortical expansion the associating or coördinating fibre systems became more elaborate, complex, and far-reaching.

With the aid of the microscope the maturing of the brain elements can be followed from the earliest stages of embryonic life to the adult period. The Flechsig method has shown how the function of nerve fibres within the brain is only established when the myelin sheath has developed.

But this development of mature nerve fibres does not occur simultaneously throughout the brain, but step by step in a definite order of succession; equally important bundles are myelinated simultaneously, but those of dissimilar importance develop one after another in accordance with *Flechsig's law*. The successive myelinization of fibre bundles to and from the cerebral cortex corresponds to the successive awakenings of mental activities and faculties in the growing child. Flechsig's method of investigation has been of great service in the elucidation of the problems of cerebral localization.

Craniocerebral Topography.—The position of the principal fissures and convolutions of the cerebrum and their relation to the outer surface of the scalp (Fig. 673) have been the subject of much investigation, and many systems have been devised by which one may localize these parts from an exploration of the external surface of the head.

These plans can only be regarded as approximately correct for several reasons; in the first place, because the relations of the convolutions and fissures to the surface are found to be quite

FIG. 715.—Drawing to illustrate craniocerebral topography. (Taken from a cast in the Museum of the Royal College of Surgeons of England, prepared by Professor Cunningham.)

variable in different individuals; secondly, because the surface area of the scalp is greater than the surface area of the brain, so that lines drawn on the one cannot correspond exactly to fissures or convolutions on the other; thirdly, because the fissures and convolutions in two individuals are never precisely alike. Nevertheless, the principal fissures and convolutions can be mapped out with sufficient accuracy for all practical purposes, so that any particular convolution can be generally exposed by removing with the trephine a certain portion of the skull's area. An excellent method is given by Chipault in his *Chirurgie opératoire du système nerveux*, 1894, vol. i. The following systems have been the longest in vogue:

The various landmarks on the outside of the skull, which can be easily felt, and which serve as indications of the position of the parts beneath, have been already referred to, and the relation of the fissures and convolutions to these landmarks is as follows:

Intercerebral or Longitudinal Fissure.—This corresponds to a line drawn from the glabella at the root of the nose to the external occipital protuberance.

The Sylvian Fissure.—The position of the sylvian fissure is marked by a line starting from a point 3 cm. ($1\frac{1}{4}$ inches) horizontally behind the external angular process of the frontal bone to a point 2 cm. ($\frac{1}{2}$ inch) below the most prominent point of the parietal eminence. The first 2 cm. ($\frac{1}{2}$ inch) will represent the basisylvian fissure, the remainder the sylvian fissure proper. The sylvian point is therefore 5 cm. (2 inches) behind and about 1 cm. ($\frac{1}{2}$ inch) above the level of the external angular process. The presylvian ramus of the fissure passes upward from this point parallel to, and immediately behind, the coronal suture.

The Tentorial Hiatus or Transverse Fissure.—This is between the cerebrum and cerebellum, and corresponds to a line drawn from the inion to the external auditory meatus.

FIG. 716.—Krönlein's method for determining the portions of certain fissures of the brain.

Central Fissure.—To find the dorsal end of the central fissure, a measurement should be taken from the glabella to the external occipital protuberance. The position of the top of the fissure will be, measuring from in front, 55.6 per cent. of the whole distance from the glabella to the external occipital protuberance. Professor Thane adopts a somewhat simpler method. He divides the distance from the glabella to the external occipital protuberance over the top of the head into two equal parts, and, having thus defined the middle point of the vertex, he takes a point half an inch behind it as the top of the sulcus. This is not quite so accurate as the former method; but it is sufficiently so for all practical purposes, and on account of its simplicity is very generally adopted. From this point the fissure runs downward and forward for 9 to 10 cm. ($3\frac{3}{4}$ to 4 inches), its axis making an angle of about 70 degrees with the middle line. In order to mark this groove, two strips of metal may be employed—one, the shorter, being fixed to the middle of the other at the angle mentioned. If the longer strip is now placed along the sagittal suture so that the junction of the two strips is over the point corresponding to the top of the furrow,

the shorter, oblique strip will indicate the direction and 9 to 10 cm. will mark the length of the furrow. Dr. Wilson has devised an instrument, called a cyrtometer, which combines the scale of measurements for localizing the fissure with data for representing its length and direction.¹

The **Occipital Fissure** on the dorsal surface of the cerebrum runs outward at right angles to the great longitudinal fissure for about 2 to 3 cm. ($\frac{3}{4}$ to $1\frac{1}{4}$ inches), from a point 0.5 cm. ($\frac{1}{4}$ inch) in front of the lambda. Reid states that if the sylvian line be continued onward to the sagittal suture, the last 2 to 3 cm. of this line will indicate the position of the fissure.

The **Precentral Fissure** begins 2 cm. ($\frac{3}{4}$ inch) in front of the middle of the central fissure and extends nearly, but not quite, to the sylvian fissure.

The **Superfrontal Fissure** runs backward from the supraorbital notch, parallel with the line of the longitudinal fissure to 1 cm. ($\frac{3}{4}$ inch) in front of the line indicating the position of the central fissure.

The **Subfrontal Fissure** follows the course of the supertemporal ridge on the frontal bone.

The **Interparietal Fissure**, comprising the parietal, subcentral, and paroccipital fissures, begins on a level with the junction of the middle and lower third of the central fissure, on a line carried across the head from the back of the root of one auricle to that of the other. After passing upward it curves backward, lying parallel to the longitudinal fissure, midway between it and the parietal eminence; then curves downward to end midway between the posterior fontanelle and the parietal eminence.

Krönlein's method for determining the portions of certain fissures of the brain is very useful and easy of application (Fig. 716). It is as follows: (1) The base line, ZM , is a horizontal line running at the level of the lower border of the orbit and the upper border of the external auditory meatus. (2) Another horizontal line, KK' , is drawn parallel to ZM . The second horizontal line is on a level with the supraorbital ridge. (3) A vertical line, ZK , is erected from ZM at the middle of the zygoma and is carried to the line KK' . (4) Another vertical line, AR , is erected from the base line at the level of the articulation of the mandible and is carried to R . (5) A third vertical line, MP , is erected from the base line at the posterior border of the mastoid process and is carried to the middle line of the skull, which is marked P . (6) A line is drawn from K to P . The portion of this line between R and P corresponds to the central fissure. (7) The angle PKK' is bisected by the line KS . KS corresponds to the sylvian fissure, and K is directly over the sylvian point. To reach the anterior branch of the middle meningeal, apply the trephine at K ; to reach the posterior branch, apply it at K' . In absciss of the temporal lobe the trephine should be applied, according to von Bergmann, in the region $AaKM$.

THE MENINGES, OR MENINGEAL MEMBRANES OF THE BRAIN (MENINGES ENCEPHALI).

Dissection.—To examine the brain with its membranes, the skullcap must be removed. In order to effect this, saw through the external table, the section commencing, in front, about 2 cm. ($\frac{3}{4}$ inch) above the margin of the orbits, and extending, behind, to a little above the level of the occipital protuberance. Then break the internal table with the chisel and hammer, to avoid injuring the investing membranes or brain; loosen and forcibly detach the skullcap, and the dura will be exposed. The adhesion between the bone and the dura often is very intimate, particularly along the sutures.

The membranes of the brain are from without inward—the **dura**, **arachnoid**, and the **pia**.

The Dura of the Brain (*Dura Mater Encephali*) (Figs. 717, 722).

The dura of the brain is a thick and dense, inelastic, fibrous membrane which lines the interior of the skull. It is a covering for the brain and is also the internal cranial periosteum. It is composed of two layers closely connected, except in certain situations, where, as already described (p. 723), they separate to form sinuses for the passage of venous blood. Upon the outer surface of the cranial dura, in the situation of the longitudinal sinus, may be seen numerous small whitish bodies, the **glandulae Pacchionii** (*granulationes arachnoideales*). Its outer surface is rough and fibrillated, and adheres closely to the inner surface

¹ Lancet, 1888, vol. 1, p. 408

of the bones, the adhesion being most marked opposite the sutures and at the base of the skull. Its inner surface is smooth and lined by a layer of endothelium. It sends inward four processes which divide the cavity of the skull into a series of freely communicating compartments, for the lodgement and protection of the different parts of the brain; and it is prolonged to the outer surface of the skull, through the various foramina which exist at the base, and thus becomes continuous with the pericranium; its fibrous layer forms sheaths for the nerves which pass through these apertures. At the base of the skull it sends a fibrous prolongation into the foramen cecum; it sends a series of tubular prolongations around the filaments of the olfactory nerves as they pass through the cribriform plate, and another around the nasal nerve as it passes through the nasal slit; a prolongation is also continued through the sphenoidal fissure into the orbit, and another is carried into the same cavity through the optic foramen, forming a sheath for the optic nerve, which is continued as far as the eyeball. In the posterior fossa it

FIG. 717.—The structure of the dura. Section through the cranial vault of a child, slightly enlarged. (Poirier and Charpy.)

FIG. 718.—The tentorium cerebelli. (Poirier and Charpy.)

sends a process into the internal auditory meatus, ensheathing the facial and auditory nerves; another through the jugular foramen, forming a sheath for the structures which pass through this opening; and a third through the anterior condylar foramen. Around the margin of the foramen magnum it is closely adherent to the bone, and is continuous with the spinal dura.

Processes of the Dura (*processus durae matris*).—The processes of the dura which project into the cavity of the skull are formed by reduplication of the inner or meningeal layer of the membrane, and are four in number—the **falx cerebri**, the **tentorium cerebelli**, the **falx cerebelli**, and the **diaphragma sellae**.

The **falx cerebri** (Figs. 718 and 719), so named from its sickle-like form, is a strong arched process which descends vertically in the intercerebral fissure between the two hemispheres of the brain. It is narrow in front, where it is attached to the crista galli of the ethmoid bone, and broad behind, where it is connected with the upper surface of the tentorium cerebelli. Its upper margin is convex, and attached to the inner surface of the skull, in the middle line, as far back as the internal occipital protuberance; it contains the **superior or great longitudinal sinus** (*sinus sagittalis superior*). Its lower margin is free, concave, and

FIG. 719.--Falx cerebri and tentorium cerebelli, left lateral view. (Testut.)

presents a sharp, curved edge, which contains the **falcine or inferior longitudinal sinus** (*sinus sagittalis inferior*). The **tentorial or straight sinus** (*sinus rectus*) is formed by the attachment of the falx cerebri to the tentorium cerebelli.

The **tentorium cerebelli** (Figs. 718 and 719) is an arched lamina of dura, elevated in the middle and slightly inclined toward the circumference. It intervenes between the upper surface of the cerebellum and the occipital lobes of the cerebrum. It is attached, behind, by its convex border to the transverse ridges upon the inner surface of the occipital bone, and there encloses on each side the **transverse or lateral sinus** (*sinus transversus*); forward, to the superior margin of the petrous portion of the temporal bone on either side, there enclosing the **superpetrosal sinus** (*sinus petrosus superior*); and at the apex of this bone the free or internal border and the attached or external border meet, and, crossing one another, are continued forward, to be attached to the anterior and posterior clinoid processes respectively.

Along the middle line of its upper surface the posterior border of the falx is attached, the **tentorial or straight sinus** being placed at their point of junction. Its frontal border is free and concave, and with the dorsum sellae forms a large oval opening. This opening is called the **incisura tentorii** and transmits the mesencephalon.

The **falx cerebelli** (*falcula*) (Fig. 718) is a small triangular process of dura received into the indentation between the two lateral lobes of the cerebellum behind. Its base is attached, above, to the under and back part of the tentorium cerebelli; its posterior margin, to the lower division of the vertical crest on the inner surface of the occipital bone. As it descends it sometimes divides into two smaller folds, which are lost on the sides of the foramen magnum.

The **diaphragma sellae** (Fig. 718) is a small, circular, horizontal fold, which constitutes a roof for the sella turcica. This almost completely covers the hypophysis, presenting merely a small central opening (*foramen diaphragmatis sellae*) for the passage of the infundibulum.

Structure (Fig. 717).—The dura consists of white fibrous tissue with connective-tissue cells and elastic fibres arranged in flattened laminae, which are imperfectly separated by lacunar spaces and bloodvessels into two layers, **endosteal** and **meningeal**. The **endosteal layer** is the internal periosteum for the cranial bones and contains the bloodvessels for their supply.

FIG 720.—Crucial prolongation of the dura. Frontal section passing through the tentorium cerebelli. The torcular herophili is seen in the centre. (Poirier and Charpy.)

At the margin of the foramen magnum it becomes continuous with the periosteum lining the vertebral canal. The **meningeal or supporting layer** is lined on its inner surface by a layer of nucleated endothelium, similar to that found on serous membranes. By its reduplication the meningeal layer forms the **falx cerebri**, the **tentorium cerebelli** and **falx cerebelli**, and the **diaphragma sellae**. The two layers are connected by fibres which intersect each other obliquely.

The **arteries of the dura** (see section on Arteries) are very numerous, but are chiefly distributed to the bones. Those found in the anterior fossa are the **anterior meningeal branches of the anterior and posterior ethmoidal** and **internal carotid**, and a **branch from the middle meningeal**. Those in the middle fossa are the **middle and small meningeal branches of the internal maxillary**; a **branch from the ascending pharyngeal**, which enters the skull through the foramen lacerum medium; **branches from the internal carotid**, and a **recurrent branch from the lacrimal**. Those in the posterior fossa are **meningeal branches from the occipital**, one of which enters the skull through the jugular foramen, and the other through the mastoid foramen; the **posterior meningeal from the vertebral**; occasional **meningeal branches from the ascending pharyngeal**, which enter the skull through the jugular and anterior condylar foramina; and a **branch from the middle meningeal**.

The **veins** which return the blood from the dura (see p. 719), and partly from the bones, anastomose with the diploic veins (see p. 730). They terminate in the various sinuses, with the exception of two which accompany the middle meningeal artery, and pass out of the skull at the foramen spinosum to join the internal maxillary vein; above, the meningeal veins communicate with the superior longitudinal sinus. The **sinuses** are considered on pages 723 to 730 inclusive.

On either side of the superior longitudinal sinus, especially near its middle, and also near the lateral and straight sinuses, are numerous spaces in the dura which communicate with the sinus, either by a small opening or a distinct venous channel. These spaces are the **parasinoidal sinuses** (*lacunae laterales*) (Fig. 720). Many of the meningeal veins do not open directly into the sinuses, but indirectly through the parasinoidal sinuses. These venous lacunae are often invaginated by arachnoid villi, and they communicate with the underlying cerebral veins, and also with the diploic and emissary veins.

The nerves of the dura are filaments from the trochlear, the ophthalmic division of the trigeminal, the semilunar or Gasserian ganglion, the vagus, the hypoglossal, and the sympathetic.

The Arachnoid (*Arachnoidea Encephali*) (Fig. 721).

The cranial arachnoid is a delicate membrane which envelops the brain, lying between the pia internally and the dura externally; from this latter membrane it is separated by a very fine slit or space, the **subdural space** (*cavum subdurale*). The subdural space contains a very minute quantity of fluid of the nature of lymph.

FIG. 721.—The arachnoid upon the base of the brain. On the right the arachnoid has been partly removed to show the cerebrum and cerebellum with their superficial veins. (Poirier and Charpy.)

It is prolonged upon emerging nerves and joins the lymph spaces of the nerves. The subdural space does not communicate with the subarachnoid space.

The arachnoid invests the brain loosely, being separated from direct contact with the cerebral substance by the pia, and a quantity of loose areolar tissue, the **subarachnoidean areolar tissue**. On the upper surface of the cerebrum the arachnoid

is thin and transparent, and may be easily demonstrated by injecting a stream of air beneath it by means of a blowpipe; it passes over the convolutions without dipping down into the fissures between them, but does pass into the sylvian and intercerebral fissures and is prolonged upon the nerves as a sheath. At the base of the brain the arachnoid is thicker, and slightly opaque toward the central part; it covers the orbital surface of the anterior lobes and extends across between the two temporal lobes so as to leave a considerable interval between it and the brain, the *cisterna basalis*.

The **subarachnoid space** (*cavum subarachnoideale*) (Fig. 722) is the interval between the arachnoid and pia. It is not only on the surface, but dips between the convolutions. It is not, properly speaking, a *space*, for it is occupied everywhere by a spongy tissue consisting of trabeculae of delicate connective tissue covered with endothelium, which pass from the pia to the arachnoid, and in the meshes of which the subarachnoid fluid is contained. This so-called space is small on the surface of the cerebrum; but at the base of the brain the subarachnoid tissue is less abundant and its meshes larger.

FIG. 722.—The subarachnoid space. (Schematic.) (Poirier and Charpy.)

In certain regions the arachnoid and pia are farther apart than was previously indicated, and these spaces are called **subarachnoid cisternæ** (*cisternae subarachnoidalis*). The largest space is the continuation of the posterior part of the subarachnoid space of the spinal cord. It is called the **postcisterna** (*cisterna cerebellomedullaris*). It is a space formed by the arachnoid passing across the back and under portions of the medulla oblongata and cerebellum. It communicates with the fourth ventricle by three foramina. The largest opening is the **foramen of Magendie** (*metapore; apertura medialis ventriculi quarti*). It is in the middle line of the tela choroidea. At the end of each recessus lateralis of the fourth ventricle there is also an opening, and each opening is called the **foramen of Luschka** or of **Key and Retzius** (*apertura lateralis ventriculi quarti*). The **cisterna pontis** is the continuation upward of the anterior part of the subarachnoid space of the cord. About the medulla oblongata it is continuous with the postcisterna, so this important nerve centre is surrounded by a large subarachnoid space. The **cerebral cisterna** or **cisterna basalis** (*cisterna interpeduncularis*) is formed by the arachnoid extending between the two temporal lobes, and contains the arteries forming the circle of Willis. The **anterior subarachnoid space** (*cisterna pontis, interpeduncularis et chiasmatis*) includes the cisterna pontis, the cisterna basalis, and the cisterna of the optic chiasm. There is a cisterna between the inferior edge of the falx cerebri and the superior surface of the corpus callosum which contains the anterior cerebral arteries, a cisterna in the sylvian fissure (*cisterna sylviana*)

which contains the anterior cerebral artery, and a cisterna between the corpora quadrigemina which contains the vena magna Galeni.

The **cerebrospinal fluid** (*coeliolympha*; *liquor cerebrospinalis*) fills the subarachnoid space. It is a clear, limpid fluid, having a saltish taste and a slightly alkaline reaction. According to Lassaigne, it consists of 98.5 parts of water, the remaining 1.5 per cent. being solid matters, animal and saline. It varies in quantity, being most abundant in old persons, and is quickly reproduced. Its chief use is probably to afford mechanical protection to the nerve centres, and to prevent the effects of concussions communicated from without.

Structure.—The arachnoid consists of bundles of connective tissue, the fine fibres of which form one layer and cross each other in every direction. At the level of the large fissures, and especially around the circle of Willis, it is reinforced by thick fibrous tissue. Both surfaces are covered with endothelium. There are no bloodvessels in the arachnoid; the vessels which appear to be in it are really in the pia. There is no positive proof that nerves are present in the arachnoid. It is true that Bochdalek and Luschka long ago described arachnoid nerves, but these observations have never been corroborated.

The Arachnoid Villi or Pacchionian Bodies (*Granulationes Arachnoideales*).

The arachnoid villi, erroneously called glandulae Pacchioni, are numerous small whitish or purplish projections, usually collected into clusters of variable size, which are found in the following situations: (1) Upon the outer surface of the dura, in the vicinity of the superior longitudinal sinus, being received into small depressions on the inner surface of the calvarium. (2) On the inner surface of the dura. (3) In the superior longitudinal sinus and the other sinuses.

FIG. 723.—Velum interpositum. (Poirier and Charpy.)

A hasty examination would lead us to suppose that these bodies spring from the dura, but, as a matter of fact, they originate from the arachnoid. They are not glandular in structure, but are simply enlarged normal villi of the arachnoid. In their growth they appear to perforate the dura, and when a group of villi is of large size it causes absorption of the bone, and comes to be lodged in a pit or depression (*foveola granularis* [*Pacchioni*]) on the inner table of the skull. Their manner of growth is as follows: At an early period they project through minute

holes in the inner layer of the dura, which open into large venous spaces situated in the tissues of the membrane, on either side of the longitudinal sinus and communicating with it. In their onward growth the villi push the outer layer of the dura before them, and this forms over them a delicate membranous sheath. In structure they consist of spongy trabecular tissue, covered over by a membrane, which is continuous with the arachnoid. The space between these two coverings, derived from the dura and arachnoid respectively, corresponds to and is continuous with the subdural space. The spongy tissue of which they are composed

FIG. 724.—The anterior cerebral and choroid arteries. (Spalteholz.)

is continuous with the trabecular tissue of the subarachnoid space; so that fluid injected into the subarachnoid space finds its way into the Pacchionian bodies, and through their coverings filters into the superior longitudinal sinus. They are supposed to be a means of getting rid of an excess of cerebrospinal fluid when its quantity is increased above normal, or for replenishing the cerebrospinal fluid from the blood plasma when needed. Another means of getting rid of cerebrospinal fluid is absorption by the lymph spaces of the cranial nerves, which possess sheaths of arachnoid up to the points at which they emerge from the skull.

These bodies are not found in infancy, and very rarely until the **third year**. They are usually found after the tenth year; and from this period they increase in number as age advances. Occasionally they are wanting.

The Pia of the Brain (*Pia Mater Encephali*) (Figs. 722, 723).

The pia of the brain is a vascular membrane, and derives its blood from the internal carotid and vertebral arteries. It consists of a minute plexus of blood-vessels, held together by an extremely fine areolar tissue. It invests the entire surface of the brain, dipping down between the convolutions and *laminæ*, and is prolonged into the interior, forming the velum interpositum and the choroid plexuses of the lateral and fourth ventricles.

FIG. 725.—The arteries of the medial surface of the right cerebral hemisphere. (Spalteholz.)

The **velum interpositum** or the **tela chorioidea superior** (*tela chorioidea ventriculi tertii*) (Fig. 723) is the prolongation of the pia into the interior of the brain through the medium of the transverse fissure. It is a double triangular vascular fold, that lies between the body of the fornix above and the thalami and the epithelial roof of the third ventricle below, and passes forward to the foramen of Monro. At each edge of the velum interpositum is the **choroid plexus** (*plexus chorioideus ventriculi lateralis*; *paraplexus*) of the corresponding lateral ventricle. In front the two plexuses join behind the foramen of Monro, and at the point of junction two lesser choroid plexuses pass back along the under surface of the velum interpositum to the third ventricle, the **diaplexus** or **median plexus** (*plexus chorioideus ventriculi tertii*). The **velar veins** or **veins of Galen** (p. 722) are two veins which lie on either side of the middle of the velum interpositum and pass back. Each velar vein is formed by the union of the vein from the corpus striatum and the choroid vein from the choroid plexuses. The two velar veins unite and form the **vena magna** (*Galen*), which empties into the straight sinus.

The pia of the surfaces of the hemispheres, where it covers the gray substance of the convolutions, is very vascular, and gives off from its inner surface a multitude of minute vessels, which extend perpendicularly for some distance into the cerebral substance. At the base of the brain, in the situation of the anterior and posterior perforated substance, a number of long, straight vessels are given off, which pass through the white substance to reach the gray substance in the interior. On the cerebellum the membrane is more delicate, and the vessels from its inner surface are shorter. The pia of the spinal cord is thicker, firmer, and less vascular than that of the brain, and as it is traced upward over the medulla oblongata it is seen to preserve these characters. At the upper border of the medulla oblongata it is prolonged over the lower half of the fourth ventricle, forming, before it is reflected onto the under surface of the cerebellum, a covering for the fourth ventricle called the *tela chorioidea inferior* (*metatela*; *tela chorioidea ventriculi quarti*); this carries the choroid plexus of the fourth ventricle (*plexus chorioideus ventriculi quarti*).

The arteries of the pia (see pp. 617, 619, and 623) (Figs. 724 and 725) are the anterior, middle, and posterior cerebral, anterior choroid and choroid, superior, anterior inferior, and posterior inferior cerebellar. (The vessels of the cerebral ganglionic system and of the cortical arterial system are considered on p. 620).

The veins of the pia (see pp. 721, 722, and 723) are the basilar vein, the velar veins (Fig. 723), the veins constituting the choroid plexuses of the third ventricle, the lateral ventricles, and the fourth ventricle; the cerebral veins (Fig. 721) and the cerebellar veins (Fig. 721).

The nerves of the pia accompany the branches of the arteries and are derived chiefly from the sympathetic. A few fibres are derived from certain cranial nerves, all of which are probably of the afferent variety.

THE CRANIAL NERVES (NERVI CEREBRALES).

The irregularities of origin and distribution of the cranial nerves, as compared with the relatively simple spinal nerves, are so great and their functions were formerly so little known that the older anatomists contented themselves with numbering them in order, beginning at the frontal end of the brain, and named them with reference to their anatomic connections. The enumeration of the cranial nerves was as variously given, almost, as there were writers upon the subject; the systems of Willis and of Sömmerring were most in vogue for a time, but the latter prevails today. In Sömmerring's arrangement twelve pairs of cranial nerves are recognized, but, on morphological and functional grounds, the nerves of the seventh and eighth pairs should each be considered as being composed of two nerves, the eleventh pair should be included with the nerves of the tenth, and the optic "nerve" is rather a diverticulum of the brain itself than a nerve in the strict sense. Furthermore, while some of the nerves are sensor or motor in a sense strictly comparable with the spinal nerves, others are mixed in function, and yet others constitute nerves of special sense and lack general sensibility. The numerical names, based upon the order in which they pass through the foramina in the base of the cranium, are being abandoned gradually for the more appropriate functional names, but not yet entirely so. Thus *glossopharyngeal* has not yet given way to "*gustatory*;" "*vagus*" is shorter than "*pneumogastric*"—a term which is misleading for a nerve which is distributed not only to lungs and stomach, but also to the meninges, the pharynx and œsophagus, larynx and trachea, heart and pericardium, liver and spleen.

The cranial nerves, as usually enumerated, together with their superficial "origin" or attachment to the brain and their foramina of exit from the skull, are tabulated on page 852. The central olfactory pathway is described on page 959, and the central connections of the optic tracts are given on page 912. The central connections of the remaining cranial nerves are described on pages 879 to 903.

The following is a brief summary of the twelve pairs of cranial nerves, indicating their functional nature:

No.	Name.	Functional nature.
I.	<i>Olfactory (fila).</i>	Smell sense.
II.	<i>Optic.</i>	Visual sense.
III.	<i>Oculomotor.</i>	Motor to muscles of eyeball and orbit.
IV.	<i>Trochlear.</i>	Motor to Superior oblique muscle of eyeball.
V.	<i>Trigeminal.</i>	Mixed: Sensor to face, tongue, and teeth; motor to muscles of mastication.
VI.	<i>Abducent.</i>	Motor to External rectus muscle of eyeball.
VII.	<i>Facial.</i>	Motor to muscles of scalp and face.
	<i>Nervus intermedius.</i>	Mixed: Sensor (gustatory) to tongue; excitoglandular to submaxillary and sublingual salivary glands.
VIII.	<i>Acoustic:</i>	
	I. <i>Cochlearis.</i>	Hearing sense.
	II. <i>Vestibularis.</i>	Equilibratory.
IX.	<i>Glossopharyngeal.</i>	Mixed: Sensor (and gustatory) to tongue and pharynx; motor (?) to Stylopharyngeus muscle.
X.	<i>Vagus.</i>	Mixed: Sensorimotor to respiratory tract and part of alimentary tract.
XI.	<i>Spinal accessory.</i>	
	I. <i>Accessory to vagus.</i>	Motor to muscles of palate, pharynx, etc.; respiratory organs; inhibitory to heart.
	II. <i>Spinal part.</i>	Motor to Trapezius and Sternomastoid muscles.
XII.	<i>Hypoglossal.</i>	Motor to muscles of tongue.

THE FIRST OR OLFACTORY NERVE (N. OLFACTORIUS).

The **olfactory nerves** or **fila** are the special nerves of the sense of smell, and are about twenty in number on each side. These filaments constitute the first or olfactory nerves and are the axones of the **olfactory cells**, lying in the small olfactory region in the upper part of the superior turbinated process of the ethmoid and corresponding portion of the nasal septum and are macroscopically differentiated from the respiratory region in being of a more brownish hue (Fig. 726). The olfactory fila are amyelinic and exhibit a plexiform arrangement in the deeper layers. After piercing the cribriform plate of the ethmoid they become attached to the under surface of the **olfactory bulb**, an oval mass of a grayish color, which rests on the cribriform plate of the ethmoid bone and forms the anterior expanded extremity of a slender process of brain substance, named the **olfactory tract**. The olfactory tract and bulb have already been described (p. 928). The **olfactory tubercle** (*trigonum olfactorium*) is a small triangular mass of gray substance between the diverging roots of the optic tract (p. 929).

Each nerve is surrounded by tubular prolongations from the dura and pia, the former being lost on the periosteum lining the nose, the latter in the neurilemma of the nerve. The nerves, as they enter the nares, are divisible into two groups—an **inner group**, larger than those on the outer wall, spread out over the upper third of the septum; and an **outer set**, which is distributed over the superior turbinated process and the surface of the ethmoid in front of it. As the filaments descend, they appear to unite in a plexiform network, and are believed by most observers to terminate by becoming continuous with the deep extremities of the olfactory cells.

The olfactory nerves differ in structure from other nerves in being composed exclusively of amyelinic fibres. They are deficient in the white substance of Schwann, and consist of axones with a distinct nucleated sheath, in which there are, however, fewer nuclei than in ordinary amyelinic fibres.

The central olfactory pathways are described on page 959.

Applied Anatomy.—Destruction of the olfactory tract of one side causes loss of smell (*anosmia*) on the side of the injury, because the olfactory tract is practically uncrossed. In severe injuries to the head the olfactory bulb may become separated from the olfactory nerves, thus producing loss of the sense of smell, and with this a considerable loss in the sense of taste, as much of the perfection of the sense of taste is due to the sapid substances, being also odorous and

FIG. 726.—Extent of true olfactory mucous membrane (v. Brunn.)

simultaneously exciting the sense of smell. When the sense of smell is lost, an individual cannot distinguish the *flavor* of food, but he can distinguish that a substance is salt, or sweet, or bitter, or acid. The most usual cause of injury to the olfactory nerve is fracture of the base of the skull, the line of fracture passing through the cribriform plate of the ethmoid bone, but a blow upon the face, forehead, or back of the head which does not produce fracture may injure the nerves.

THE SECOND OR OPTIC NERVE (N. OPTICUS).

The fibres of the optic nerve, the special nerve of the sense of sight, are the central processes of the retinal ganglion cells which, after converging to the optic papilla, leave the eyeball by piercing its fibrous and vascular tunics as a cylindric cord. The point of emergence is situated a little mesad (3 to 4 mm.— $\frac{1}{8}$ to $\frac{1}{6}$ inches) of the posterior pole of the globe. Behind the eyeball the nerve passes backward and inward through the orbital fat and optic foramen to enter the middle fossa of the cranium. The total length of the nerve averages 45 to 50 mm. ($1\frac{3}{4}$ to 2 inches). The two nerves converge to decussate partially, forming the chiasm.

The **optic chiasm** (*chiasma opticum*) (Figs. 727 and 728 and p. 911) is somewhat quadrilateral in form, rests upon the olivary eminence and on the anterior part of the diaphragma sellae, being bounded above by the lamina terminalis; behind by the tuber cinereum; on either side by the anterior perforated substance. Within the commissure the optic nerves of the two sides undergo a partial decussation (Figs. 668 and 728), described in detail on pages 911 and 912.

From the optic chiasm the **optic tracts** wind as flattened bands obliquely caudo-laterad around the crura cerebri to subdivide, each into two bands, one (mesal root) passing to the medial geniculate body and not a true continuation of the optic path (see Gudden's commissure, p. 912), the other (lateral root) passing to the lateral geniculate body, the pulvinar, and the superior quadrigeminal body (p. 912).

The **optic path** has been described on page 911.

Applied Anatomy.—The optic nerve is peculiarly liable to become the seat of *neuritis* or undergo *atrophy* in affections of the central nerve system, and, as a rule, the pathological relationship between the two affections is exceedingly difficult to trace. There are, however, certain points in connection with the anatomy of this nerve which tend to throw light upon the frequent association of these affections with intracranial disease: (1) From its mode of development and from its structure the optic nerve must be regarded as a prolongation of the brain substance, rather than as an ordinary cerebrospinal nerve. (2) As it passes from the brain it receives sheaths from the three cerebral membranes—a perineural sheath from the pia, an intermediate sheath from the arachnoid, and an outer sheath from the dura, which is also connected with the periosteum as it passes through the optic foramen. These sheaths are separated from each other by spaces which communicate with the subdural and subarachnoid spaces respectively. The innermost or perineural sheath sends a process around the arteria centralis retinae into the interior of the nerve, and enters immediately into its structure. Thus, inflammatory infections of the meninges or of the brain may readily extend themselves along these spaces or along the interstitial connective tissue in the nerve.

FIG. 727.—The left optic nerve and optic tracts.

FIG. 728.—Course of the fibres in the optic chiasm.

The course of the fibres in the optic chiasm has an important pathological bearing, and has been the subject of much controversy. Microscopic examination, experiments, and pathology all seem to point to the fact that there is a partial decussation of the fibres, each tract supplying the corresponding half of each eye, so that the right tract supplies the right half of each eye, and the left tract the left half of each eye. At the same time, Charcot believes—and his view has met with general acceptance—that the fibres which do not decussate at the optic chiasm will decussate in the corpora quadrigemina, so that lesion of the cerebral centre of one side causes complete blindness of the opposite eye, because both sets of decussating fibres are destroyed. Whereas should one tract—say the right—be destroyed by disease, there will be blindness of the right half of both retinae.

A sagittal section through the optic chiasm would divide the decussating fibres, and would therefore produce blindness of the inner half of each eye; while a section at the margin of the side of the optic chiasm would produce blindness of the external half of the retina of the same side.

The optic nerve may also be affected in injuries or diseases involving the orbit, in fractures of the anterior fossa of the base of the skull, in tumors of the orbit itself, or those invading this cavity from neighboring parts.

THE THIRD OR OCULOMOTOR NERVE (N. OCULOMOTORIUS) (Figs. 729, 730).

The third or oculomotor nerve supplies all the muscles of the orbit except the Superior oblique and External rectus; it also supplies, through its connection with the ciliary ganglion, the Sphincter muscle of the iris and the Ciliary muscle. It is a rather large nerve, of cylindric form and firm texture.

Its *apparent origin* is from the oculomotor groove along the ventromesal border of the crus. The deep origin may be traced through the substantia nigra, red nucleus, and tegmentum of the crus to a nucleus situated on either side of the median line beneath the floor of the aqueduct. The nucleus of the oculomotor nerve also receives fibres from the abducent nerve of the opposite side. The nucleus of the oculomotor nerve, considered from a physiological standpoint, can be subdivided into several smaller groups of cells, each group controlling a particular muscle (see p. 902).

On emerging from the brain, the nerve is invested with a sheath of pia, and enclosed in a prolongation from the arachnoid. It passes between superior cerebellar and posterior cerebral arteries, and then pierces the dura in front of and external to the posterior clinoid process, passing between the two processes from the free and attached borders of the tentorium, which are prolonged forward to be connected with the anterior and posterior clinoid processes of the sphenoid bone. It passes along the outer wall of the cavernous sinus (Figs. 505 and 506); above the other orbital nerves, receiving in its course one or two filaments from the cavernous plexus of the sympathetic, and a communicating branch from the first division of the trigeminal nerve. It then divides into two branches, which enter the orbit through the sphenoidal fissure, between the two heads of the External rectus muscle (Fig. 729). On passing through the fissure, the nerve divides into the frontal and lacrimal branches of the eye, which are placed between its two divisions (Fig. 730).

The **superior division** (*ramus superior*) (Fig. 730), the smaller, passes inward over the optic nerve, and supplies the Superior rectus and Levator palpebrae muscles. The **inferior division** (*ramus inferior*) (Fig. 730), the larger, divides into three branches. One passes beneath the optic nerve to the Internal rectus; another, to the Inferior rectus; and the third, the longest of the three, passes forward between the Inferior and External recti to the Inferior oblique. From

FIG. 729.—Nerves of the orbit, seen from above.

this latter a short, thick branch, *radix brevis ganglii ciliaris*, is given off to the lower part of the ciliary or lenticular ganglion and forms its *short or motor root* (Figs. 730 and 733). All these branches enter the muscles on their ocular surface, except that to the Inferior oblique, which enters its posterior border.

Applied Anatomy.—*Paralysis* of the oculomotor nerve may be the result of many causes: as cerebral disease; conditions causing pressure on the cavernous sinus; periostitis of the bone entering into the formation of the sphenoidal fissure; fracture of the orbit. It results, when complete, in (1) ptosis, or drooping of the upper eyelid, in consequence of the Levator palpebrae being paralyzed; (2) external strabismus, on account of the unopposed action of the External rectus muscle, which is not supplied by the oculomotor nerve, and is not therefore paralyzed; (3) dilatation of the pupil, because the sphincter fibres of the iris are paralyzed; (4) loss of power of accommodation, as the Sphincter pupillæ, the Ciliary muscle, and the Internal rectus are paralyzed; (5) slight prominence of the eyeball, owing to most of its muscles being relaxed.

FIG. 730.—Plan of the oculomotor nerve.

Occasionally paralysis may affect only a part of the nerve; that is to say, there may be, for example, a dilated and fixed pupil, with ptosis, but no other signs. *Irritation* of the nerve causes spasm of one or other of the muscles supplied by it; thus, there may be internal strabismus from spasm of the Internal rectus; accommodation for near objects only from spasm of the Ciliary muscle, or contraction of the pupil (myosis), from irritation of the sphincter of the pupil.

The oculomotor nerve is particularly liable to become involved in a syphilitic periarteritis where it passes between the superior cerebellar and posterior cerebral arteries; associated with locomotor ataxia various partial or complete paralyses of the nerve are often seen.

THE FOURTH OR TROCHLEAR NERVE (N. TROCHLEARIS) (Figs. 629, 633).

The **fourth or trochlear nerve** is, with the exception of the n. intermedius, the smallest of the cranial nerves, and supplies the Superior oblique muscle.

It *arises* from a nucleus in the floor of the mid-brain aqueduct at the level of the inferior quadrigeminal body. From its origin the nerve runs outward, curving around the central aqueduct gray to turn inward and backward into the superior medullary velum, decussating with the corresponding nerve of the opposite side and *emerging* from the surface laterad of the frenulum veli, immediately behind (or caudad of) the posterior quadrigeminal body.

Emerging from the superior medullary velum, the nerve is directed outward across the superior peduncle of the cerebellum, and then winds forward around the outer side of the crus cerebri, immediately above the pons, pierces the dura in the free border of the tentorium, just behind, and external to, the posterior clinoid process, and passes forward in the outer wall of the cavernous sinus, between the oculomotor nerve and the ophthalmic division of the trigeminal nerve (Figs. 505 and 506). It crosses the oculomotor nerve and enters the

orbit through the sphenoidal fissure (Fig. 738). It now becomes the highest of all the nerves, lying at the inner extremity of the fissure internal to the frontal nerve. In the orbit it passes inward, above the origin of the Levator palpebrae, and finally enters the orbital surface of the Superior oblique muscle.

Branches of Communication.—In the outer wall of the cavernous sinus it forms communications with the cavernous plexus of the sympathetic and with the ophthalmic division of the trigeminal nerve. In the sphenoidal fissure it occasionally gives off a branch to assist in the formation of the lacrimal nerve.

Branches of Distribution.—It gives off a recurrent branch, which passes backward between the layers of the tentorium cerebelli, dividing into two or three filaments which may be traced as far back as the wall of the lateral sinus.

Applied Anatomy.—The trochlear nerve when *paralyzed* causes loss of function in the Superior oblique, so that the patient is unable to turn his eye downward and outward. Should the patient attempt to do this, the eye on the affected side is twisted inward, producing *diplopia* or double vision. Accordingly, it is said that the first symptom of this disease which presents itself is giddiness when going down hill or in descending stairs, owing to the double vision produced by the patient looking at his steps while descending.

THE FIFTH, TRIGEMINAL, OR TRIFACIAL NERVE (N. TRIGEMINUS)

(Figs. 732, 733).

The **fifth, trigeminal, or trifacial nerve** is the largest cranial nerve. It resembles a spinal nerve (1) in having two roots, motor and sensor; (2) in having a ganglion developed on its sensor root. It is the great sensor nerve of the head and face and the motor nerve of the muscles of mastication; its upper two divisions are entirely sensor, the third division is partly sensor and partly motor. It *arises* by two roots; of these, the ventral is the smaller, and is the **motor root** (Fig. 648); the dorsal, the larger and **sensor root**. It *emerges* from the side of the pons near the upper border, by a small motor and a large sensor root. The small root consists of three or four bundles; the large root consists of numerous bundles of fibres, varying in number from seventy to a hundred. The two roots are separated from each other by a few of the transverse fibres of the pons. The *deep termination* of the large or sensor root is chiefly in a long tract in the medulla oblongata, the **lower sensor nucleus**, which is continuous below with the substantia gelatinosa Rolandi. The fibres from this nucleus form the so-called **ascending root of the fifth nerve**; they pass upward through the pons and join with fibres from the **upper sensor nucleus** (Fig. 648), which is situated to the outer side of the motor nucleus, from which the lower part of the motor root takes origin. The *deep origin* of the small or motor root is derived partly from a nucleus embedded in the gray substance of the upper part of the floor of the fourth ventricle and partly from a collection of nerve cells situated at the side of the aqueduct from which the fibres pass caudad under the name of the **mesencephalic or descending root of the fifth nerve** (Fig. 648).

The two roots of the nerve pass forward below the tentorium as it bridges over the notch on the inner part of the superior border of the petrous portion of the temporal bone (Fig. 732); they then run between the bone and the dura to the apex of the petrous portion of the temporal bone, where the fibres of the sensor root appear to enter into the formation of the **large semilunar or Gasserian ganglion** (Figs. 731 and 732), while the motor root passes beneath the ganglion without having any connection with it, and joins outside the cranium with one of the trunks derived from it (Figs. 731 and 732).

The **Gasserian or semilunar ganglion**¹ (*ganglion semilunare*) (Figs. 731 and 732) is lodged in an osteofibrous space, the **cavum Meckelii** (Fig. 719), near the

¹A Viennese anatomist, Raimund Balthasar Hirsch (1765), was the first who recognized the ganglionic nature of the swelling on the sensor root of the fifth nerve, and called it, in honor of his otherwise unknown teacher, Jon. Laur. Gasser, the "Ganglion Gasserii." Julius Casserius, whose name is given to the musculocutaneous nerve of the arm, was professor at Padua, 1545 to 1605. (See Hyrtl, *Lehrbuch der Anatomie*, p. 895 and p. 55.)

apex of the petrous portion of the temporal bone. The ganglion is of somewhat crescentic form, with its convexity turned forward. Its upper surface is intimately adherent to the dura. Besides the small or motor root, the large **superficial petrosal nerve** lies underneath the ganglion.

FIG. 731.—The right semilunar or Gasserian ganglion, viewed from the medial side. (Spalteholz.)

Branches of Communication.—This ganglion receives on its inner side filaments from the carotid plexus of the sympathetic.

Branches of Distribution.—It gives off minute branches to the tentorium cerebelli and the dura in the middle fossa of the cranium. From its *anterior (convex)* border, which is directed forward and outward, three large branches proceed—

the **ophthalmic**, **superior maxillary**, and **inferior maxillary**. The ophthalmic and superior maxillary consist exclusively of fibres derived from the large root and ganglion, and are solely nerves of common sensation. The third division, or inferior maxillary, is joined outside the cranium by the motor root, and is, therefore, strictly speaking, the only portion of the trigeminal nerve which can be said to resemble a spinal nerve.

Associated with the three divisions of the trigeminal nerve are four small ganglia—the **ophthalmic**, **sphenopalatine**, **otic**, and **submaxillary ganglia**.

The **ophthalmic nerve** (*n. ophthalmicus*), or **first division** of the trigeminal, is a sensor nerve. It supplies sensor branches to the cornea, ciliary muscle, and iris, to the lacrimal gland,

FIG. 732.—The course of the motor root of the trigeminal nerve. (Poirier and Charpy.)

to a part of the mucous lining of the nasal fossæ, and to the integument of the eyelids, eyebrow, forehead, and nose (Fig. 737). It is the smallest of the three divisions of the fifth, arising from the upper part of the Gasserian ganglion. It is a short, flattened band, about 2 cm. ($\frac{1}{2}$ inch) in length, which passes forward

along the outer wall of the cavernous sinus (Figs. 505 and 506), below the oculomotor and trochlear nerves (Fig. 731), and just before entering the orbit, through the sphenoidal fissure, divides into three branches—**lacrimal**, **frontal**, and **nasal**.

Branches of Communication.—The ophthalmic nerve is joined by filaments from the cavernous plexus of the sympathetic, and gives off minute branches to communicate with the oculomotor and abducent nerves, and not infrequently with the trochlear.

Branches of Distribution.—It gives off recurrent filaments (*n. tentorii*) which pass between the layers of the tentorium cerebelli, and then divides into—

Lacrimal.

Frontal.

Nasal.

The **lacrimal nerve** (*n. lacrimalis*) (Figs. 733 and 734) is the smallest of the three branches of the ophthalmic. It sometimes receives a filament from the trochlear nerve, but this is possibly derived from the branch of communication which passes from the ophthalmic to the trochlear. It passes forward in a separate tube of dura, and enters the orbit through the narrowest part of the sphenoidal fissure (Fig. 738). In the orbit it runs along the upper border of the External rectus muscle, with the lacrimal artery, and communicates with the temporomalar branch of the superior maxillary nerve. It enters the lacrimal gland and gives off several filaments, which supply the gland and the conjunctiva. Finally, it pierces the superior palpebral ligament, and terminates in the integument of the upper eyelid, joining with filaments of the facial nerve. The lacrimal nerve is occasionally absent, when its place is taken by the temporal branch of the superior maxillary. Sometimes the latter branch is absent, and a continuation of the lacrimal is substituted for it.

The **frontal nerve** (*n. frontalis*) (Figs. 729 and 733) is the largest division of the ophthalmic, and may be regarded, both from its size and direction, as the continuation of the nerve. It enters the orbit above the muscles, through the sphenoidal fissure (Fig. 738), and runs forward along the middle line, between the Levator palpebrae and the periosteum. Midway between the apex and the base of the orbit it divides into two branches, **supratrochlear** and **supraorbital**.

The **supratrochlear branch** (*n. supratrochlearis*) (Fig. 729), the smaller of the two, passes inward, above the pulley of the Superior oblique muscle, and gives off a descending filament, which joins with the infratrochlear branch of the nasal nerve. It then leaves the orbit between the pulley of the Superior oblique and the supraorbital foramen, curves up on to the forehead close to the bone, ascends beneath the Corrugator supercilii and Occipitofrontalis muscles, and, dividing into branches which pierce these muscles, it supplies the integument of the lower part of the forehead on either side of the middle line and sends filaments to the conjunctiva and skin of the upper eyelid.

The **supraorbital branch** (*n. supraorbitalis*) (Fig. 738) passes forward through the supraorbital foramen, and gives off, in this situation, **palpebral filaments** to the upper eyelid. It then ascends upon the forehead, and terminates in cutaneous and pericranial branches. The **cutaneous branches**, two in number, an inner and an outer, supply the integument of the cranium as far back as the vertex. They are at first situated beneath the Occipitofrontalis, the inner branch perforating the frontal portion of the muscle, the outer branch its tendinous aponeurosis. The **pericranial branches** are distributed to the pericranium over the frontal and parietal bones.

The **nasal nerve** (*n. nasociliaris*) (Figs. 729 and 733) is intermediate in size between the frontal and lacrimal, and is more deeply placed than the other branches of the ophthalmic. It enters the orbit by way of the sphenoidal fissure (Fig. 738) between the two heads of the External rectus, and passes obliquely inward across the optic nerve, beneath the Superior rectus and Superior oblique muscles,

to the inner wall of the orbit. Here it passes through the **anterior ethmoidal foramen**, and, entering the cavity of the cranium, traverses a **shallow groove** on the front of the cribriform plate of the ethmoid bone, and passes **down**, through the slit by the side of the crista galli, into the nose (Fig. 735), where it divides into two branches, an internal and an external branch. The **internal branch** (*rami nasales mediales*) supplies the mucous membrane near the **fore part** of the septum of the nose. The **external branch** (*rami nasales laterales*) descends in a groove on the inner surface of the nasal bone, and supplies a few filaments to the mucous membrane covering the fore part of the outer wall of the nares as far as the inferior turbinate process; it then leaves the cavity of the nose, between the lower border of the nasal bone and the upper lateral cartilage of the nose, and, passing down beneath the Compressor nasi, supplies the integument of the ala and the tip of the nose, joining with the facial nerve.

The branches of the nasal nerve are the **ganglionic**, **long ciliary**, and **infratrochlear**.

The **ganglionic branch** or the **long root of the ciliary ganglion** (*radix longa ganglii ciliaris*) (Figs. 730 and 733) is a slender branch, about 1 to 2 cm. in length, which usually **arises** from the nasal nerve, between the two heads of the External rectus

FIG. 733.—Nerves of the orbit and ophthalmic ganglion, side view.

muscle. It passes forward on the outer side of the optic nerve, and enters the postero-superior angle of the ciliary ganglion, forming its long root. It is sometimes joined by a filament from the cavernous plexus of the sympathetic or from the superior division of the oculomotor nerve.

The **long ciliary nerves** (*nn. ciliares longi*), two or three in number, are given off from the nasal as it crosses the optic nerve. They accompany the **short ciliary nerves** (Figs. 730 and 733) from the ciliary ganglion, pierce the posterior part of the sclera, and, running forward between it and the choroid, are distributed to the Ciliary muscle, iris, and cornea.

The **infratrochlear branch** (*n. infratrochlearis*) (Fig. 729) is given off just before the nasal nerve passes through the anterior ethmoidal foramen. It runs forward along the upper border of the Internal rectus muscle, and is joined, beneath the pulley of the Superior oblique, by a filament from the supratrochlear nerve. It then passes to the inner angle of the eye, and supplies the integument of the eyelids and side of the nose, the conjunctiva, the lacrimal sac, and the caruncula lacrimalis.

The **ophthalmic, lenticular, or ciliary ganglion** (*ganglion ciliare*) is a small, quadrangular, flattened ganglion of a reddish-gray color, and about the size of a pin's head, situated at the back part of the orbit between the optic nerve and the External rectus muscle, lying generally on the outer side of the ophthalmic artery. It is enclosed in a quantity of loose fat, which makes its exposure by dissection somewhat difficult.

Its **branches of communication or roots** are three, all of which enter its posterior border. One, the **long or sensor root** (*radix longa ganglii ciliaris*), is derived from the nasal branch of the ophthalmic and joins its postero-superior angle. The second, the **short or motor root** (*radix brevis ganglii ciliaris*), is a short, thick nerve, occasionally divided into two parts, which is derived from the branch of the oculomotor to the Inferior oblique muscle, and is connected with the postero-inferior angle of the ganglion. The third, the **sympathetic root** (*radix sympathetica ganglii ciliaris*), is a slender filament from the cavernous plexus of the sympathetic. This is frequently blended with the long root, although it sometimes passes to the ganglion separately. The ganglion occasionally receives a filament of communication from the **sphenopalatine ganglion**.

Its **branches of distribution** are the **short ciliary nerves** (*nn. ciliares breves*) (Figs. 730 and 733). These are delicate filaments, from six to ten in number, which arise from the fore part of the ganglion in two bundles, connected with its superior and inferior angles; the lower bundle is the larger. They run forward with the ciliary arteries in a wavy course, one set above and the other below the optic nerve, and are accompanied by the long ciliary branches of the nasal nerve. They pierce the sclera at the back part of the globe, pass forward in delicate grooves on its inner surface, and are distributed to the Ciliary muscle, iris, and cornea. One small branch is said to penetrate the optic nerve with the arteria centralis retinae.

The **superior maxillary nerve** (*n. maxillaris*) (Figs. 729 and 732), or **second division of the trigeminal**, is a sensor nerve. It is intermediate, both in position and size, between the ophthalmic and inferior maxillary. It commences at the middle of the Gasserian ganglion as a flattened plexiform band, and, passing horizontally forward, it leaves the skull through the foramen rotundum, where it becomes more cylindrical in form and firmer in texture. It then crosses the sphenomaxillary fossa (Fig. 67), inclines outward on the back of the maxilla, and enters the orbit through the sphenomaxillary fissure; it traverses the infra-orbital canal in the floor of the orbit, and appears upon the face at the infra-orbital foramen.¹ At its termination the nerve lies beneath the Levator labii superioris muscle, and divided into a leash of branches, which spread out upon the side of the nose, the lower eyelid, and upper lip, joining with filaments of the facial nerve.

Branches of Distribution.—The branches of this nerve may be divided into four groups: (1) Those given off in the **cranium**. (2) Those given off in the **sphenomaxillary fossa**. (3) Those in the **infraorbital canal**. (4) Those on the **face**.

In the cranium	Meningeal or dural.
Sphenomaxillary fossa . .	{ Orbital or temporomalar.
	{ Sphenopalatine.
	{ Posterior superior dental.
Infraorbital canal	{ Middle superior dental.
	{ Anterior superior dental.
On the face	{ Palpebral.
	{ Nasal.
	{ Labial.

¹ After it enters the infraorbital canal the nerve is usually called the **infraorbital** (*n. infraorbitalis*), and is therefore, the terminal branch of the superior maxillary nerve (Fig. 737).

The **Meningeal or Dural Branch** (*n. meningeus medius*) is given off from the superior maxillary nerve directly after its origin from the Gasserian ganglion; it accompanies the middle meningeal artery and supplies the dura of the middle fossa of the base of the skull.

The **Orbital or Temporomalar Branch** (*n. zygomaticus*) (Figs. 733 and 734) arises in the sphenomaxillary fossa, enters the orbit by the sphenomaxillary fissure, and divides at the back of that cavity into two branches, temporal and malar.

The **temporal branch** (*ramus zygomaticotemporalis*) runs along the outer wall of the orbit in a groove in the malar bone, receives a branch of communication from the lacrimal, and, passing through a foramen in the malar bone, enters the temporal fossa. It ascends between the bone and the substance of the Temporal muscle, pierces this muscle and the temporal fascia about an inch above the

FIG. 734.—Distribution of the second and third divisions of the trigeminal nerve and submaxillary ganglion.

zygoma, and is distributed to the integument covering the temple and side of the forehead, communicating with the facial and the auriculotemporal branch of the inferior maxillary nerve. As it pierces the temporal fascia it gives off a slender twig, which runs between the two layers of the fascia to the outer angle of the orbit. The **malar branch** (*ramus zygomaticofacialis*) passes along the external inferior angle of the orbit, emerges upon the face through a foramen in the malar bone, and, perforating the Orbicularis palpebrarum muscle, supplies the skin on the prominence of the cheek, where it is named the **subcutaneous malar**. It joins with the facial and the palpebral branches of the superior maxillary.

The **Sphenopalatine Branches** (*nn. sphenopalatini*) (Fig. 734), two in number, descend to the sphenopalatine ganglion, of which ganglion they are the sensor or short roots.

The **Posterior Superior Dental Branches** (*rami alveolares superiores posteriores*) (Fig. 734) arise from the trunk of the nerve just as it is about to enter the infra-orbital canal; they are generally two in number, but sometimes arise by a single trunk, and immediately divide and pass downward on the tuberosity of the maxilla. They give off several twigs to the gums and neighboring parts of the mucous membrane of the cheek, **superior gingival branches** (*rami gingivales superiores*). They then enter the posterior dental canals on the zygomatic surface of the maxilla, and, passing from behind forward in the substance of the bone, communicate with the middle dental nerve by a plexus formation, and give off branches to the lining membrane of the antrum and three twigs to each molar tooth. These twigs enter the foramina at the apices of the fangs and supply the pulp.

The **Middle Superior Dental Branch** (*ramus alveolaris superior medius*) is given off from the superior maxillary nerve in the back part of the infraorbital canal, and runs downward and forward in a special canal in the outer wall of the antrum to supply the two bicuspid teeth. It communicates with the posterior and anterior dental branches by a plexus formation (*plexus dentalis superior*).

At its point of communication with the posterior branch, above the root of the second bicuspid tooth, is a slight thickening which is the so-called **ganglion of Valentin**; and at its point of communication with the anterior branch is a second enlargement, which is called the **ganglion of Bochdalek**. Neither of these is a true ganglion.

The **Anterior Superior Dental Branch** (*ramus alveolaris superior anteriores*), of large size, is given off from the superior maxillary nerve just before its exit from the infraorbital foramen; it enters a special canal in the anterior wall of the antrum, and divides into a series of branches which supply the incisor and canine teeth. It communicates with the middle dental nerve by a plexus, and gives off a **nasal branch**, which passes through a minute canal into the nasal fossa, and supplies the mucous membranes of the fore part of the inferior meatus and the floor of the cavity, communicating with the nasal branches from the sphenopalatine ganglion.

The **Palpebral Branches** (*rami palpebrales inferiores*) pass upward beneath the Orbicularis palpebrarum muscle. They supply the integument and conjunctiva of the lower eyelid, joining at the outer angle of the orbit with the facial nerve and the malar branch of the orbital.

The **Nasal Branches** (*rami nasales interni*) pass inward; they supply the integument of the side of the nose and join with the nasal branch of the ophthalmic.

The **Labial Branches** (*rami labiales superiores*), the largest and most numerous, descend beneath the Levator labii superioris muscle, and are distributed to the integument of the upper lip, the mucous membrane of the mouth, and the labial glands.

All these branches are joined, immediately beneath the orbit, by filaments from the facial nerve, forming an intricate plexus, the **infraorbital plexus**.

The **Sphenopalatine or Meckel's Ganglion** (*ganglion sphenopalatinum*) (Fig. 735), the largest of the ganglia associated with the branches of the trigeminal nerve, is deeply placed in the sphenomaxillary fossa, close to the sphenopalatine foramen. It is triangular or heart-shaped, of a reddish-gray color, and is situated just below the superior maxillary nerve as it crosses the fossa.

Branches of Communication.—Like the other ganglia of the trigeminal nerve, it possesses a motor, a sensor, and a sympathetic root. Its **sensor root** is derived from the superior maxillary nerve through its two sphenopalatine branches (p. 986). These branches of the nerve, given off in the sphenomaxillary fossa, descend to the ganglion. Their fibres, for the most part, pass in front of the ganglion, as they proceed to their destination, in the palate and nasal fossa, and are not incorporated in the ganglionic mass; some few of the fibres, however,

The **ascending branches** (*rami orbitales*) are two or three delicate filaments which enter the orbit by the sphenomaxillary fissure, and supply the periosteum and the nonstriated muscle parts of the Levator palpebrae or Superior tarsal muscle, the Inferior tarsal muscle, and the Orbital muscle of Müller. According to Luschka, some filaments pass through foramina in the suture between the os planum of the ethmoid and frontal bone to supply the mucous membrane of the posterior ethmoidal and sphenoidal sinuses.

The **descending or palatine branches** (*nn. palatini*) (Fig. 735) are distributed to the roof of the mouth, the soft palate, tonsil, and lining membrane of the nose. They are almost a direct continuation of the sphenopalatine branches of the superior maxillary nerve, and are three in number—**anterior, middle, and posterior**.

The **anterior palatine nerve**¹ (*n. palatinus anterior*) descends through the **posterior palatine canal**, emerges upon the hard palate at the posterior palatine foramen, and passes forward in a groove in the hard palate, nearly as far as the incisor teeth. It supplies the gums, the mucous membrane, and glands of the hard palate, and communicates in front with the termination of the **nasopalatine nerve** (see below). While in the posterior palatine canal it gives off **inferior nasal branches** (*rami nasales posteriores inferiores*), which enter the nose through openings in the palate bone and ramify over the turbinated bone and middle and inferior meatuses; and, at its exit from the canal, a palatine branch is distributed to both surfaces of the soft palate.

The **middle palatine nerve** (*n. palatinus medius*) descends through one of the accessory posterior palatine canals, distributing branches to the uvula, tonsil, and soft palate. It is occasionally wanting.

The **posterior palatine nerve** (*n. palatinus posterior*) descends with a minute artery through the posterior palatine canal, and emerges by a separate opening behind the posterior palatine foramen. It supplies the soft palate, tonsil, and uvula. The middle and posterior palatine join with the tonsillar branches of the glossopharyngeal to form a plexus around the tonsil (*circulus tonsillaris*).

The **internal branches** are distributed to the septum and outer wall of the nasal fossæ. They are the **superior nasal** and the **nasopalatine**.

The **superior nasal branches** (*rami nasales posteriores superiores*), four or five in number, enter the back part of the nasal fossa by the sphenopalatine foramen. They supply the mucous membrane covering the superior and middle turbinated processes, and that lining the posterior ethmoidal cells, a few being prolonged to the upper and back part of the septum.

The **nasopalatine nerve** (*n. nasopalatinus*) also enters the nasal fossa through the sphenopalatine foramen; it passes inward across the roof of the nose, below the orifice of the sphenoidal sinus, to reach the septum, and then runs obliquely downward and forward along the lower part of the septum, to the anterior palatine foramen, lying between the periosteum and mucous membrane. It descends to the roof of the mouth through the **anterior palatine canal** (Fig. 735). The two nerves are here contained in separate and distinct canals, situated in the intermaxillary suture, and termed the **foramina of Scarpa**, the left nerve being usually anterior to the right one. In the mouth they become united, supply the mucous membrane behind the incisor teeth, and join with the anterior palatine nerves. The nasopalatine nerve furnishes a few small filaments to the mucous membrane of the septum.

Posterior Branch.—The **pharyngeal or pterygopalatine nerve** (Fig. 735) is a small branch arising from the back part of the **sphenopalatine ganglion**. It passes through the pterygopalatine canal with the pterygopalatine artery, and is distributed to the mucous membrane of the upper part of the pharynx, behind the Eustachian tube.

¹ Formerly called the *great palatine nerve*.

The Inferior Maxillary or Mandibular Nerve (*n. mandibularis*) (Figs. 733 and 734).—The **inferior maxillary** or third division of the **trigeminal nerve** distributes branches to the teeth and gums of the mandible, the integument of the temple and external ear, the lower part of the face and lower lip, and the muscles of mastication; it also supplies the tongue with a large branch. It is the largest of the three divisions of the trigeminal, and is made up of two roots—a **large** or **sensor root**, proceeding from the inferior angle of the Gasserian ganglion; and a **small** or **motor root**, which passes beneath the ganglion and unites with the sensor root just after its exit from the skull through the **foramen ovale** (Figs. 731 and 734). Immediately beneath the base of the skull this nerve divides into two trunks, **anterior** and **posterior**. Previous to its division the primary trunk gives off from its inner side a recurrent (meningeal) branch and the nerve to the Internal pterygoid muscle.

The **Recurrent or Meningeal Branch** (*n. spinosus*) is given off directly after its exit from the foramen ovale. It passes backward into the skull through the **foramen spinosum** with the middle meningeal artery. It divides into two branches, **anterior** and **posterior**, which accompany the main divisions of the artery and supply the dura. The posterior branch also supplies the mucous lining of the mastoid cells. The anterior branch communicates with the dural branch of the superior maxillary nerve.

The **Internal Pterygoid Nerve** (*n. pterygoideus internus*), given off from the inferior maxillary previous to its division, is intimately connected at its **origin** with the otic ganglion. It is a long and slender branch, which passes inward to enter the deep surface of the Internal pterygoid muscle.

The **anterior** and smaller division of the inferior maxillary nerve, which receives nearly the whole of the motor root of the trigeminal nerve, divides into branches which supply the muscles of mastication. They are the **masseteric**, **deep temporal**, **buccal**, and **external pterygoid branches** (Fig. 734).

The **masseteric branch** (*n. massetericus*) passes outward, above the External pterygoid muscle, in front of the temporomandibular articulation and behind the tendon of the Temporal muscle; it crosses the sigmoid notch with the masseteric artery, to the deep surface of the Masseter muscle, in which it ramifies nearly as far as its anterior border. It gives a filament to the temporomandibular joint.

The **deep temporal branches** (*nn. temporales profundi*), two in number, **anterior** and **posterior**, supply the deep surface of the Temporal muscle. The **posterior branch** (*n. temporalis profundus posterior*), of small size, is placed at the back of the temporal fossa. It sometimes arises in common with the masseteric branch. The **anterior branch** (*n. temporalis profundus anterior*) is frequently given off with the buccal nerve; it is reflected upward, at the pterygoid ridge of the sphenoid, to the front of the temporal fossa. Frequently a third branch (*middle deep temporal*) is present.

The **buccal** or **buccinator branch** (*n. buccinatorius*) passes forward between the two heads of the External pterygoid; and downward beneath or through the fibres of the Temporal muscle; it gives a branch to the External pterygoid during its passage through that muscle, and a few ascending filaments to the Temporal muscle, one of which occasionally joins with the anterior branch of the deep temporal nerve. The **superior** or **upper branch** supplies the integument and upper part of the Buccinator muscle, joining with the facial nerve around the facial vein. The **inferior** or **lower branch** passes forward to the angle of the mouth; it supplies the integument and Buccinator muscle, as well as the mucous membrane lining the inner surface of that muscle, and joins the facial nerve.¹

¹ There seems to be no reason to doubt that the branch supplying the Buccinator muscle is entirely a nerve of ordinary sensation, and that the true motor supply of this muscle is from the facial.

The **external pterygoid nerve** (*n. pterygoideus externus*) is most frequently derived from the buccal, but it may be given off separately from the anterior trunk of the inferior maxillary nerve. It enters the muscle on its inner surface.

The **posterior** and larger division of the inferior maxillary nerve is for the most part sensor, but receives a few filaments from the motor root. It divides into three branches—**auriculotemporal**, **lingual**, and **inferior dental** (Fig. 734).

The **auriculotemporal nerve** (*n. auriculotemporalis*) (Fig. 736) generally arises by two roots, between which the middle meningeal artery passes. It runs backward beneath the External pterygoid muscle to the inner side of the neck of the mandible. It then turns upward with the temporal artery, between the external auditory canal and the condyle of the mandible, under cover of the parotid gland, and, escaping from beneath this structure, ascends over the zygoma and divides into two **temporal branches**.

The **branches of communication** of the auriculotemporal nerve are with the facial and with the otic ganglion. The branches of communication with the facial (*rami anastomotici cum n. faciali*), usually two in number, pass forward from behind the neck of the condyle of the mandible, to join this nerve at the posterior border of the Masseter muscle. The filaments of communication with the otic ganglion are derived from the commencement of the auriculotemporal nerve.

The **branches of distribution** are:

Anterior auricular.	Parotid.
Articular.	Superficial temporal.
Branches to the external auditory meatus.	

The **anterior auricular branches** (*nn. auriculares anteriores*) are usually two in number. They supply the front of the upper part of the pinna, being distributed principally to the skin covering the front of the helix and tragus.

A branch to the temporomandibular articulation, the **articular branch**, is usually derived from the auriculotemporal nerve.

The **parotid branches** (*rami parotidei*) supply the parotid gland.

The **superficial temporal branches** (*rami temporales superficiales*) accompany the temporal artery to the vertex of the skull, and supply the integument of the temporal region, communicating with the facial nerve, and with the temporal branch of the temporomalar from the superior maxillary nerve.

The **branches to the external auditory meatus** (*n. meatus auditorii externi*), two in number, enter the canal between the bony and cartilaginous portion of the meatus. They supply the skin lining the meatus; the upper one sending a filament to the membrana tympani (*ramus membranae tympani*).

The **lingual nerve** (*n. lingualis*) (Fig. 734) supplies the papillæ and mucous membrane of the **anterior two-thirds of the tongue**, and is deeply placed throughout the whole of its course. It lies at first beneath the External pterygoid muscle, being placed to the inner side and in front of the inferior dental nerve, and is occasionally joined to this nerve by a branch which may cross the internal maxillary artery. The **chorda tympani nerve** also joins it at an acute angle in this situation. The nerve then passes between the Internal pterygoid muscle and the inner side of the ramus of the mandible, and crosses obliquely to the side of the tongue over the Superior constrictor of the pharynx and the Styloglossus muscles, and then between the Hyoglossus muscle and the deep part of the submaxillary gland; the nerve finally runs across the submaxillary or Wharton's duct, and along the side of the tongue to its apex, lying immediately beneath the mucous membrane.

The **branches of communication** are with the inferior dental and hypoglossal nerves and the submaxillary ganglion, and, apparently only, with the facial through the chorda tympani. The branches to the submaxillary ganglion are two or three

in number; those connected with the hypoglossal nerve form a plexus at the anterior margin of the Hyoglossus muscle.

The **branches of distribution** supply the mucous membrane of the mouth, the gums, the sublingual gland, and the mucous membrane of the anterior two-thirds of the tongue; the terminal filaments communicate at the tip of the tongue, with the hypoglossal nerve. The chorda tympani fibres which join the lingual nerve are probably taste fibres and excitoglandular for the submaxillary and sublingual salivary glands.

The **inferior dental nerve** (*n. alveolaris inferior*) (Fig. 734) is the largest of the branches of the inferior maxillary nerve. It passes downward with the inferior dental artery, at first beneath the External pterygoid muscle, and then between the internal lateral ligament and the ramus of the mandible to the **dental foramen**. It then passes forward in the **dental canal** of the mandible, lying beneath the teeth, as far as the **mental foramen**, where it divides into two terminal branches, incisor and mental.

The **branches** of the inferior dental are the **mylohyoid, dental, incisor, and mental**.

The **mylohyoid** (*n. mylohyoideus*) is derived from the inferior dental just as that nerve is about to enter the **dental foramen**. It descends in a groove on the inner surface of the ramus of the mandible, in which it is retained by a process of fibrous membrane. It reaches the under surface of the Mylohyoid muscle, and supplies it and the anterior belly of the Digastric.

The **dental branches** supply the molar and bicuspid teeth. They correspond in number to the fangs of those teeth, each nerve entering the orifice at the point of the fang and supplying the pulp of the tooth.

The **incisor branch** is continued onward within the bone to the middle line, and supplies the canine and incisor teeth.

The dental branches and the incisor branch form a plexus (*plexus dentalis inferior*), and from this plexus come the branches to the teeth (*rami dentales inferiores*) and to the gums (*rami gingivales inferiores*).

The **mental branch** (*n. mentalis*) emerges from the bone at the **mental foramen**, and divides beneath the Depressor anguli oris muscle into two or three branches; one descends to supply the skin of the chin, and another (sometimes two) ascends to supply the skin and mucous membrane of the lower lip. These branches communicate freely with the facial nerve.

Two small ganglia are connected with the inferior maxillary nerve—the **otic** with the trunk of the nerve, and the **submaxillary** with its lingual branch.

The **Otic Ganglion** (*ganglion oticum*) (Fig. 734) is a small, oval-shaped, flattened ganglion of a reddish-gray color, situated immediately below the foramen ovale, on the inner surface of the inferior maxillary nerve, and surrounding the origin of the internal pterygoid nerve. It is in relation, *externally*, with the trunk of the inferior maxillary nerve, at the point where the motor root joins the sensor portion; *internally*, with the cartilaginous part of the Eustachian tube, and the origin of the Tensor palati muscle; *behind*, it lies in relation with the middle meningeal artery.

Branches of Communication.—This ganglion is connected with the internal pterygoid branch of the inferior maxillary nerve by two or three short, delicate filaments. From this nerve the ganglion may obtain a motor root, and possibly also a sensor root, as these filaments from the nerve to the Internal pterygoid perhaps contain sensor fibres. The otic ganglion communicates with the glossopharyngeal and facial nerves through the **small superficial petrosal nerve** (Figs. 736 and 739) continued from the tympanic plexus, and through this communication it probably receives its sensor root from the **glossopharyngeal** and its motor root from the **facial**; its communication with the sympathetic is effected by a filament

from the plexus surrounding the middle meningeal artery. The ganglion also communicates with the auriculotemporal nerve (*ramus anastomoticus cum n. auriculotemporalis*). This communicating filament is probably a branch from the glossopharyngeal which passes to the ganglion, and through it and the auriculotemporal nerve to the parotid gland. A slender filament, the **sphenoidal**, ascends from it to the Vidian nerve.

Branches of Distribution.—Its branches of distribution are a filament to the Tensor tympani (*n. tensoris tympani*) and one to the Tensor palati (*n. tensoris veli palatini*). The former passes backward on the outer side of the Eustachian tube; the latter arises from the ganglion, near the origin of the internal pterygoid nerve, and passes forward. The fibres of these nerves are, however, mainly derived from the nerve to the Internal pterygoid muscle.

The **Submaxillary Ganglion** (*ganglion submaxillare*) (Fig. 734) is of small size, fusiform in shape, and situated above the deep portion of the submaxillary gland, near the posterior border of the Mylohyoid muscle, being connected by filaments with the lower border of the lingual nerve.

FIG. 736.—The otic ganglion and its branches

Branches of Communication.—This ganglion is suspended from the lingual nerve by two filaments (*rami communicantes cum n. linguali*), which join it separately at its fore and back part. It also receives a branch from the chorda tympani, and communicates with the sympathetic by filaments from the sympathetic plexus around the facial artery.

Branches of Distribution.—These are five or six in number; they arise from the lower part of the ganglion, and supply the mucous membrane of the mouth and the submaxillary or Wharton's duct, some being lost in the submaxillary gland (*rami submaxillares*). The branch of communication from the lingual nerve to the fore part of the ganglion is by some regarded as a branch of distribution, by which filaments of the chorda tympani pass from the ganglion to the lingual nerve, and by it are conveyed to the sublingual gland and the tongue.

Surface Marking.—It will be seen from the above description that the three terminal branches of the three divisions of the trigeminal nerve emerge from foramina in the bones of the skull and pass on to the face; the terminal branch of the first division emerging through the

supraorbital foramen; that of the second through the infraorbital foramen; and the third through the mental foramen. The supraorbital foramen is situated at the junction of the internal and middle third of the supraorbital arch. If a straight line is drawn from this point to the lower border of the mandible, so that it passes between the two bicuspid teeth of the mandible, it will pass over the infraorbital and mental foramina, the former being situated about one centimetre (two-fifths of an inch) below the margin of the orbit, and the latter varying in position according to the age of the individual. In the adult it is midway between the upper and lower borders of the mandible; in the child it is nearer the lower border; and in the edentulous jaw of old age it is close to the upper margin.

Applied Anatomy.—In fracture of the base of the skull the trigeminal nerve or one of its branches may be injured. It seems certain that occasionally, though seldom, the trigeminal nerve may be actually divided by such an injury. The trigeminal nerve may be affected in its entirety, or its sensor or motor root may be affected, or one of its primary main divisions. In injury to the sensor root there is anesthesia of the half of the face on the side of the lesion, with the exception of the skin over the parotid gland; insensibility of the conjunctiva, followed, if the eye is not temporarily protected with a watch glass, by destructive inflammation of the cornea,

FIG. 737.—Sensor areas of the head, showing the general distribution of the three divisions of the fifth nerve. Gerrish's Anatomy. (Modified from Testut.)

partly, it is held, from loss of trophic influence, and partly it is certain, from the irritation produced by the presence of foreign bodies on it, which are not perceived by the patient, and therefore not expelled by the act of winking; dryness of the nose, loss to a considerable extent of the sense of taste, and diminished secretion of the lacrimal and salivary glands. In injury to the motor root there is impaired action of the mandible from paralysis of the muscles of mastication on the affected side.

The trigeminal nerve is often the seat of *neuralgia*, and each of the three divisions has been divided or a portion of the nerve excised for this affection. The *supraorbital nerve* may be exposed by making an incision an inch and a half in length along the supraorbital margin below the eyebrow, which is to be drawn upward, the centre of the incision corresponding to the supraorbital notch. The skin and *Orbicularis palpebrarum* having been divided, the nerve can be easily found emerging from the notch and lying in some loose cellular tissue. It should be drawn up by a blunt hook and divided, or, what is better, a portion of it should be removed.

The *infraorbital nerve* has been divided at its exit by an incision on the cheek; or the floor of the orbit has been exposed, the infraorbital canal opened up, and the anterior part of the nerve resected; or the whole nerve, together with Meckel's ganglion as far back as the foramen rotundum, has been removed. This latter operation, though undoubtedly a severe proceeding, appears to have been followed by better results than has nerve resection. The operation is performed as follows. The maxilla is first exposed by a T-shaped incision, one limb of the incision

passing along the lower margin of the orbit, the other from the centre of the first cut vertically down the cheek toward the angle of the mouth. The nerve is then found, is divided, and a piece of silk is tied to it as a guide. A small trephine (one-half inch) is then applied to the bone below, but including the infraorbital foramen, and the antrum opened. The trephine is now applied to the posterior wall of the antrum, and the sphenomaxillary fossa exposed. The infraorbital canal is now opened up from below by fine cutting pliers or a chisel, and the nerve drawn down into the trephine hole, it being held on the stretch by means of the piece of silk; it is severed with fine curved scissors as near the foramen rotundum as possible, any branches coming off from the ganglion being also divided.¹

The *mental branch of the inferior dental nerve* may be divided at its exit from the foramen through an incision made through the mucous membrane where it is reflected from the alveolar process on to the lower lip; or a portion of the trunk of the *inferior dental nerve* may be resected through an incision on the cheek through the Masseter muscle, exposing the outer surface of the ramus of the mandible. A trephine is then applied over the position of the inferior dental foramen and the outer table removed, so as to expose the inferior dental canal. The nerve is dissected out of the portion of the canal exposed, and, having been divided after its exit from the mental foramen, it is by traction on the end exposed in the trephine hole, drawn out entire, and cut off as high up as possible.² The inferior dental nerve has also been divided through an incision within the mouth, the bony point guarding the inferior dental foramen forming the guide to the nerve. The *buccal nerve* may be divided by an incision through the mucous membrane of the mouth and the Buccinator muscle just in front of the anterior border of the ramus of the mandible (Stimson).

In inveterate neuralgia of one or two of the branches of the trigeminal nerve a peripheral operation may cure the case, but seldom does. It often gives relief, perhaps for months. In neuralgia of the second division or third division, or of the second division and third division, Abbe, of New York, opens the skull and divides the nerve or nerves by an intracranial operation, removes a piece of nerve so that the foramen of exit is empty, and covers the foramen with rubber tissue, to hinder regrowth of the nerve. Other operators, after removing a piece from each nerve, have plugged the foramina of the exit with dentists' cement or silver foil.

Rose's method of neurectomy is very valuable for neuralgia of the second division. It is a modification of the Braun-Lossen method. The infraorbital nerve is exposed, a ligature is tied about it, the roof of the infraorbital canal is chiselled open, and the nerve is freed as far back as possible. An incision is made from below the external angular process outward along the zygoma to in front of the lobule of the ear, downward to just above the angle of the mandible, and forward for two inches. The flap is raised and the zygoma is exposed. The root of the zygoma is drilled at two points, and the zygomatic process of the temporal bone is drilled at two points. The bone is sawed in two places between the drill holes. The freed arch is lifted down and back, the tendon of the Temporal muscle is drawn backward, and the pterygomaxillary fossa is thus exposed. The internal maxillary artery is divided between two ligatures. The External pterygoid muscle is separated from the greater wing of the sphenoid and from the root of the external pterygoid process. The superior maxillary nerve is grasped and twisted off as near the ganglion as possible. The entire nerve is then drawn back from the infraorbital foramen and removed. The wound is then closed. If the third division is also haunted by neuralgia, it too should be removed a few weeks after the performance of Rose's operation.

If a peripheral operation fails, or if all the branches of the trigeminal are involved, the Gasserian ganglion must be removed, or the sensor root of the trigeminal must be divided, as suggested by Frazier and Spiller.

Removal of the Gasserian ganglion was suggested by J. Ewing Mears in 1884, and was first carried out by Rose in 1890. The method chiefly in vogue was devised by Hartley, and was first performed by him in 1891. An osteoplastic flap is made in front of the ear, the dura is exposed and lifted. Following Krause's advice, the third division is exposed and clamped. The second division is exposed and clamped. The nerves are loosened from their beds and then are rolled about the clamps. This twisting pulls out the ganglion intact along with the motor root, and also the sensor root from the pons. A difficulty in the Hartley operation is the danger of division of the middle meningeal artery. If this happens, the surgeon may be able to arrest bleeding and proceed with the operation. If the vessel is torn off at the foramen spinosum, it will be necessary to pack the wound and postpone any further operative manipulation for forty-eight hours. Dr. Harvey Cushing has modified Hartley's operation by trephining the wall of the temporal fossa very low down. He opens the skull below the arch of the meningeal vessels, and thus avoids the middle meningeal artery at the foramen spinosum, and also the sulcus arteriosus of the parietal bone. After the removal of the ganglion, Professor Keen, in order to prevent undue inflammation of the eye, sews the eyelids of the affected side together, leaving a space open at each angle, and covers the eye with a watch crystal. Boric acid solution

is flushed into the opening at the external angle at frequent intervals. The stitches are removed from the lid in from eight to ten days.

The *lingual* nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the mandible, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is thought of, the operation is not practicable.

THE SIXTH OR ABDUCENT NERVE (N. ABDUCENS) (Fig. 733).

The **sixth or abducent nerve** supplies the External rectus muscle. Its *superficial origin* is by several filaments from the postpontile groove, between pons and pyramid. Its *deep origin* is from the upper part of the floor of the fourth ventricle, close to the median line, beneath the eminentia abducentis (Fig. 648). From the nucleus of the abducent nerve some fibres are supposed to pass through the medial longitudinal bundle to the oculomotor nucleus of the opposite side and into the oculomotor nerve, along which they are carried to the Internal rectus muscle. See, however, the description already given on page 903.

The nerve pierces the dura on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery (Fig. 505). It enters the orbit through the sphenoidal

FIG. 738.—Relations of structures passing through the sphenoidal fissure.

fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura (Fig. 738). It then passes between the two heads of the External rectus muscle, and is distributed to that muscle on its ocular surface.

Branches of Communication.

—It is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.

Relations to One Another of the Oculomotor, Trochlear, Ophthalmic Division of the Trigeminal, and Abducent Nerves as they Pass to the Orbit.

—The oculomotor, trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, as they pass to the orbit, bear a certain relation to one another in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the **cavernous sinus** (Figs. 505 and 506) the oculomotor, trochlear, and ophthalmic division of the trigeminal are placed on the outer wall of the sinus, in their numerical order, both from above downward and from within outward. The abducent nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the oculomotor and trigeminal nerves become divided into branches, and the abducent nerve approaches the rest so that their relative position becomes considerably changed.

In the **sphenoidal fissure** (Fig. 738) the trochlear nerve and the frontal and lacrimal branches of the ophthalmic division of the trigeminal lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus muscle. The superior division of the oculomotor nerve is the highest of these; beneath this lies the nasal branch of the ophthalmic nerve; then the inferior division of the oculomotor nerve; and the abducent nerve lowest of all.

In the **orbit** (Figs. 729 and 733) the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic nerve lie on the same plane immediately beneath the periosteum, the trochlear nerve being internal and resting on the Superior oblique muscle, the frontal nerve resting on the Levator palpebrae muscle, and the lacrimal nerve on the External rectus muscle. Next in order comes the superior division of the oculomotor nerve, lying immediately beneath the Superior rectus muscle, and then the nasal branch of the ophthalmic nerve, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the ciliary ganglion on its outer side, between it and the External rectus muscle. Below the optic nerve is the inferior division of the oculomotor nerve and the abducent nerve, which lie on the outer side of the orbit.

Applied Anatomy.—It is often stated that the abducent nerve is more frequently involved in *fractures of the base of the skull* than any other of the cranial nerves. As a matter of fact, however, it is injured in only about 2 per cent. of cases of fracture of the skull (Putscher). Cases have been reported in which the nerve was actually severed. The nerve may be injured by traction, pressure of a blood clot, of a tumor, or of an arteriovenous aneurism. The result of paralysis of this nerve is internal or *convergent squint*. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

THE SEVENTH OR FACIAL NERVE (N. FACIALIS) (Figs. 739, 740).

The **seventh or facial nerve** is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the external ear, the posterior belly of the Digastric, and the Stylohyoid. The chorda tympani (or nervus intermedius) is referred to as the sensor portion of the facial.

Its **superficial origin** is from the upper end of the medulla oblongata, in the groove between the olive and restiform body. Its **deep origin** is from a nucleus situated in

the floor of the fourth ventricle, beneath the superior fovea (Fig. 648). The facial nucleus is deeply placed in the reticular formation of the lower part of the pars dorsalis pontis, a little external and ventral to the nucleus of the abducent nerve. From this origin the fibres pursue a curved course in the substance of the pars dorsalis pontis. They first pass backward and inward, and then turn upward and forward, forming the **genu internum**, which with the nucleus abducentis produces an eminence, the **eminentia teres or abducentis**, on the floor of the fourth ventricle, and finally bend sharply downward and outward around the upper end of the nucleus of origin of the abducent nerve, to reach their superficial origin between the olive and restiform body. From the nucleus of the oculomotor

FIG. 739.—The course and connection of the facial nerve in the temporal bone.

is flushed into the opening at the external angle at frequent intervals. The stitches are removed from the lid in from eight to ten days.

The *lingual* nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the mandible, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is thought of, the operation is not practicable.

THE SIXTH OR ABDUCENT NERVE (N. ABDUCENS) (Fig. 733).

The **sixth or abducent nerve** supplies the External rectus muscle. Its *superficial origin* is by several filaments from the postpontile groove, between pons and pyramid. Its *deep origin* is from the upper part of the floor of the fourth ventricle, close to the median line, beneath the eminentia abducentis (Fig. 648). From the nucleus of the abducent nerve some fibres are supposed to pass through the medial longitudinal bundle to the oculomotor nucleus of the opposite side and into the oculomotor nerve, along which they are carried to the Internal rectus muscle. See, however, the description already given on page 903.

The nerve pierces the dura on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery (Fig. 505). It enters the orbit through the sphenoidal

fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura (Fig. 738). It then passes between the two heads of the External rectus muscle, and is distributed to that muscle on its ocular surface.

Branches of Communication.

—It is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.

Relations to One Another of the Oculomotor, Trochlear, Ophthalmic Division of the Trigeminal, and Abducent Nerves as they Pass to the Orbit.

—The oculomotor, trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, as they pass to the orbit, bear a certain relation to one another in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the **cavernous sinus** (Figs. 505 and 506) the oculomotor, trochlear, and ophthalmic division of the trigeminal are placed on the outer wall of the sinus, in their numerical order, both from above downward and from within outward. The abducent nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the oculomotor and trigeminal nerves become divided into branches, and the abducent nerve approaches the rest so that their relative position becomes considerably changed.

FIG. 738.—Relations of structures passing through the sphenoidal fissure.

In the **sphenoidal fissure** (Fig. 738) the trochlear nerve and the frontal and lacrimal branches of the ophthalmic division of the trigeminal lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus muscle. The superior division of the oculomotor nerve is the highest of these; beneath this lies the nasal branch of the ophthalmic nerve; then the inferior division of the oculomotor nerve; and the abducent nerve lowest of all.

In the **orbit** (Figs. 729 and 733) the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic nerve lie on the same plane immediately beneath the periosteum, the trochlear nerve being internal and resting on the Superior oblique muscle, the frontal nerve resting on the Levator palpebrae muscle, and the lacrimal nerve on the External rectus muscle. Next in order comes the superior division of the oculomotor nerve, lying immediately beneath the Superior rectus muscle, and then the nasal branch of the ophthalmic nerve, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the ciliary ganglion on its outer side, between it and the External rectus muscle. Below the optic nerve is the inferior division of the oculomotor nerve and the abducent nerve, which lie on the outer side of the orbit.

Applied Anatomy.—It is often stated that the abducent nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. As a matter of fact, however, it is injured in only about 2 per cent. of cases of fracture of the skull (Putscher). Cases have been reported in which the nerve was actually severed. The nerve may be injured by traction, pressure of a blood clot, of a tumor, or of an arteriovenous aneurism. The result of paralysis of this nerve is internal or convergent squint. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

THE SEVENTH OR FACIAL NERVE (N. FACIALIS) (Figs. 739, 740).

The **seventh or facial nerve** is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the external ear, the posterior belly of the Digastric, and the Stylohyoid. The chorda tympani (or nervus intermedius) is referred to as the sensor portion of the facial.

Its **superficial origin** is from the upper end of the medulla oblongata, in the groove between the olive and restiform body. Its **deep origin** is from a nucleus situated in the floor of the fourth ventricle, beneath the superior fovea (Fig. 648).

The facial nucleus is deeply placed in the reticular formation of the lower part of the pars dorsalis pontis, a little external and ventral to the nucleus of the abducent nerve. From this origin the fibres pursue a curved course in the substance of the pars dorsalis pontis. They first pass backward and inward, and then turn upward and forward, forming the **genu internum**, which with the nucleus abducentis produces an eminence, the **eminentia teres or abducentis**, on the floor of the fourth ventricle, and finally bend sharply downward and outward around the upper end of the nucleus of origin of the abducent nerve, to reach their superficial origin between the olive and restiform body. From the nucleus of the oculomotor

FIG. 739.—The course and connection of the facial nerve in the temporal bone.

nerve some fibres arise which descend in the medial longitudinal bundle and join the facial just before it leaves the pars dorsalis pontis; these fibres are said to supply the anterior belly of the Occipitofrontalis, the Orbicularis palpebrarum, and the Corrugator supercilii, as these muscles have been observed to escape paralysis in lesions of the nucleus of the facial nerve.

The **acoustic or auditory nerve** lies to the outer side of the facial nerve; and between the two is a small fasciculus, the **nervus intermedius** or **pars intermedia** of **Wrisberg**, which apparently arises from the medulla oblongata and joins the facial nerve in the internal auditory meatus. The central processes of the ganglion cells, known as the **nervus intermedius**, end in the upper end of the nucleus of the glossopharyngeal nerve. If it is to be classified as part of the facial then the nervus intermedius may be regarded as the **sensor root of the facial nerve**, analogous to the sensor root of the trigeminal, and its real nucleus of origin consists of the geniculate ganglion (see p. 884). It will be remembered that a portion of the nervus intermedius is efferent (excitoglandular), arising from the nucleus salivatorius (p. 884).

FIG. 740.—Plan of the facial and intermediate nerves and their communication with other nerves.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the middle peduncle of the cerebellum, and enters the **internal auditory meatus** with the auditory nerve and artery. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve, and the nervus intermedius is placed between the two and joins the inner angle of the geniculate ganglion. Beyond the ganglion its fibres are generally regarded as forming the chorda tympani (see p. 1000).

At the bottom of the meatus the facial nerve enters the **canalis facialis** or **aqueductus Fallopii** and follows the course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the **stylomastoid foramen** (Figs. 50 and 739). It is at first directed outward between the cochlea and vestibule toward the inner wall of the tympanum; it

then bends suddenly backward and arches downward behind the tympanum to the stylomastoid foramen. At the point in the aqueduct of Fallopius where the nerve changes its direction (*geniculum n. facialis*), it presents a reddish, gangli-form swelling, the **geniculate ganglion** (*ganglion geniculi*) or *intumescencia gangli-formis* (Fig. 739). The geniculate ganglion receives a branch from the vestibular division of the auditory nerve. On emerging from the stylomastoid foramen the facial nerve runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the mandible into two primary branches, **temporofacial** and **cervicofacial**, from which numerous offshoots are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offshoots diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of **pes anserinus** is given to the divisions of the facial nerve in and near the parotid gland.

Branches of Communication (Fig. 740).—The communications of the facial nerve may be thus arranged:

In the internal auditory meatus	{ With the acoustic nerve. The <i>nervus intermedius</i> , which is between the facial and acoustic, is supposed to give branches to both. The branch given to the acoustic accompanies it for a certain distance, and then departs from it to join the geniculate ganglion.
From the geniculate ganglion	{ With the acoustic as explained above. With the sphenopalatine ganglion by the large superficial petrosal nerve. With the otic ganglion by the small superficial petrosal nerve. With the sympathetic on the middle meningeal artery by the external superficial petrosal nerve.
In the canalis facialis or Fallopiian } aqueduct	{ With the auricular branch of the <i>vagus</i> .
At its exit from the stylomastoid } foramen	{ With the glossopharyngeal. With the <i>vagus</i> . With the great auricular. With the auriculotemporal.
Behind the ear	With the small occipital.
On the face	With three divisions of the <i>trigeminal</i> .
In the neck	With the superficial cervical.

In the internal auditory meatus some minute filaments pass between the facial and acoustic nerves.

The **large superficial petrosal nerve** arises from the geniculate ganglion and consists chiefly of sensor branches which are distributed to the muscles of the soft palate. It probably also contains a few motor branches from the motor root of the sphenopalatine (Meckel's) ganglion. It passes through the hiatus canalis facialis (Fallopian) and runs in a groove on the surface of the petrous portion of the temporal bone beneath the *stylomastoid foramen* in the foramen lacerum medium. It receives a twig from the *trigeminal* and in the foramen is joined by the great deep petrosal nerve of the *sympathetic* plexus on the internal carotid artery, to form the *Vidian nerve*. The nerve passes through the Vidian canal and ends in the sphenopalatine ganglion. The geniculate ganglion is connected with the otic ganglion by the small superficial petrosal nerve.

joins the small superficial petrosal nerve; and also with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal nerve (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve. Just before the facial nerve emerges from the stylomastoid foramen it generally receives a twig of communication from the auricular branch of the vagus.

After its exit from the stylomastoid foramen, it sends a twig to the glossopharyngeal, another to the vagus nerve, and communicates with the great auricular branch of the cervical plexus, with the auriculotemporal branch of the inferior maxillary nerve in the parotid gland, with the small occipital nerve behind the ear, on the face with the terminal branches of the three divisions of the fifth, and in the neck with the transverse cervical.

Branches of Distribution (Fig. 740).—The branches of distribution of the facial nerves may be thus arranged:

Within the canalis facialis or aquaeductus Fallopii	{ Tympanic, to the Stapedius muscle. Chorda tympani.
At its exit from the stylomastoid foramen	{ Posterior Auricular. Digastric. Stylohyoid.
On the face	{ Temporofacial. . . { Temporal. Malar. Infraorbital. Buccal. Mandibular. Cervical. Cervicofacial . . .

The **Tympanic Branch** (*n. stapedius*) (Fig. 740) arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The **Chorda Tympani** (Figs. 739 and 740) is apparently given off from the facial as it passes vertically downward at the back of the tympanum, about 5 mm. ($\frac{1}{8}$ inch) before its exit from the stylomastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture (*iter chordae posterius*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It traverses the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, crosses over the handle of the malleus, emerges from the cavity through a foramen at the inner end of the Glaserian fissure, which is called the **canal of Huguier** (*iter chordae anterior*). It then descends between the two Pterygoid muscles on the inner aspect of the spine of the sphenoid, which it sometimes grooves, and joins the lingual nerve at an acute angle. A portion of the nerve (excitoglandular division) passes to the submaxillary ganglion; the rest is continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds. These constitute the nerves of taste for this portion of the tongue. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion. As already stated, the chorda tympani nerve is regarded as the peripheral portion of the nervus intermedius (see p. 998).

The **Posterior Auricular Nerve** (*n. auriculus posterior*) (Figs. 740 and 741) arises close to the stylomastoid foramen, and passes upward in front of the mastoid process and between the mastoid process and the external ear, where it is joined by a filament from the auricular branch of the vagus, and communicates with the

mastoid branch of the great auricular and with the small occipital. As it ascends between the external auditory meatus and the mastoid process it divides into two branches, the auricular and the occipital branches. The auricular branch supplies the Retrahens aurem and the small muscles on the cranial surface of the pinna. The occipital branch (*ramus occipitalis*), the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipitofrontalis.

The **Digastric Branch of the Facial Nerve** (*ramus digastricus*) arises close to the stylomastoid foramen; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glossopharyngeal nerve (*ramus anastomoticus cum n. glossopharyngeo*).

The **Stylohyoid Branch** (*ramus stylohyoideus*) frequently arises by a common trunk with the digastric; it is long and slender, and passes inward to enter the Stylohyoid muscle about its middle.

The **Temporofacial Division** (Figs. 740 and 741), the larger of the two terminal branches of the facial, passes upward and forward through the parotid gland, crosses the external carotid artery and temporomaxillary vein, and passes over the neck of the condyle of the mandible, being connected in this situation with the auriculotemporal branch of the inferior maxillary nerve. It breaks up into branches which are distributed over the temple and upper part of the face; these are divided into three sets—temporal, malar, and infraorbital.

The **temporal branches** (*rami temporales*) cross the zygoma to the temporal region, supplying the Attrahens and Attollens aurem muscles, and join with the temporal branch of the temporomalar division of the superior maxillary nerve, and with the auriculotemporal branch of the inferior maxillary nerve. The more anterior branches supply the frontal portion of the Occipitofrontalis, the Orbicularis palpebrarum, and Corrugator supercilii muscles, and join with the supraorbital and lacrimal branches of the ophthalmic.

The **malar branches** (*rami zygomatici*) pass across the malar bone to the outer angle of the orbit, where they supply the Orbicularis palpebrarum muscle and join with filaments from the lacrimal nerve and the malar branch (*subcutaneus malae*) of the superior maxillary nerve.

The **infraorbital branches** (*rami buccales*), of larger size than the rest, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The **superficial branches** run beneath the skin and above the superficial muscles of the face, which they supply; some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The **deep branches** pass beneath the Zygomatici and the Levator labii superioris, supplying the Levator anguli oris, the Levator labii superioris alaeque nasi, and the small muscles of the nose, and form a plexus, **infraorbital plexus**, by joining with the branches of the infraorbital branch of the superior maxillary nerve and the buccal branches of the cervicofacial.

The **Cervicofacial Division** of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the mandible it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—buccal, mandibular, and cervical.

The **buccal branches** (*rami buccales*) cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infraorbital branches of the temporofacial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The **mandibular branch** (*ramus marginalis mandibulae*) passes forward beneath

the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The **cervical branch** (*ramus colli*) runs forward beneath the Platysma, and forms a series of arches across the side of the neck over the suprahyoid region. A branch descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

FIG. 741.—The nerves of the scalp, face, and side of the neck.

Applied Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis (*facial palsy*) may depend either upon (1) central causes—*i. e.*, blood clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in *bulbar paralysis*. Or (2) it may be paralyzed in its passage through the petrous bone by damage due to *middle-ear disease* or by *fractures of the base of the skull*. Or (3) it may be affected at or after its exit from the stylomastoid foramen. This is commonly known as *Bell's paralysis*. It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the mandible.

When the cause is central, the abducent nerve is usually paralyzed as well, and there is also hemiplegia on the opposite side. In these cases the electric reactions are the same as in health; whereas, when the paralysis is due to a lesion in the course of the nerve, the reactions of degeneration develop. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is

unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the *chorda tympani*. The mouth is dry, because the salivary glands are not secreting; the sense of hearing is affected from paralysis of the *Stapedius*, but there is no hemiplegia. When the cause of the paralysis is from fracture of the base of the skull, the acoustic nerve and the petrosal nerves, which are connected with the *intumescencia ganglioformis*, are also involved. When the injury to the nerve is after its exit from the *stylomastoid foramen*, all the muscles of expression except the *Levator palpebrae*, together with the posterior belly of the *Digastric* and *Stylohyoid*, are paralyzed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed, and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the nasolabial furrow; the nostril of the paralyzed side cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the *Buccinator*.

The facial nerve is at fault in cases of so-called *histrionic spasm*, which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the mandible. The parotid is turned forward, and the dissection carried along the anterior border of the *Sternomastoid* muscle and mastoid process until the upper border of the posterior belly of the *Digastric* is found. The nerve is parallel to this on about a level with the middle of the mastoid process. When found, the nerve may be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve. In facial paralysis of extracerebral origin it may be advisable to expose the nerve, cut it across, and anastomose the distal end of the paralyzed nerve to the accessory nerve, or, better, to the hypoglossal nerve (facioaccessory anastomosis or faciohypoglossal anastomosis). The idea was first proposed by Ballance, and has been put in practice by Ballance and Stewart, Keen, Cushing, Paure, Kennedy, and others.

THE EIGHTH OR ACOUSTIC NERVE (N. ACOUSTICUS) (Fig. 742).

The eighth or acoustic or auditory nerve comprises two distinct sets of fibres which, although both are devoted to the transmission of afferent impulses, differ in their peripheral distribution and in their central connections. The two divisions appear blended in the interval between the medulla oblongata and the internal auditory meatus, running obliquely laterofrontad in company with the facial nerve and internal auditory artery. At the internal auditory meatus the two divisions of the nerve are separable, the vestibular division above, the cochlear below.

The cochlear nerve (*radix cochlearis*) is the true nerve of hearing, lacking general sensibility, however, and therefore a nerve of special sense. The fibres of this division arise from the cells of the spiral ganglion of the cochlea as axones of bipolar cells whose dendrites or peripheral processes terminate about the (auditory) hair cells of the organ of Corti. The central connections of the cochlear division are described on page 883.

The vestibular nerve (*radix vestibularis*) conducts impulses of equilibratory sense from the semicircular canals, utricle, and saccule to the vestibular nuclei. The ganglion of origin of this nerve differs from ordinary sensor ganglia in that its cells are of bipolar structure, having retained this embryonic characteristic of the ganglion cells throughout life. The central processes of the cells of the vestibular ganglion (or ganglion of Scarpa) enter the medulla oblongata with the trunk of the cochlear nerve in the postpontile groove, laterad of the facial nerve, to establish central connections already described on page 883. The peripheral processes constitute the two main branches of the nerve—viz., (a) the utriculoampullar and (b) the sacculoampullar.

The upper or utriculoampullar branch divides into:

(a) The utricular branch, passing through the superior macula cribrosa of the vestibule to end in the macula acustica of the utricle.

(b) The **superior ampullar branch**, accompanying the utricular branch, to end in the crista acustica of the ampulla of the superior semicircular canal.

(c) The **lateral ampullar**, to the ampulla of the lateral semicircular canal.

The lower or **sacculoampullar branch** is somewhat longer and divides into:

(a) The **posterior ampullar**, passing through the foramen singulare and the inferior macula cribrosa to end in the ampulla of the posterior semicircular canal.

(b) The **saccular branch**, passing through the middle macula cribrosa to end in the macula acustica of the sacculus.

FIG. 742.—Distribution of the acoustic nerve. (Semidiagrammatic.) (Testut.)

Applied Anatomy.—The acoustic nerve is frequently injured; together with the facial nerve, in fractures of the middle fossa of the base of the skull implicating the internal auditory meatus. The nerve may be either torn across, producing permanent deafness, it may be bruised, or it may be pressed upon by extravasated blood or inflammatory exudation, when the deafness will in all probability be temporary. The nerve may also be injured by violent blows on the head without fracture, and deafness may follow loud explosions of dynamite, etc., probably from some lesion of this nerve, which is more liable to be injured than the other cranial nerves on account of its structure. The test that the nerve is destroyed and that the deafness is not due to some lesion of the auditory apparatus is obtained by placing a vibrating tuning-fork on the head. The vibrations will be heard in cases where the auditory apparatus is at fault, but not in cases of destruction of the auditory nerve.

Tinnitus aurium is commonly present in cases of ear disease. The sounds are variable in intensity and nature—buzzing, hissing, whistling, rushing, bell-ringing, and so forth. In the insane, tinnitus is associated with delusions and hallucinations of hearing, and may be due to nothing more than impacted cerumen in the meatus.

THE NINTH OR GLOSSOPHARYNGEAL NERVE (N. GLOSSOPHARYNGEUS) (Figs. 743, 744).

The **ninth or glossopharyngeal nerve** is distributed, as its name implies, to the tongue and pharynx, being the nerve of ordinary sensation to the mucous membrane of the pharynx, fauces, and tonsil; and the nerve of taste to all parts of the tongue to which it is distributed.

Its (apparent) *superficial origin* is by three or four filaments, closely connected, from the upper part of the medulla oblongata, in the dorsolateral groove (Fig. 743).

The central connections are described on page 882. The small motor component arises from cells in the nucleus ambiguus. The real origin of the sensor fibres of the glossopharyngeal must be looked for in the jugular and petrosal ganglia which are developed from the neural crest.

From its superficial origin it passes outward across the flocculus, and leaves the skull at the central part of the jugular foramen, in a separate sheath of the dura external to and in front of the vagus and spinal accessory nerves (Fig. 744). In its passage through the jugular foramen it grooves the lower border of the petrous portion of the temporal bone, and at its exit from the skull passes forward between the jugular vein and internal carotid artery, and descends ventrad of the latter vessel, and beneath the styloid process of the temporal bone and the muscles connected with it, to the lower border of the Stylopharyngeus muscle. The nerve now curves inward, forming an arch on the side of the neck, and lying upon the Stylopharyngeus muscle and the Middle constrictor of the pharynx. It then passes beneath the Hyoglossus muscle, and is finally distributed to the mucous membrane of the fauces and base of the tongue, and the mucous glands of the mouth and tonsil.

FIG. 743.—Origin, ganglia, and communication of the ninth, tenth, and eleventh cranial nerves.

In passing through the jugular foramen the nerve presents, in succession, two gangliform enlargements. The superior and smaller is called the **jugular ganglion**; the inferior and larger, the **petrous ganglion** or the **ganglion of Andersch**.

The **superior or jugular ganglion** (*ganglion superius*) is situated in the upper part of the groove in which the nerve is lodged during its passage through the jugular foramen. It is of very small size, and involves only part of the trunk of the nerve. It is usually regarded as a detached portion from the lower ganglion.

The **inferior or petrous ganglion** (*ganglion inferius*) is situated in a depression in the lower border of the petrous portion of the temporal bone; it is larger than the superior ganglion and involves the whole of the fibres of the nerve. From this ganglion arise those filaments which connect the glossopharyngeal with the vagus and sympathetic nerves.

Branches of Communication.—The branches of communication are with the vagus, sympathetic, and facial.

The branches to the vagus are two filaments, arising from the petrous ganglion, one of which passes to the auricular branch of the vagus, and one to the upper ganglion of the vagus.

The petrous ganglion is connected by a filament with the superior cervical ganglion.

The branch of communication with the facial perforates the posterior belly of the Digastric muscle. It arises from the trunk of the nerve below the petrous ganglion, and joins the facial just after its exit from the stylomastoid foramen.

Branches of Distribution.—The branches of distribution are the tympanic, carotid, pharyngeal, muscular, tonsillar, and lingual.

The **Tympanic Branch** or **Jacobson's Nerve** (*n. tympanicus*) arises from the petrous ganglion, and enters a small bony canal in the lower surface of the petrous portion of the temporal bone, the lower opening of which is situated on the bony ridge which separates the carotid canal from the jugular fossa. It ascends to the tympanum, enters that cavity by an aperture in its floor close to the inner wall, and divides into branches which are contained in grooves upon the surface of the promontory. These branches form a **tympanic plexus** (*plexus tympanicus*). This

is flushed into the opening at the external angle at frequent intervals. The stitches are removed from the lid in from eight to ten days.

The *lingual* nerve is occasionally divided with the view of relieving the pain in cancerous disease of the tongue. This may be done in that part of its course where it lies below and behind the last molar tooth. If a line is drawn from the middle of the crown of the last molar tooth to the angle of the mandible, it will cross the nerve, which lies about half an inch behind the tooth, parallel to the bulging alveolar ridge on the inner side of the body of the bone. If the knife is entered three-quarters of an inch behind and below the last molar tooth and carried down to the bone, the nerve will be divided. Hilton divided it opposite the second molar tooth, where it is covered only by the mucous membrane, and Lucas pulls the tongue forward and over to the opposite side, when the nerve can be seen standing out as a firm cord under the mucous membrane by the side of the tongue and can be easily seized with a sharp hook and divided or a portion excised. This is a simple enough operation on the cadaver, but when the disease is extensive and has extended to the floor of the mouth, as is generally the case when division of the nerve is thought of, the operation is not practicable.

THE SIXTH OR ABDUCENT NERVE (N. ABDUCENS) (Fig. 733).

The **sixth or abducent nerve** supplies the External rectus muscle. Its *superficial origin* is by several filaments from the postpontile groove, between pons and pyramid. Its *deep origin* is from the upper part of the floor of the fourth ventricle, close to the median line, beneath the eminentia abducentis (Fig. 648). From the nucleus of the abducent nerve some fibres are supposed to pass through the medial longitudinal bundle to the oculomotor nucleus of the opposite side and into the oculomotor nerve, along which they are carried to the Internal rectus muscle. See, however, the description already given on page 903.

The nerve pierces the dura on the basilar surface of the sphenoid bone, runs through a notch immediately below the posterior clinoid process, and enters the cavernous sinus. It passes forward through the sinus, lying on the outer side of the internal carotid artery (Fig. 505). It enters the orbit through the sphenoidal

fissure, and lies above the ophthalmic vein, from which it is separated by a lamina of dura (Fig. 738). It then passes between the two heads of the External rectus muscle, and is distributed to that muscle on its ocular surface.

Branches of Communication.

—It is joined by several filaments from the carotid and cavernous plexuses, and by one from the ophthalmic nerve.

Relations to One Another of the Oculomotor, Trochlear, Ophthalmic Division of the Trigeminal, and Abducent Nerves as they Pass to the Orbit.

—The oculomotor, trochlear, the ophthalmic division of the trigeminal, and the abducent nerves, as they pass to the orbit, bear a certain relation to one another in the cavernous sinus, at the sphenoidal fissure, and in the cavity of the orbit, which will now be described.

In the **cavernous sinus** (Figs. 505 and 506) the oculomotor, trochlear, and ophthalmic division of the trigeminal are placed on the outer wall of the sinus, in their numerical order, both from above downward and from within outward. The abducent nerve lies at the outer side of the internal carotid artery. As these nerves pass forward to the sphenoidal fissure, the oculomotor and trigeminal nerves become divided into branches, and the abducent nerve approaches the rest so that their relative position becomes considerably changed.

FIG. 738.—Relations of structures passing through the sphenoidal fissure.

In the **sphenoidal fissure** (Fig. 738) the trochlear nerve and the frontal and lacrimal branches of the ophthalmic division of the trigeminal lie upon the same plane, the former being most internal, the latter external, and they enter the cavity of the orbit above the muscles. The remaining nerves enter the orbit between the two heads of the External rectus muscle. The superior division of the oculomotor nerve is the highest of these; beneath this lies the nasal branch of the ophthalmic nerve; then the inferior division of the oculomotor nerve; and the abducent nerve lowest of all.

In the **orbit** (Figs. 729 and 733) the trochlear nerve and the frontal and lacrimal divisions of the ophthalmic nerve lie on the same plane immediately beneath the periosteum, the trochlear nerve being internal and resting on the Superior oblique muscle, the frontal nerve resting on the Levator palpebrae muscle, and the lacrimal nerve on the External rectus muscle. Next in order comes the superior division of the oculomotor nerve, lying immediately beneath the Superior rectus muscle, and then the nasal branch of the ophthalmic nerve, crossing the optic nerve from the outer to the inner side of the orbit. Beneath these is found the optic nerve, surrounded in front by the ciliary nerves, and having the ciliary ganglion on its outer side, between it and the External rectus muscle. Below the optic nerve is the inferior division of the oculomotor nerve and the abducent nerve, which lie on the outer side of the orbit.

Applied Anatomy.—It is often stated that the abducent nerve is more frequently involved in fractures of the base of the skull than any other of the cranial nerves. As a matter of fact, however, it is injured in only about 2 per cent. of cases of fracture of the skull (Putscher). Cases have been reported in which the nerve was actually severed. The nerve may be injured by traction, pressure of a blood clot, of a tumor, or of an arteriovenous aneurism. The result of paralysis of this nerve is internal or *convergent squint*. When injured so that its function is destroyed, there is, in addition to the paralysis of the External rectus muscle, often a certain amount of contraction of the pupil, because some of the sympathetic fibres to the radiating muscle of the iris pass along with this nerve.

THE SEVENTH OR FACIAL NERVE (N. FACIALIS) (Figs. 739, 740).

The **seventh or facial nerve** is the motor nerve of all the muscles of expression in the face, and of the Platysma and Buccinator; the muscles of the external ear, the posterior belly of the Digastric, and the Stylohyoid. The chorda tympani (or nervus intermedius) is referred to as the sensor portion of the facial.

Its **superficial origin** is from the upper end of the medulla oblongata, in the groove between the olive and restiform body. Its **deep origin** is from a nucleus situated in

the floor of the fourth ventricle, beneath the superior fovea (Fig. 648). The facial nucleus is deeply placed in the reticular formation of the lower part of the pars dorsalis pontis, a little external and ventral to the nucleus of the abducent nerve. From this origin the fibres pursue a curved course in the substance of the pars dorsalis pontis. They first pass backward and inward, and then turn upward and forward, forming the **genu internum**, which with the nucleus abducentis produces an eminence, the **eminentia teres** or **abducentis**, on the floor of the fourth ventricle, and finally bend sharply downward and outward around the upper end of the nucleus of origin of the abducent nerve, to reach their superficial origin between the olive and restiform body. From the nucleus of the oculomotor

FIG. 739.—The course and connection of the facial nerve in the temporal bone.

nerve some fibres arise which descend in the medial longitudinal bundle and join the facial just before it leaves the pars dorsalis pontis; these fibres are said to supply the anterior belly of the Occipitofrontalis, the Orbicularis palpebrarum, and the Corrugator supercilii, as these muscles have been observed to escape paralysis in lesions of the nucleus of the facial nerve.

The **acoustic or auditory nerve** lies to the outer side of the facial nerve; and between the two is a small fasciculus, the **nervus intermedius** or **pars intermedia** of **Wrisberg**, which apparently arises from the medulla oblongata and joins the facial nerve in the internal auditory meatus. The central processes of the ganglion cells, known as the **nervus intermedius**, end in the upper end of the nucleus of the glossopharyngeal nerve. If it is to be classified as part of the facial then the nervus intermedius may be regarded as the **sensor root of the facial nerve**, analogous to the sensor root of the trigeminal, and its real nucleus of origin consists of the geniculate ganglion (see p. 884). It will be remembered that a portion of the nervus intermedius is efferent (excitoglandular), arising from the nucleus salivatorius (p. 884).

FIG. 740.—Plan of the facial and intermediate nerves and their communication with other nerves.

The facial nerve, firmer, rounder, and smaller than the auditory, passes forward and outward upon the middle peduncle of the cerebellum, and enters the **internal auditory meatus** with the auditory nerve and artery. Within the meatus the facial nerve lies in a groove along the upper and anterior part of the auditory nerve, and the nervus intermedius is placed between the two and joins the inner angle of the geniculate ganglion. Beyond the ganglion its fibres are generally regarded as forming the chorda tympani (see p. 1000).

At the bottom of the meatus the facial nerve enters the **canalis facialis** or **aqueductus Fallopii** and follows the course of that canal through the petrous portion of the temporal bone, from its commencement at the internal meatus to its termination at the **stylomastoid foramen** (Figs. 50 and 739). It is at first directed outward between the cochlea and vestibule toward the inner wall of the tympanum; it

then bends suddenly backward and arches downward behind the tympanum to the stylomastoid foramen. At the point in the aqueduct of Fallopius where the nerve changes its direction (*geniculum n. facialis*), it presents a reddish, gangli-form swelling, the **geniculate ganglion** (*ganglion geniculi*) or *intumescencia gangliiformis* (Fig. 739). The geniculate ganglion receives a branch from the vestibular division of the auditory nerve. On emerging from the stylomastoid foramen the facial nerve runs forward in the substance of the parotid gland, crosses the external carotid artery, and divides behind the ramus of the mandible into two primary branches, **temporofacial** and **cervicofacial**, from which numerous offshoots are distributed over the side of the head, face, and upper part of the neck, supplying the superficial muscles in these regions. As the primary branches and their offshoots diverge from each other, they present somewhat the appearance of a bird's claw; hence the name of **pes anserinus** is given to the divisions of the facial nerve in and near the parotid gland.

Branches of Communication (Fig. 740).—The communications of the facial nerve may be thus arranged:

In the internal auditory meatus	{	With the acoustic nerve. The nervus intermedius, which is between the facial and acoustic, is supposed to give branches to both. The branch given to the acoustic accompanies it for a certain distance, and then departs from it to join the geniculate ganglion.
	{	With the acoustic as explained above.
	{	With the sphenopalatine ganglion by the large superficial petrosal nerve.
From the geniculate ganglion	{	With the otic ganglion by the small superficial petrosal nerve.
	{	With the sympathetic on the middle meningeal artery by the external superficial petrosal nerve.
In the canalis facialis or Fallopiian } aqueduct	{	With the auricular branch of the vagus.
At its exit from the stylomastoid } foramen	{	With the glossopharyngeal.
	{	With the vagus.
	{	With the great auricular.
	{	With the auriculotemporal.
Behind the ear	{	With the small occipital.
On the face	{	With three divisions of the trigeminal.
In the neck	{	With the superficial cervical.

In the internal auditory meatus some minute filaments pass between the facial and acoustic nerves.

The **large superficial petrosal nerve** arises from the geniculate ganglion and consists chiefly of sensor branches which are distributed to the mucous membrane of the soft palate. It probably also contains a few motor fibres which form the motor root of the sphenopalatine (Meckel's) ganglion. It passes forward through the hiatus canalis facialis (Fallopian) and runs in a groove on the anterior surface of the petrous portion of the temporal bone beneath the Gasserian ganglion to the foramen lacerum medium. It receives a twig from the tympanic plexus, and in the foramen is joined by the great deep petrosal, from the sympathetic plexus on the internal carotid artery, to form the Vidian nerve. This nerve passes through the Vidian canal and ends in the sphenopalatine (Meckel's) ganglion. The geniculate ganglion is connected with the otic ganglion by a branch which

joins the small superficial petrosal nerve; and also with the sympathetic filaments accompanying the middle meningeal artery, by the external petrosal nerve (Bidder). From the gangliform enlargement, according to Arnold, a twig is sent back to the auditory nerve. Just before the facial nerve emerges from the stylomastoid foramen it generally receives a twig of communication from the auricular branch of the vagus.

After its exit from the stylomastoid foramen, it sends a twig to the glossopharyngeal, another to the vagus nerve, and communicates with the great auricular branch of the cervical plexus, with the auriculotemporal branch of the inferior maxillary nerve in the parotid gland, with the small occipital nerve behind the ear, on the face with the terminal branches of the three divisions of the fifth, and in the neck with the transverse cervical.

Branches of Distribution (Fig. 740).—The branches of distribution of the facial nerves may be thus arranged:

Within the canalis facialis or aquaeductus Fallopii	{ Tympanic, to the Stapedius muscle. Chorda tympani.
At its exit from the stylomastoid foramen	{ Posterior Auricular. Digastric. Stylohyoid.
On the face	{ Temporofacial. . . { Temporal. Malar. Infraorbital. Buccal. Cervicofacial . . { Mandibular. Cervical.

The **Tympanic Branch** (*n. stapedius*) (Fig. 740) arises from the nerve opposite the pyramid; it passes through a small canal in the pyramid and supplies the Stapedius muscle.

The **Chorda Tympani** (Figs. 739 and 740) is apparently given off from the facial as it passes vertically downward at the back of the tympanum, about 5 mm. ($\frac{1}{8}$ inch) before its exit from the stylomastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture (*iter chordae posterius*) on its posterior wall between the opening of the mastoid cells and the attachment of the membrana tympani, and becomes invested with mucous membrane. It traverses the cavity of the tympanum, between the fibrous and mucous layers of the membrana tympani, crosses over the handle of the malleus, emerges from the cavity through a foramen at the inner end of the Glaserian fissure, which is called the **canal of Huguier** (*iter chordae anterior*). It then descends between the two Pterygoid muscles on the inner aspect of the spine of the sphenoid, which it sometimes grooves, and joins the lingual nerve at an acute angle. A portion of the nerve (excitoglandular division) passes to the submaxillary ganglion; the rest is continued onward through the muscular substance of the tongue to the mucous membrane covering its anterior two-thirds. These constitute the nerves of taste for this portion of the tongue. A few of its fibres probably pass through the submaxillary ganglion to the sublingual gland. Before joining the lingual nerve it receives a small communicating branch from the otic ganglion. As already stated, the chorda tympani nerve is regarded as the peripheral portion of the nervus intermedius (see p. 998).

The **Posterior Auricular Nerve** (*n. auriculus posterior*) (Figs. 740 and 741) arises close to the stylomastoid foramen, and passes upward in front of the mastoid process and between the mastoid process and the external ear, where it is joined by a filament from the auricular branch of the vagus, and communicates with the

mastoid branch of the great auricular and with the small occipital. As it ascends between the external auditory meatus and the mastoid process it divides into two branches, the auricular and the occipital branches. The **auricular branch** supplies the Retrahens aurem and the small muscles on the cranial surface of the pinna. The **occipital branch** (*ramus occipitalis*), the larger, passes backward along the superior curved line of the occipital bone, and supplies the occipital portion of the Occipitofrontalis.

The **Digastric Branch of the Facial Nerve** (*ramus digastricus*) arises close to the stylomastoid foramen; it divides into several filaments, which supply the posterior belly of the Digastric; one of these perforates that muscle to join the glossopharyngeal nerve (*ramus anastomoticus cum n. glossopharyngeo*).

The **Stylohyoid Branch** (*ramus stylohyoideus*) frequently arises by a common trunk with the digastric; it is long and slender, and passes inward to enter the Stylohyoid muscle about its middle.

The **Temporofacial Division** (Figs. 740 and 741), the larger of the two terminal branches of the facial, passes upward and forward through the parotid gland, crosses the external carotid artery and temporomaxillary vein, and passes over the neck of the condyle of the mandible, being connected in this situation with the auriculotemporal branch of the inferior maxillary nerve. It breaks up into branches which are distributed over the temple and upper part of the face; these are divided into three sets—**temporal**, **malar**, and **infraorbital**.

The **temporal branches** (*rami temporales*) cross the zygoma to the temporal region, supplying the Attrahens and Attollens aurem muscles, and join with the temporal branch of the temporomalar division of the superior maxillary nerve, and with the auriculotemporal branch of the inferior maxillary nerve. The more anterior branches supply the frontal portion of the Occipitofrontalis, the Orbicularis palpebrarum, and Corrugator supercilii muscles, and join with the supraorbital and lacrimal branches of the ophthalmic.

The **malar branches** (*rami zygomatici*) pass across the malar bone to the outer angle of the orbit, where they supply the Orbicularis palpebrarum muscle and join with filaments from the lacrimal nerve and the malar branch (*subcutaneus malae*) of the superior maxillary nerve.

The **infraorbital branches** (*rami buccales*), of larger size than the rest, pass horizontally forward to be distributed between the lower margin of the orbit and the mouth. The **superficial branches** run beneath the skin and above the superficial muscles of the face, which they supply; some branches are distributed to the Pyramidalis nasi, joining at the inner angle of the orbit with the infratrochlear and nasal branches of the ophthalmic. The **deep branches** pass beneath the Zygomatici and the Levator labii superioris, supplying the Levator anguli oris, the Levator labii superioris alaeque nasi, and the small muscles of the nose, and form a plexus, **infraorbital plexus**, by joining with the branches of the infraorbital branch of the superior maxillary nerve and the buccal branches of the cervicofacial.

The **Cervicofacial Division** of the facial nerve passes obliquely downward and forward through the parotid gland, crossing the external carotid artery. In this situation it is joined by branches from the great auricular nerve. Opposite the angle of the mandible it divides into branches which are distributed on the lower half of the face and upper part of the neck. These may be divided into three sets—**buccal**, **mandibular**, and **cervical**.

The **buccal branches** (*rami buccales*) cross the Masseter muscle. They supply the Buccinator and Orbicularis oris, and join with the infraorbital branches of the temporofacial division of the nerve, and with filaments of the buccal branch of the inferior maxillary nerve.

The **mandibular branch** (*ramus marginalis mandibulae*) passes forward beneath

the Platysma and Depressor anguli oris, supplying the muscles of the lower lip and chin, and communicating with the mental branch of the inferior dental nerve.

The **cervical branch** (*ramus colli*) runs forward beneath the Platysma, and forms a series of arches across the side of the neck over the suprahyoid region. A branch descends vertically to join with the superficial cervical nerve from the cervical plexus; others supply the Platysma.

FIG. 741.—The nerves of the scalp, face, and side of the neck.

Applied Anatomy.—The facial nerve is more frequently paralyzed than any of the other of the cranial nerves. The paralysis (*facial palsy*) may depend either upon (1) central causes—*i. e.*, blood clots or intracranial tumors pressing on the nerve before its entrance into the internal auditory meatus. It is also one of the nerves involved in *bulbar paralysis*. Or (2) it may be paralyzed in its passage through the petrous bone by damage due to *middle-ear disease* or by *fractures of the base of the skull*. Or (3) it may be affected at or after its exit from the stylomastoid foramen. This is commonly known as *Bell's paralysis*. It may be due to exposure to cold or to injury of the nerve, either from accidental wounds of the face or during some surgical operation, as removal of parotid tumors, opening of abscesses, or operations on the mandible.

When the cause is central, the abducent nerve is usually paralyzed as well, and there is also hemiplegia on the opposite side. In these cases the electric reactions are the same as in health; whereas, when the paralysis is due to a lesion in the course of the nerve, the reactions of degeneration develop. When the nerve is paralyzed in the petrous bone, in addition to the paralysis of the muscles of expression, there is loss of taste in the anterior part of the tongue, and the patient is

unable to recognize the difference between bitters and sweets, acids and salines, from involvement of the chorda tympani. The mouth is dry, because the salivary glands are not secreting; the sense of hearing is affected from paralysis of the Stapedius, but there is no hemiplegia. When the cause of the paralysis is from fracture of the base of the skull, the acoustic nerve and the petrosal nerves, which are connected with the intumescencia gangliiformis, are also involved. When the injury to the nerve is after its exit from the stylomastoid foramen, all the muscles of expression except the Levator palpebrae, together with the posterior belly of the Digastric and Stylohyoid, are paralyzed. There is smoothness of the forehead, and the patient is unable to frown; the eyelids cannot be closed, and the lower lid droops, so that the punctum is no longer in contact with the globe, and the tears run down the cheek; there is smoothness of the cheek and loss of the nasolabial furrow; the nostril of the paralyzed side cannot be dilated; the mouth is drawn to the sound side, and there is inability to whistle; food collects between the cheek and gum from paralysis of the Buccinator.

The facial nerve is at fault in cases of so-called *histrionic spasm*, which consists in an almost constant and uncontrollable twitching of the muscles of the face. This twitching is sometimes so severe as to cause great discomfort and annoyance to the patient and to interfere with sleep, and for its relief the facial nerve has been stretched. The operation is performed by making an incision behind the ear from the root of the mastoid process to the angle of the mandible. The parotid is turned forward, and the dissection carried along the anterior border of the Sternomastoid muscle and mastoid process until the upper border of the posterior belly of the Digastric is found. The nerve is parallel to this on about a level with the middle of the mastoid process. When found, the nerve may be stretched by passing a blunt hook beneath it and pulling it forward and outward. Too great force must not be used, for fear of permanent injury to the nerve. In facial paralysis of extracerebral origin it may be advisable to expose the nerve, cut it across, and anastomose the distal end of the paralyzed nerve to the accessory nerve, or, better, to the hypoglossal nerve (facioaccessory anastomosis or faciohypoglossal anastomosis). The idea was first proposed by Ballance, and has been put in practice by Ballance and Stewart, Keen, Cushing, Paure, Kennedy, and others.

THE EIGHTH OR ACOUSTIC NERVE (N. ACOUSTICUS) (Fig. 742).

The eighth or acoustic or auditory nerve comprises two distinct sets of fibres which, although both are devoted to the transmission of afferent impulses, differ in their peripheral distribution and in their central connections. The two divisions appear blended in the interval between the medulla oblongata and the internal auditory meatus, running obliquely laterofrontad in company with the facial nerve and internal auditory artery. At the internal auditory meatus the two divisions of the nerve are separable, the vestibular division above, the cochlear below.

The cochlear nerve (*radix cochlearis*) is the true nerve of hearing, lacking general sensibility, however, and therefore a nerve of special sense. The fibres of this division arise from the cells of the spiral ganglion of the cochlea as axones of bipolar cells whose dendrites or peripheral processes terminate about the (auditory) hair cells of the organ of Corti. The central connections of the cochlear division are described on page 883.

The vestibular nerve (*radix vestibularis*) conducts impulses of equilibratory sense from the semicircular canals, utricle, and saccule to the vestibular nuclei. The ganglion of origin of this nerve differs from ordinary sensor ganglia in that its cells are of bipolar structure, having retained this embryonic characteristic of the ganglion cells throughout life. The central processes of the cells of the vestibular ganglion (or ganglion of Scarpa) enter the medulla oblongata with the trunk of the cochlear nerve in the postpontile groove, laterad of the facial nerve, to establish central connections already described on page 883. The peripheral processes constitute the two main branches of the nerve—viz., (a) the utriculoampullar and (b) the sacculoampullar.

The upper or utriculoampullar branch divides into:

(a) The utricular branch, passing through the superior macula cribrosa of the vestibule to end in the macula acustica of the utricle.

passes forward between the vein and artery, and lower down in the neck becomes superficial below the Digastric muscle. The nerve then loops around the occipital artery, and crosses the external carotid and its lingual branch below the tendon of the Digastric muscle. It passes beneath the tendon of the Digastric, the Stylohyoid, and the Mylohyoid muscles, lying between the last-named muscle and the Hyoglossus (Fig. 748), and communicates at the anterior border of the Hyoglossus with the lingual nerve (Fig. 747); it is then continued forward in the fibres of the Geniohyoglossus muscle as far as the tip of the tongue, distributing branches to its muscle substance.

Branches of Communication (Fig. 747).—The branches of communication are with the—

Vagus.

Sympathetic.

First and second cervical nerves.

Lingual.

The communication with the vagus takes place close to the exit of the nerve from the skull, numerous filaments passing between the hypoglossal and the ganglion of the trunk of the vagus through the mass of connective tissue which unites the two nerves. It also communicates with the pharyngeal plexus by a minute filament as it winds around the occipital artery.

The communication with the sympathetic takes place opposite the atlas by branches derived from the superior cervical ganglion, and in the same situation the nerve is joined by filaments derived from the loop connecting the first two cervical nerves.

The communication with the lingual nerve takes place near the anterior border of the Hyoglossus muscle by numerous filaments which ascend upon it.

Branches of Distribution (Fig. 747).—The branches of distribution are:

Meningeal or Dural.

Descendens hypoglossi.

Thyrohyoid.

Muscular.

Of these branches, the descendens hypoglossi and the branches to the Infrahyoid muscles are not actually derived from the hypoglossal nerve, but, as is shown in Fig. 747, are branches from the loop formation (better called *ansa cervicalis*) of the first with the second and third cervical nerves. A part of the loop, commonly called the descendens hypoglossi, is enclosed, for a short distance, in the sheath which invests the hypoglossal nerve.

Meningeal or Dural Branches (Fig. 705).—As the hypoglossal nerve passes through the anterior condylar foramen it gives off, according to Luschka, several filaments to the dura in the posterior fossa of the base of the skull.

The **Descendens Hypoglossi** (*ramus descendens*) (Figs. 747 and 748) is a long slender branch, which leaves the hypoglossal where it turns around the occipital artery. It consists mainly of fibres which pass to the hypoglossal nerve from the first and second cervical nerves in the above-mentioned communication. It descends in front of or within the sheath of the common carotid artery, giving off a branch to the anterior belly of the Omohyoid, and then joins the communicating branches from the second and third cervical nerves, just below the middle of the neck, to form a loop, the *ansa hypoglossi*. From the convexity of this loop branches pass to supply the Sternohyoid, Sternothyroid, and the posterior belly of the Omyhyoid. According to Arnold, another filament descends in front of the vessels into the thorax, and joins the cardiac and phrenic nerves.

The **Thyrohyoid Branch** (*ramus thyrohyoideus*) (Fig. 747) is a small branch arising from the hypoglossal near the posterior border of the Hyoglossus; it passes obliquely across the great cornu of the hyoid bone and supplies the Thyrohyoid muscle.

The **Muscular Branches** (Fig. 747) are distributed to the Styloglossus, Hyoglossus, Geniohyoid, and Geniohyoglossus muscles and to the Chondroglossus, when present. At the under surface of the tongue numerous slender branches (*rami linguales*) pass upward into the substance of the organ to supply its Intrinsic muscles.

FIG. 748.—Hypoglossal nerve, cervical plexus, and their branches.

Applied Anatomy.—A wound in the submaxillary region may injure the hypoglossal nerve and result in motor paralysis of the corresponding half of the tongue. The hypoglossal nerve is an important guide in the operation of ligation of the lingual artery (see p. 594). It runs forward on the Hyoglossus muscle just above the great cornu of the hyoid bone, and forms the upper boundary of the triangular space (Lesser's triangle) in which the artery is to be sought for by cutting through the fibres of the Hyoglossus muscle.

THE SPINAL NERVES (NERVI SPINALES).

The spinal nerves spring from the spinal cord, and are transmitted through the intervertebral foramina on either side of the spinal column. There are thirty-one pairs of spinal nerves, which are arranged in the following groups, corresponding to the region of the vertebral column through which they pass:

Cervical	8 pairs.
Thoracic	12 "
Lumbar	5 "
Sacral	5 "
Coccygeal	1 pair.

It will be observed that each group of nerves corresponds in number with the vertebrae in that region, except the cervical and coccygeal. Sometimes there is no thirty-first pair. Occasionally below the thirty-first pair there may be one or even two filamentous pairs which do not pass out of the vertebral canal.

Each spinal nerve arises by two roots, an **anterior, ventral, or motor root** and a **posterior, dorsal, or sensor root**, the latter being distinguished by a ganglion termed the **spinal ganglion**.

The Anterior or Ventral Root (*radix anterior*).—The *superficial origin* is from the antero-lateral columns of the cord, corresponding to the situation of the anterior cornu of gray substance. Each root is composed of from four to eight filaments.

The *deep origin* can be traced from cells in the gray substance of the anterior cornu of the same as well as of the opposite side. The majority of the axones arise from the various groups of cells in the anterior cornu of the same side,

while others arise from the large cells of the anterior cornu of the opposite side, the axones passing across the median plane in the anterior white commissure. The axone bundles, after leaving the gray substance, penetrate horizontally through the longitudinal bundles of the antero-lateral column to emerge as described above.

The Posterior or Dorsal Root (*radix posterior*).—The *superficial origin* is by filaments (*fila radicularia*), from the postero-lateral fissure of the cord. The *real origin* of these fibres is from the nerve cells in the posterior root ganglion, from which they can be traced into the cord in two main bundles, the course of which has already been studied (p. 839). The posterior or dorsal root of the first cervical nerve is exceptional in that it is smaller than the anterior; it is occasionally wanting.

Within the vertebral canal the nerve roots are separated from each other by the *ligamentum denticulatum* (Fig. 750). In the cervical region the spinal portion of the spinal accessory nerve separates the roots.

The **spinal ganglia** are collections of nerve cells on the posterior root of each

FIG. 749—A portion of the spinal cord, showing its right lateral surface. The dura is opened and arranged to show the nerve roots. (Testut.)

of the spinal nerves. Each ganglion is oval in shape and of a reddish color; and its size bears a proportion to that of the nerve root upon which it is situated; it is bifid internally where it is joined by the two bundles of the posterior nerve root. The ganglia are usually placed in the intervertebral foramina, ectad of the point where the nerves perforate the dura. There are, however, exceptions to this rule. Thus, the ganglia upon the first and second cervical nerves lie on the neural arches of the atlas and axis respectively; those of the sacral nerves are placed within the vertebral canal; and that on the coccygeal nerve, also in the canal, is situated at some distance from the apparent origin of the posterior root.

Structure.—The ganglion in an embryo is composed of bipolar nerve cells. In an adult the bipolar nerve cells by fusion of their two poles form unipolar elements. The process of each unipolar cell divides into two a short distance from the cell. One of the processes from each cell passes to the spinal cord, and the other passes into the spinal nerve. Two other forms of cells are, however, present—viz.: (a) the cells of Dogiel, whose axones ramify close to the cell (type II of Golgi), and are distributed entirely within the ganglion; and (b) multipolar cells similar to those found in the sympathetic ganglia. On the posterior roots of the lumbar and sacral nerves, between the spinal ganglia and the cord, small cellular masses occasionally exist. They are called **accessory or aberrant ganglia** (*ganglia aberrantia*).

Each typical spinal nerve contains **somatic** and **splanchnic** fibre systems, as well as fibres connecting these systems with each other.

1. The **somatic** fibres are efferent and afferent. The *efferent* fibres originate in the cells of the anterior cornu of the spinal gray substance, and run outward through the anterior nerve roots to the spinal nerve. They convey impulses to the voluntary muscles and are continuous from their origin to their peripheral distribution. The *afferent* fibres (peripheral axones) convey impressions from the skin, etc., and originate in the unipolar nerve cells of the spinal ganglia. The central axones enter the spinal cord through the posterior nerve roots, to be continued to the medulla oblongata, to end in the nuclei of the gracile and cuneate funiculi (Goll and Burdach), or they may end by arborization around efferent neurones in the same or opposite side of the cord, completing in this way reflex arcs.

2. The **sympathetic** fibres are also efferent and afferent. The *efferent* fibres originate in the visceral motor gray substance of the spinal cord and are conveyed through the anterior nerve root and the white ramus communicans to the corresponding ganglion of the sympathetic chain; here they may end by forming synapses around its cells, or may run through the ganglion to end in another of the chain or in a more distally placed ganglion in one of the sympathetic plexuses, the impulses being relayed in other neurones to be carried to the bloodvessels of the trunk and limbs or to the viscera. The *afferent* fibres are derived partly from unipolar and partly from the multipolar cells of the spinal ganglia. Their peripheral processes are carried outward through the white rami communicantes, and after passing through one or more sympathetic ganglia without interruption, terminate in the tissues of the viscera. The central processes of the unipolar cells enter the spinal cord through the posterior nerve root and form synapses around either somatic or visceral efferent neurones, thus completing reflex arcs. The dendrites of the multipolar nerve cells form synapses around the cells of Dogiel in the spinal ganglia, and by this path the original impulse is transferred from the sympathetic to the somatic system, through which it is conveyed to the sensorium.

Points of Emergence of the Spinal Nerves.—The roots of the spinal nerves from their origin in the cord run obliquely caudad to their point of exit from the intervertebral foramina, the amount of obliquity varying in different regions of the spine, and being greater in the lower than in the upper part. The level of their emergence from the cord is within certain limits variable, and of course does not correspond to the point of emergence of the nerve from the intervertebral foramina (Fig. 752).

Each nerve root receives a covering from the pia, and is loosely invested by the arachnoid, the latter being prolonged as far as the points where the roots pierce the dura. The two roots pierce the dura separately, each receiving a sheath from this membrane; this sheath is continuous with the epineurium of the nerve where the roots join to form the spinal nerve.

Divisions.—Immediately beyond the ganglion the two roots coalesce, their fibres intermingle, and the trunk thus formed constitutes the **spinal nerve**; it passes out of the intervertebral foramen, and divides into a **posterior or dorsal primary division** for the supply of the dorsal part of the body, and an **anterior or ventral primary division** for the supply of the ventral part of the body (Fig. 750). Each division contains fibres from both roots.

Before dividing, each spinal nerve gives off a small **recurrent or meningeal branch** (*ramus meningeus*) (Fig. 750) which reënters the vertebral canal through the intervertebral foramen and supplies the membranes and bloodvessels of the cord, the vertebræ, and the vertebral ligaments.

The **posterior or dorsal primary divisions** (*rami posteriores*) (Fig. 750) of the spinal nerves are generally smaller than the anterior; they arise from the trunk

resulting from the union of the roots, in the intervertebral foramina; and, passing dorsad, divide into **internal or medial** and **external or lateral branches**, which are distributed to the muscles and integument behind the spine. The posterior

FIG. 750.—Plan of the constitution of a spinal nerve. (W. Keiller, in Gerrish's Text-book of Anatomy.)

primary divisions of the spinal nerves form two small plexuses, the **posterior cervical plexus** and the **posterior sacral plexus**. The first cervical, the fourth and fifth sacral, and the coccygeal nerves do not divide into external and internal branches.

FIG. 751.—Scheme showing structure of a typical spinal nerve.

The **anterior or ventral primary divisions** (*rami anteriores*) (Fig. 750) of the spinal nerves supply the parts of the body ventrad of the spine, including the limbs. They are for the most part larger than the posterior primary divisions. Each division, soon after its origin, receives a slender filament from the sympathetic which is called the **gray ramus communicans**. In the thoracic region the anterior

primary divisions of the spinal nerves are quite separate from each other, and are uniform in their distribution; but in the cervical, lumbar, and sacral regions they form intricate plexuses previous to their distribution. The anterior primary divisions of certain thoracic, lumbar, and sacral nerves give off a delicate collection of nerve filaments to the sympathetic cord. These are called the **white rami communicantes** or the **visceral branches of the spinal nerves**.

Posterior or Dorsal Primary Divisions of the Spinal Nerves.—The posterior or dorsal primary divisions are here described together, inasmuch as they do not enter into the formation of the important plexuses (cervical, lumbar, and sacral) exclusively made up of the anterior primary divisions.

FIG. 752.—Distribution of cutaneous nerves.

The Posterior or Dorsal Divisions of the Cervical Nerves (*rami posteriores*).—The posterior division of the first cervical nerve (Fig. 753) differs from the posterior divisions of the other cervical nerves in not dividing into an internal and external branch. It is larger than the anterior division, and escapes from the vertebral canal between the occipital bone and the posterior arch of the atlas and beneath the vertebral artery. It enters the suboccipital triangle formed by

the Rectus capitis posticus major, the Obliquus superior and Obliquus inferior; it gives branches also to the Rectus capitis posticus minor and to the Complexus. From the branch which supplies the Inferior oblique a communicating filament is given off which joins the second cervical nerve. This nerve also occasionally gives off a cutaneous filament, which accompanies the occipital artery and communicates with the occipitalis major and minor nerves.

The posterior division of the second cervical nerve is much larger than the anterior division, and is the largest of all the posterior cervical divisions. It emerges from the vertebral canal between the anterior arch of the atlas and lamina of the axis, below the Inferior oblique. It supplies a twig to this muscle, and receives a communicating filament from the first cervical. It then divides into an internal or medial and an external or lateral branch.

The internal or medial branch, called, from its size and distribution, the **great occipital nerve** (*n. occipitalis major*) (Fig. 753), ascends obliquely inward between the Obliquus inferior and the Complexus, and pierces the latter muscle and the Trapezius near their attachments to the occipital bone. It is now joined by a filament from the posterior division of the third cervical nerve, the **anastomotic**, and, ascending on the back part of the head with the occipital artery, divides into two branches, which supply the integument of the scalp as far forward as the vertex, communicating with the occipitalis minor. It gives off an **auricular branch** to the back part of the ear and **muscular branches** to the Complexus.

The **external or lateral branch** is often joined by the external branch of the posterior division of the third cervical nerve, and supplies the Splenius, Trachelomastoid, and Complexus.

FIG. 753.—Posterior primary divisions of the upper three cervical nerves. (Testut.)

The posterior division of the third cervical nerve (Fig. 753) is intermediate in size between those of the second and fourth. Its internal or cutaneous branch passes between the Complexus and Semispinalis, and, piercing the Splenius and Trapezius, supplies the skin over the latter muscle; while under the Trapezius it gives off a branch called the **third occipital nerve** (*n. occipitalis tertius*), which pierces the Trapezius and supplies the skin on the lower and back part of the head. It lies to the inner side of the occipitalis major, with which it is connected. The external branch often joins that of the second cervical.

The posterior division of the suboccipital nerve and the internal branches of the posterior divisions of the second and third cervical nerves are occasionally

joined beneath the Complexus by communicating loops to form the **posterior cervical plexus** (Cruveilhier).

The **posterior divisions of the lower five cervical nerves** pass dorsad, and divide, behind the Intertransversales muscles, into **internal or medial** and **external or lateral branches**.

The **internal branches**, the larger, are distributed differently in the upper and lower part of the neck. Those derived from the fourth and fifth nerves pass between the Complexus and Semispinalis muscles, and, having reached the spinous processes, perforate the aponeurosis of the Splenius and Trapezius, and are continued outward to the integument over the Trapezius, while those derived from the three lowest cervical nerves are the smallest, and are placed beneath the Semispinalis colli, which they supply, and then pass into the Interspinalis, Multifidus spinae, and Complexus, and send twigs through this latter muscle to supply the integument near the spinous processes.

The **external branches** supply the muscles at the side of the neck—viz., the Cervicalis ascendens, Transversalis colli, and Trachelomastoid.

The Posterior Divisions of the Thoracic Nerves (*rami posteriores*).—The posterior divisions of the thoracic nerves are smaller than the anterior, pass dorsad between the transverse processes, and divide into **internal or medial** and **external or lateral branches**.

The **internal or medial branches** of the posterior divisions of the six upper thoracic nerves pass inward between the Semispinalis dorsi and Multifidus spinae muscles, which they supply, and then, piercing the origins of the Rhomboidei and Trapezius muscles, become cutaneous by the side of the spinous processes and ramify in the integument. The medial branches of the six lower thoracic nerves are distributed to the Multifidus spinae, without giving off any cutaneous filaments.

The **external or lateral branches** increase in size from above downward. They pass through the Longissimus dorsi muscle to the cellular interval between it and the Iliocostalis muscle, and supply those muscles, as well as their continuations upward to the head, and also the Levatores costarum muscles; the five or six lower nerves also give off cutaneous filaments, which pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The **cutaneous branches** of the posterior primary divisions of the thoracic nerves are twelve in number. From each *ramus medialis* of the upper six nerves comes a *ramus cutaneus medialis*, and from each *ramus lateralis* of the lower six nerves comes a *ramus cutaneus lateralis*. The six upper cutaneous nerves are derived from the internal branches of the posterior divisions of the thoracic nerves. They pierce the origins of the Rhomboidei and Trapezius muscles, and become cutaneous by the side of the spinous processes, and then ramify in the integument. They are frequently furnished with gangliform enlargements. The six lower cutaneous nerves are derived from the external branches of the posterior divisions of the thoracic nerves. They pierce the Serratus posticus inferior and Latissimus dorsi muscles in a line with the angles of the ribs, and then ramify in the integument.

The Posterior Divisions of the Lumbar Nerves (*rami posteriores*).—The posterior divisions of the lumbar nerves diminish in size from above downward; they pass postero-laterad between the transverse processes, and divide into **internal or medial** and **external or lateral branches**.

The **internal branches** (*rami mediales*), the smaller, pass inward close to the articular processes of the vertebræ, and supply the Multifidus spinae and Interspinales muscles.

The **external branches** (*rami laterales*) supply the Erector spinae and Intertransverse muscles. The three upper branches give off cutaneous nerves which

pierce the aponeurosis of the Latissimus dorsi muscle and descend over the back part of the crest of the ilium, to be distributed to the integument of the gluteal region, some of the filaments passing as far as the trochanter major (Fig. 771).

The posterior division of the *fifth* lumbar nerve usually sends a branch which forms a loop with the posterior division of the first sacral nerve.

The Posterior Divisions of the Sacral Nerves (*rami posteriores*) (Fig. 772).—The posterior divisions of the sacral nerves are small, diminish in size from above downward, and emerge, except the last, from the sacral canal by the posterior sacral foramina. The *upper three* are covered at their exit from the sacral canal by the Multifidus spinae muscle, and divide into *internal* or *medial* and *external* or *lateral* branches.

The *internal branches* (*rami mediales*) are small, and supply the Multifidus spinae muscle.

The *external branches* (*rami laterales*) join with one another, and with the last lumbar and fourth sacral nerves, in the form of loops on the posterior surface of the sacrum, constituting the *posterior sacral plexus*. From these loops branches pass to the outer surface of the great sacrosciatic ligament, where they form a second series of loops beneath the Gluteus maximus muscle. Cutaneous branches from this second series of loops, usually two or three in number, pierce the Gluteus maximus muscle along the line drawn from the posterior superior spine of the ilium to the tip of the coccyx. They supply the integument over the posterior part of the gluteal region.

The *posterior divisions* of the *lower two* sacral nerves are small and lie below the Multifidus spinae muscle. They do not divide into internal and external branches, but join with each other, and with the posterior division of the coccygeal nerve to form the *posterior sacrococcygeal nerve*, which passes through the sacrosciatic ligament, and forms loops on the back of the sacrum, filaments from which supply the integument over the coccyx.

The Posterior Division of the Coccygeal Nerve.—The coccygeal nerve divides into its anterior and posterior divisions in the vertebral canal. The posterior division is the smaller, and it does not divide into internal and external branches, but receives, as already stated, a communicating branch from the last sacral, and is lost in the integument over the dorsum of the coccyx.

Anterior or Ventral Primary Divisions of the Spinal Nerves.—The *anterior primary divisions of the spinal nerves* (*rami anteriores*) supply the antero-lateral parts of the trunks and the limbs; they are, for the most part, larger than the posterior divisions. In the thoracic region they run independently of one another, but in the cervical, lumbar, and sacral regions they unite near their origins to form *plexuses*.

The Anterior or Ventral Divisions of the Cervical Nerves (*rami anteriores*).—The *anterior primary divisions of the cervical nerves*, with the exception of the first, pass laterad between the anterior and posterior Intertransverse muscles, lying on the grooved upper surfaces of the transverse processes, and emerge between the muscles attached to the anterior and posterior tubercles of these processes. The anterior primary division of the *first* or *suboccipital nerve* issues from the vertebral canal above the posterior arch of the atlas and runs forward around the lateral aspect of its superior articular process, internal to the vertebral artery. In most cases it descends internal to and in front of the Rectus lateralis, but in some cases it pierces the muscle.

The anterior primary divisions of the *upper four cervical nerves* unite to form the *cervical plexus*, and each receives a gray ramus communicans from the superior cervical ganglion of the sympathetic cord. Those of the *lower four cervical*, together with the greater part of the first thoracic, form the *brachial plexus*. They

each receive a gray ramus communicans, those for the fifth and sixth being derived from the middle, and those for the seventh and eighth from the inferior, cervical ganglion of the sympathetic.

THE CERVICAL PLEXUS (PLEXUS CERVICALIS) (Figs. 754, 755).

The cervical plexus is formed by the anterior divisions of the four upper cervical nerves. It is situated opposite the four upper cervical vertebræ, resting upon the Levator anguli scapulae and Scalenus medius muscles, and covered in by the Sternomastoid.

Its branches may be divided into two groups, **superficial** and **deep**, which may be thus arranged:

Superficial	{	Ascending	{ Small occipital	2, C.
		Transverse	{ Great auricular	2, 3, C.
	{	Descending or Supraclavicular	Superficial cervical	2, 3, C.
			Sternal	3, 4, C.
			Clavicular	3, 4, C.
			Acromial	3, 4, C.
			with hypoglossal	1, 2, C.
Deep	{	Internal	with vagus	1, 2, C.
			with sympathetic	1, 2, 3, 4, C.
			Rectus lateralis	1, C.
			Anterior Recti	1, 2, C.
			Communicantes hypoglossi	2, 3, C.
	{	Muscular	Phrenic	3, 4, 5, C.
			Communicating with spinal accessory	2, 3, 4, C.
			Sternomastoid	2, C.
			Trapezius	3, 4, C.
			Levator anguli scapulae	3, 4, C.
	{	External	Scalenus medius	3, 4, C.

The Superficial Branches of the Cervical Plexus.—The **Small Occipital Nerve** (*n. occipitalis minor*) (Fig. 754) arises from the second cervical nerve, sometimes also from the third; it curves around the posterior border of the Sternomastoid, and ascends, running parallel to the posterior border of the muscle, to the back part of the side of the head. Near the cranium it perforates the deep fascia, and is continued upward along the side of the head behind the ear, supplying the integument, and communicating with the great occipital, great auricular, and with the posterior auricular branch of the facial.

This nerve gives off an **auricular branch**, which supplies the integument of the upper and back part of the auricle, communicating with the mastoid branch of the great auricular. The auricular branch is occasionally derived from the great occipital nerve. The small occipital varies in size; it is occasionally double.

The **Great Auricular Nerve** (*n. auricularis magnus*) (Fig. 754) is the largest of the ascending branches. It arises from the second and third cervical nerves, winds around the posterior border of the Sternomastoid, and, after perforating the deep fascia, ascends upon that muscle beneath the Platysma to the parotid gland, where it divides into **facial**, **auricular**, and **mastoid branches**.

The **facial branches** are distributed to the integument of the face over the parotid gland; others penetrate the substance of the gland and communicate with the facial nerve.

The **auricular branches** ascend to supply the integument of the back of the pinna, except at its upper part, communicating with the auricular branches of the facial and vagus nerves. A filament pierces the pinna to reach its outer surface, where it is distributed to the lobule and lower part of the concha.

The **mastoid branch** communicates with the small occipital and the posterior

auricular branch of the facial, and is distributed to the integument behind the ear.

The **Superficial or Transverse Cervical Nerve** (*n. cutaneus colli*) (Fig. 754) arises from the second and third cervical nerves, turns around the posterior border of the Sternomastoid about its middle, and, passing obliquely forward beneath the external jugular vein to the ventral border of the muscle, perforates the deep cervical fascia, and divides beneath the Platysma into two branches, which are distributed to the antero-lateral parts of the neck.

FIG. 754.—The cutaneous branches of the right cervical plexus viewed from the right. The Platysma has been partly removed. (Spalteholz.)

The **ascending branch** (*ramus superior*) gives a filament which accompanies the external jugular vein; it then passes upward to the submaxillary region, and divides into branches, some of which form a plexus with the cervical branches of the facial nerve beneath the Platysma; others pierce that muscle and are distributed to the integument of the upper half of the neck, at its fore part, as high as the chin.

The **descending branches** (*rami inferiores*), usually represented by two or more filaments, pierce the Platysma, and are distributed to the integument of the side and front of the neck, as low as the sternum.

The **Descending or Supraclavicular Branches** (*nn. supraclaviculares*) (Fig. 754) arise from the third and fourth cervical nerves; emerging beneath the posterior border of the Sternomastoid, they descend in the posterior triangle of the neck beneath the Platysma and deep cervical fascia. Near the clavicle they perforate the fascia and Platysma to become cutaneous, and are arranged, according to their position, into three groups.

FIG. 755.—Plan of the cervical plexus. (Gerrish.)

The **Inner or Sternal Branches** (*nn. supraclaviculares anteriores*) cross obliquely over the external jugular vein and the clavicular and sternal attachments of the Sternomastoid muscle, and supply the integument as far as the median line. They furnish one or two filaments to the sternoclavicular joint.

The **Middle or Olavicular Branches** (*nn. supraclaviculares medii*) cross the clavicle, and supply the integument over the Pectoral and Deltoid muscles, communicating with the cutaneous branches of the upper intercostal nerves.

The **External or Acromial Branches** (*nn. supraclaviculares posteriores*) pass

obliquely across the outer surface of the Trapezius and the acromion, and supply the integument of the upper and back part of the shoulder.

The Deep Branches of the Cervical Plexus (Fig. 755). **Internal Series.**—The **Communicating Branches** consist of several filaments which pass from the loop between the first and second cervical nerves to the vagus, hypoglossal, and sympathetic. The branch to the hypoglossal ultimately leaves that nerve as a series

FIG. 756.—The phrenic nerve and its relations with the vagus nerve. (Toldt.)

of branches—viz., the descendens hypoglossi, the nerve to the Thyrohyoid, and the nerve to the Geniohyoid (see p. 1014). Branches from all four cervical nerves pass to the superior cervical ganglion of the sympathetic, while another communicating branch passes from the fourth to the fifth cervical.

Muscular branches supply the Anterior recti and Rectus lateralis muscles; they proceed from the first cervical nerve, and from the loop formed between it and the second.

The **Communicantes Hypoglossi** (Fig. 755) consist usually of two filaments, one being derived from the second and the other from the third cervical. These

filaments usually join to form the **descendens cervicis**, which passes downward on the outer side of the internal jugular vein, crosses in front of the vein a little below the middle of the neck, and forms a loop (*ansa hypoglossi*) with the descendens hypoglossi in front of the sheath of the carotid vessels. Occasionally, the junction of these nerves takes place within the sheath.

FIG. 757.—The right brachial plexus with its short branches, viewed from in front. The Sternomastoid and Trapezius muscles have been completely removed; the Omohyoid and Subclavius have been partially removed; a piece has been sawed out of the clavicle; the Pectoralis muscles have been incised and reflected. (Spalteholz.)

The **Phrenic** or the **Internal Respiratory Nerve of Bell** (*n. phrenicus*) (Figs. 755 and 756) arises chiefly from the fourth cervical nerve, with a few filaments from the third and a branch from the fifth, although this branch is occasionally derived from the nerve to the Subclavius. It descends to the root of the neck, running obliquely across the front of the Scalenus anticus, and beneath the Sternomastoid, the posterior belly of the Omohyoid muscles, and the transversalis colli and suprascapular vessels. It next passes over the first part of the subclavian artery, between it and the subclavian vein, and, as it enters the thorax, crosses the internal mammary artery near its origin. Within the thorax it descends nearly vertically in front of the root of the lung and by the side of the pericardium, between it and the mediastinal portion of the pleura, to the Diaphragm, where it divides into branches, some few of which are distributed to its thoracic surface, but most of which separately pierce that muscle and are distributed to its under surface (*rami phrenicoabdominales*). In the thorax it is accompanied by a branch of the internal mammary artery, the *arteria comes nervi phrenici*. The two phrenic nerves differ in their length, and also in their relations at the upper part of the thorax.

The **right phrenic nerve** is situated more deeply, and is shorter and more vertical in direction than the left; it lies on the outer side of the right innominate vein and superior vena cava.

The **left phrenic nerve** is rather longer than the right, from the inclination of the heart to the left side, and from the Diaphragm being lower on this than on the opposite side. It enters the thorax behind the left innominate vein, and crosses in front of the vagus and the arch of the aorta and the root of the lung.

Each nerve supplies filaments to the pericardium and pleura, and near the thorax is joined by a filament from the sympathetic, and, occasionally, by one from the ansa hypoglossi. Branches have been described as passing to the peritoneum.

FIG. 758.—The right brachial plexus (infraclavicular portion) in the axillary fossa, viewed from below and in front. The Pectoralis major and minor muscles have been in large part removed; their attachments have been reflected. (Spalteholz.)

From the **right nerve** one or two filaments pass to join in a small ganglion with phrenic branches of the solar plexus; and branches from this ganglion are distributed to the hepatic plexus, the suprarenal gland, and inferior vena cava. From the **left nerve** filaments pass to join the phrenic plexus of the sympathetic, but without any ganglionic enlargement.

Applied Anatomy.—Irritation of the phrenic nerve causes hiccough and persistent cough. Bilateral paralysis of the phrenic causes death from paralysis of the Diaphragm. This form of death is seen by the surgeon in fracture dislocation of the third cervical vertebra. Division of the phrenic on one side is not fatal, and is occasionally practised by the surgeon in removing a tumor of the neck. In Hearn's and Franklin's cases of removal of the vagus the phrenic was also divided. Unilateral division of the phrenic nerve causes paralysis of the corresponding half of the Diaphragm, which is difficult of recognition, because, as Gowers points out, the patient can still take deep inspirations, the thoracic muscles not being paralyzed.

The Deep Branches of the Cervical Plexus. External Series. Communicating Branches.—The deep branches of the external series of the cervical plexus

communicate with the spinal accessory nerve, in the substance of the Sternomastoid muscle, in the posterior triangle, and beneath the Trapezius.

Muscular branches are distributed to the Sternomastoid, Trapezius, Levator anguli scapulae, and Scalenus medius.

The branch for the Sternomastoid is derived from the second cervical; the Trapezius and Levator anguli scapulae receive branches from the third and fourth. The Scalenus medius is derived sometimes from the third, sometimes from the fourth, and occasionally from both nerves.

FIG. 759.—Plan of the brachial plexus. (Gerrish.)

Applied Anatomy.—The cervical plexus may be damaged by wounds or contusions, which may or may not be associated with fracture of the clavicle. Paralysis ensues, the extent depending on the degree of damage. After a contusion the paralysis is apt to be temporary and to be followed by pain and muscular spasm in the arm. Paralysis of the arm due to plexus injury may be partial or complete. In some cases there is complete motor palsy and partial sensor palsy, the sensor impulses passing along undamaged collaterals. In certain spasmodic difficulties the surgeon occasionally stretches the cervical plexus. It is reached by an incision at the posterior margin of the Sternomastoid muscle. This incision begins two inches below the level of the tip of the mastoid and is carried downward for three inches.

THE BRACHIAL PLEXUS (PLEXUS BRACHIALIS) (Figs. 757, 758).

The brachial plexus is formed by the union of the anterior primary divisions of the lower four cervical nerves and the greater part of the first thoracic nerve, receiving usually a fasciculus from the fourth cervical nerve, and frequently one from the second thoracic nerve. It extends from the lower part of the side of the neck to the axilla. It is very broad, and presents little of a plexiform arrangement at its commencement. It is narrow opposite the clavicle, becomes broad and forms a more dense interlacement in the axilla, and divides opposite the coracoid process into numerous branches for the supply of the upper limb. The nerves which form the plexus are all similar in size, and their mode of communication is subject to considerable variation, so that no one plan can be given as applying to

every case.¹ The following appears, however, to be the most constant arrangement: **above the clavicle** (*pars supraclavicularis*) the fifth and sixth cervical unite soon after their exit from the intervertebral foramina to form a common trunk. The eighth cervical and first thoracic also unite to form one trunk. So that the nerves

FIG. 760.—Cutaneous nerves of right upper extremity. Anterior view.

FIG. 761.—Cutaneous nerves of right upper extremity. Posterior view.

forming the plexus, as they lie on the *Scalenus medius* at the outer border of the *Scalenus anticus* muscle, are blended into three **trunks**—an **upper one**, formed

¹ Kerr, Bardeen, and Elting, from a study of 175 brachial plexuses, recognized seven types. In 58 per cent. the outer cord was formed from the fourth to the seventh, the inner cord from the eighth to the ninth spinal nerve, and the posterior or dorsal cord from the fourth to the ninth. In 30 per cent. the outer cord was formed from the fifth to the seventh, the inner cord from the eighth to the ninth, and the posterior cord from the fifth to the ninth.

by the junction of the fifth and sixth cervical nerves; a **middle one**, consisting of the seventh cervical nerve; and a **lower one**, formed by the junction of the eighth cervical and first thoracic nerves. As they pass beneath the clavicle, to compose the **infraclavicular part of the plexus** (*pars infraclavicularis*), each of these three trunks divides into two branches, an **anterior** and a **posterior**. The anterior divisions of the upper and middle trunks then unite to form a common cord, which is situated on the outer side of the middle part of the axillary artery, and is called the **outer cord of the brachial plexus** (*fasciculus lateralis*). The anterior division of the lower trunk passes distally on the inner side of the axillary artery in the middle of the axilla, and forms the **inner cord of the brachial plexus** (*fasciculus medialis*). The posterior divisions of all three trunks unite to form the **posterior cord of the brachial plexus** (*fasciculus posterior*), which is situated behind the second portion of the axillary artery. From this posterior cord are given off the two lower subscapular nerves, the upper subscapular nerve being given off from the posterior division of the upper trunk prior to its junction with the posterior division of the lower and middle trunks. The posterior cord divides into the circumflex and musculospiral nerves.

Branches of Communication.—The brachial plexus communicates with the cervical plexus by a branch from the fourth to the fifth cervical nerve, and with the phrenic nerve by a branch from the fifth cervical, which joins that nerve on the Anterior scalenus muscle; the fifth and sixth cervical nerves are joined by filaments to the middle cervical ganglion of the sympathetic, the seventh and eighth cervical to its inferior ganglion, and the first thoracic nerve to its first thoracic ganglion. Close to their exit from the intervertebral foramina the nerves give off the filaments to the ganglia.

Relations.—**In the neck**, the brachial plexus lies in the posterior triangle, being covered by the skin, Platysma, and deep fascia; it is crossed by the posterior belly of the Omohyoid muscle and by the transversalis colli artery. When the dorsalis scapulae artery arises from the third part of the subclavian it usually passes between the roots of the plexus. The plexus lies at first between the Scalenus anticus and medius, and then above and to the outer side of the subclavian artery; it next passes behind the clavicle and Subclavius muscle, lying upon the first serration of the Serratus magnus, and the Subscapularis muscles. It is in close relation with the apex of the lung (Luschka). **In the axilla** it is placed on the outer side of the first portion of the axillary artery; it surrounds the artery in the second part of its course, one cord lying upon the outer side of that vessel, one on the inner side, and one behind it, and at the lower part of the axillary space gives off its terminal branches to the upper extremity.

Branches of Distribution.—The branches of the brachial plexus are arranged in two groups—viz., those given off **above the clavicle**, and those **below the clavicle**.

SUPRACLAVICULAR BRANCHES.

Communicating	{ with phrenic	5, C.
	{ with sympathetic	5, 6, 7, 8, C. 1, T.
Muscular . . .	{ Rhomboids (posterior scapular)	5, C.
	{ Supraspinatus } Suprascapular	5, 6, C.
	{ Infraspinatus }	
	{ Subclavius	5, 6, C.
	{ Serratus magnus (posterior thoracic)	5, 6, 7, C.
	{ Longus colli	5, 6, 7, 8, C.
	{ Scaleni	5, 6, 7, 8, C.

The **Communicating Branch** (Figs. 756 and 759) with the **phrenic** is derived from the fifth cervical nerve or from the loop between the fifth and sixth; it joins the phrenic on the Anterior scalenus muscle. The communications with the sympathetic have already been referred to.

The **Muscular Branches** (*rami musculares*) supply the Longus colli, Scaleni, Rhomboidei, and Subclavius muscles. Those for the Longus colli and Scaleni

arise from the four lower cervical nerves at their exit from the **intervertebral foramina**.

The nerve to the **Subclavius** (*n. subclavius*) is a small filament which **arises** from the fifth cervical at its point of junction with the sixth nerve; it **descends** in front of the third part of the subclavian artery to the **Subclavius muscle**, and is usually connected by a filament with the phrenic nerve.

The **posterior scapular nerve** (*n. dorsalis scapulae*) (Figs. 757 and 759) **arises** from the fifth cervical, pierces the **Scalenus medius**, and passes beneath the **Levator anguli scapulae**, which it occasionally supplies to the **Rhomboid muscles**.

The **Long Thoracic** or the **External Respiratory Nerve of Bell** or **Posterior Thoracic Nerve** (*n. thoracalis longus*) (Figs. 757 and 764) supplies the **Serratus magnus** muscle, and is remarkable for the length of its course. It usually **arises** by three roots from the fifth, sixth, and seventh nerves, but the root from the seventh may be absent. The roots from the fifth and sixth nerves pierce the **Scalenus medius**, while that from the seventh emerges in front of that muscle. The nerve passes down behind the brachial plexus and the axillary vessels, resting on the outer surface of the **Serratus magnus**. It extends along the side of the **thorax** to the lower border of that muscle, supplying filaments to each of the muscular digitations.

The **Suprascapular Nerve** (*n. suprascapularis*) (Figs. 759 and 764) **arises** from the trunk formed by the fifth and sixth cervical nerves; passing obliquely outward beneath the **Trapezius** and the **Omohyoid**, it enters the **supraspinous fossa** below the transverse or **suprascapular ligament**, passes beneath the **supraspinatus** muscle, and curves around the external border of the spine of the scapula to the **infraspinous fossa**. In the **supraspinous fossa** it gives off two branches to the **Supraspinatus** muscle, and an articular filament to the shoulder-joint; and in the **infraspinous fossa** it gives off two branches to the **Infraspinatus** muscle, besides some filaments to the shoulder-joint and scapula.

The **Infraclavicular Branches** (Figs. 758 and 759) are derived from the three cords of the brachial plexus. The fasciculi of which they are composed may be traced through the plexuses to the spinal nerves from which they originate. They are as follows:

Outer cord	{	Musculocutaneous	5, 6, C.
		External anterior thoracic	5, 6, 7, C.
		Outer head of median	6, 7, C.
Inner cord	{	Internal anterior thoracic	8, C. 1, T.
		Internal cutaneous	8, C. 1, T.
		Lesser internal cutaneous	(8, C.) 1, T.
		Ulnar	8, C. 1, T.
		Inner head of median	8, C. 1, T.
Posterior cord	{	Upper subscapular	5, 6, C.
		Middle "	5, 6, 7, C.
		Lower "	5, 6, C.
		Circumflex	5, 6, C.
		Musculospiral	(5), 6, 7, 8, C. (1, T).

These branches from below the clavicle may be arranged according to the parts they supply:

To the thorax	Anterior thoracic.
To the shoulder	{ Subscapulars.
	{ Circumflex.
To the arm, forearm, and hand	{ Musculocutaneous.
	{ Internal cutaneous.
	{ Lesser internal cutaneous.
	{ Median.
	{ Ulnar.
	{ Musculospiral.

The **Anterior Thoracic Nerves** (*nn. thoracales anteriores*) (Figs. 758 and 759), two in number, supply the Pectoral muscles.

The **external anterior thoracic nerve** (Figs. 757 and 764), the larger of the two, *arises* from the outer cord of the brachial plexus, through which its fibres may be traced to the fifth, sixth, and seventh cervical nerves. It passes inward, across the axillary artery and vein, pierces the costocoracoid membrane, and is distributed to the under surface of the Pectoralis major muscle. It sends down a communicating filament to join the internal anterior thoracic nerve, and this communicating filament forms a loop around the inner side of the axillary artery.

The **internal anterior thoracic nerve** *arises* from the inner cord and through it from the eighth cervical and first thoracic nerves. It passes behind the first part of the axillary artery, then curves forward between the axillary artery and vein, and joins with the filament from the external nerve. It then passes to the under surface of the Pectoralis minor muscle, where it divides into a number of branches, which supply the muscle on its under surface. Some two or three branches pass through the muscle and reach the Pectoralis major.

The **Subscapular Nerves** (*nn. subscapulares*) (Figs. 758 and 759), three in number, *arise* from the posterior cord of the plexus and supply the Subscapularis, Teres major, and Latissimus dorsi muscles, and give filaments to the shoulder-joint. The fasciculi of which they are composed may be traced to the fifth, sixth, seventh, and eighth cervical nerves.

The **upper or short subscapular nerve**, the smallest, *arises* from the posterior division of the upper trunk of origin of the brachial plexus, and enters the upper part of the Subscapularis muscle; this nerve is frequently represented by two branches.

The **lower subscapular nerve** *arises* from the posterior cord of the brachial plexus, enters the axillary border of the Subscapularis, and terminates in the Teres major. The latter muscle is sometimes supplied by a separate branch.

The **middle or long subscapular nerve** (*n. thoracodorsalis*) (Fig. 716), the largest of the three, *arises* from the posterior cord of the brachial plexus and follows the course of the subscapular artery, along the posterior wall of the axilla to the Latissimus dorsi muscle, through which it may be traced as far as its lower border.

The **Circumflex Nerve** (*n. axillaris*) (Figs. 759 and 765) supplies some of the muscles, the shoulder-joint, and the integument of the shoulder (Figs. 761 and 762). It *arises* from the posterior cord of the brachial plexus, in common with the musculospiral nerve, and its fibres may be traced through the posterior cord to the fifth and sixth cervical nerves. It is at first placed behind the axillary artery, between it and the Subscapularis muscle, and passes downward and outward to the lower border of that muscle. It then winds posteriorly in company with the posterior circumflex artery, through a **quadrilateral space** bounded above by the Teres minor muscle, below by the Teres major muscle, internally by the long head of the Triceps muscle, and externally by the neck of the humerus. The nerve then divides into two branches.

The **upper branch** (Fig. 765) winds posteriorly around the surgical neck of the humerus, beneath the Deltoid, with the posterior circumflex vessels, as far as the anterior border of that muscle, supplying it, and giving off cutaneous branches, which pierce the muscle and ramify in the integument covering its lower part (Fig. 762).

The **lower branch** (Fig. 765), at its origin, distributes filaments to the Teres minor and back part of the Deltoid muscles. Upon the filaments to the former muscle an oval enlargement usually exists. The nerve then pierces the deep fascia, and supplies the integument over the lower two-thirds of the posterior surface of the Deltoid (*n. cutaneus brachii lateralis*), as well as that covering the long head of the Triceps (*caput longum n. tricipitis brachii*) (Fig. 766).

The circumflex nerve, before its division, gives off an **articular filament**, which enters the shoulder-joint below the Subscapularis muscle.

The **Musculocutaneous** (*n. musculocutaneus*) (Figs. 759 and 764) *arises* from the outer cord of the brachial plexus, opposite the lower border of the Pectoralis

FIG. 762.—Cutaneous nerves of the upper limb, anterior aspect. (W. Keiller, in Gerrish's Text-book of Anatomy.)

of the forearm to the wrist, and supplies the integument over the outer half of its anterior surface. At the wrist-joint it is placed in front of the radial artery, and some filaments, piercing the deep fascia, accompany that vessel to the dorsum of

minor muscle, receiving filaments from the fifth, sixth, and seventh cervical nerves. It perforates the Coracobrachialis muscle (Fig. 764), passes obliquely between the Biceps and Brachialis anticus muscles to the outer side of the arm, and, a little above the elbow, winds around the outer border of the tendon of the Biceps, and, perforating the deep fascia, becomes cutaneous (Fig. 760). In its course through the arm this nerve supplies the Coracobrachialis, Biceps, and the greater part of the Brachialis anticus muscles. The branch to the Coracobrachialis is given off from the nerve close to its origin, and in some instances as a separate filament from the outer cord of the plexus. The branches to the Biceps and Brachialis anticus are given off after the nerve has pierced the Coracobrachialis. The nerve also sends a small branch to the humerus, which enters the nutrient foramen with the accompanying artery, and a filament from the branch supplying the Brachialis anticus goes to the elbow-joint. The musculocutaneous furnishes the chief nerve supply to this joint.

The cutaneous portion of the musculocutaneous nerve (*n. cutaneus antebrachii lateralis*) passes behind the median cephalic vein, and divides, opposite the elbow-joint, into an anterior and a posterior branch.

The anterior branch descends along the radial border

the wrist, supplying the carpus. The nerve then passes downward to the ball of the thumb, where it terminates in cutaneous filaments. It communicates with a branch from the radial nerve and with the palmar cutaneous branch of the median.

The **posterior branch** passes downward along the back part of the radial side of the forearm to the wrist. It supplies the integument of the lower third of the forearm, communicating with the radial nerve and the external cutaneous branch of the musculospiral. The cutaneous areas supplied by the musculocutaneous nerve are indicated in Figs. 762 and 763.

Variations.—The musculocutaneous nerve presents frequent irregularities. It may adhere for some distance to the median and then pass outward, beneath the Biceps, instead of through the Coracobrachialis. Frequently some of the fibres of the median run for some distance in the musculocutaneous and then leave it to join their proper trunk. Less frequently the reverse is the case, and the median sends a branch to join the musculocutaneous. Instead of piercing the Coracobrachialis muscle the nerve may pass under it or through the Biceps. Occasionally it gives a filament to the Pronator teres muscle, and it has been seen to supply the back of the thumb when the radial nerve was absent.

The **Internal Cutaneous Nerve** (*n. cutaneus antebrachii medialis*) (Figs. 759 and 764), or **medial cutaneous nerve** of the forearm, is one of the smallest branches of the brachial plexus. It arises from the inner cord in common with the ulnar nerve and internal head of the median nerve, and, at its commencement, is placed on the inner side of the axillary artery, and afterward of the brachial artery. It derives its fibres from the eighth cervical and first thoracic nerves. This nerve gives off, near the axilla, a cutaneous filament, which pierces the fascia and supplies the integument covering the Biceps

FIG. 763.—Cutaneous nerves of the upper limb, posterior aspect. (W. Keiller. in Gerrish's Text-book of Anatomy.)

muscle nearly as far as the elbow. This filament lies a little external to the common trunk, from which it arises. It passes down the inner side of the arm,

Old terms.	New terms.
Intercostohumeral	= Intercostobrachial.
Posterior thoracic	= Long thoracic.
Nerve of Wrisberg	= Medial cutaneous nerve of upper arm. (N. cutaneus brachii medialis.)
Internal cutaneous	= Medial nerve of forearm. (N. cutaneus antebrachii medialis.)

FIG. 764.—Nerves of the left upper extremity.

pierces the deep fascia with the basilic vein, about the middle of the limb, and, becoming cutaneous, divides into two branches, **anterior** and **posterior**.

The **anterior branch**, the larger of the two, passes usually in front of, but occasionally behind, the median basilic vein. It then descends on the anterior surface of the ulnar side of the forearm, distributing filaments to the integument as far as the wrist, and communicating with a cutaneous branch of the ulnar nerve (Fig. 760).

The **posterior branch** passes obliquely downward on the inner side of the basilic vein, passes in front of, or over, the internal condyle of the humerus to the back of the forearm, and descends on the posterior surface of its ulnar side as far as the wrist, distributing filaments to the integument (Fig. 761). It communicates, above the elbow, with the lesser internal cutaneous nerve, the lower external cutaneous branch of the musculospiral, and above the wrist with the posterior cutaneous branch of the ulnar nerve. The cutaneous areas supplied by the internal cutaneous nerve are indicated in Figs. 762 and 763.

The **Lesser Internal Cutaneous Nerve**, or the **Nerve of Wrisberg** (*n. cutaneus brachii medialis*) (Figs. 759 and 764), is distributed to the integument on the inner side of the arm. It is the smallest of the branches of the brachial plexus, and, *arising* from the inner cord, receives its fibres from the first thoracic nerve. It passes through the axillary space, at first lying behind, and then on the inner side of, the axillary vein, and communicates with the intercostohumeral nerve. It descends along the inner side of the brachial artery to the middle of the arm, where it pierces the deep fascia, and is distributed to the integument of the back of the lower third of the arm, extending as far as the elbow (Figs. 761 and 762), where some filaments are lost in the integument in front of the inner condyle, and others over the olecranon. It communicates with the posterior branch of the internal cutaneous nerve.

In some cases the nerve of Wrisberg and the intercostohumeral nerve are connected by two or three filaments which form a plexus at the back part of the axilla. In other cases the intercostohumeral is of large size, and takes the place of the nerve of Wrisberg, receiving merely a filament of communication from the brachial plexus, which filament represents the latter nerve. In other cases this filament is wanting, the place of the nerve of Wrisberg being supplied entirely by the intercostohumeral.

The **Median Nerve** (*n. medianus*) (Figs. 758 and 764) extends along the middle of the arm and forearm to the hand, lying between the ulnar and musculospiral nerves, and the ulnar and the radial nerves. It *arises* by two roots, one from the outer and one from the inner cord of the brachial plexus; these embrace the lower part of the axillary artery, uniting either in front or on the outer side of that vessel. The median nerve receives filaments from the sixth, seventh, and eighth cervical and the first thoracic nerves, and sometimes from the fifth cervical as well. As it descends through the arm, it lies at first on the outer side of the brachial artery, crosses that vessel in the middle of its course, usually in front, but occasionally behind it, and lies on its inner side to the bend of the elbow, where it is situated beneath the bicipital fascia, and is separated from the elbow-joint by the Brachialis anticus muscle. In the forearm it passes between the two heads of the Pronator teres muscle and crosses the ulnar artery, but is separated from that vessel by the deep head of the Pronator teres. It descends beneath the Flexor sublimis muscle, lying on the Flexor profundus muscle, to within two inches (5 cm.) above the annular ligament, where it becomes more superficial, lying between the tendons of the Flexor sublimis and Flexor carpi radialis muscles, beneath, and rather to the radial side or under the tendon of the Palmaris longus, covered by the integument and fascia. It then passes through the **carpal canal** (*canalis carpi*) beneath the annular ligament into the palm of the hand. In its course through the fore-

arm it is accompanied by the *arteria comes nervi mediani*, a branch of the anterior interosseous artery.

Branches.—With the exception of the *nerve to the Pronator teres muscle*, which sometimes arises above the elbow-joint, and filaments to the elbow-joint, the median nerve gives off no branches in the arm. In the forearm its branches are the **muscular**, **anterior interosseous**, and **palmar cutaneous**.

The **muscular branches** (*rami musculares*) are derived from the nerve near the elbow and supply all the superficial muscles on the front of the forearm except the *Flexor carpi ulnaris*.

The **anterior or volar interosseous** (*n. interosseus [antebrachii] volaris*) (Fig. 764) supplies the deep muscles on the front of the forearm, except the inner half of the *Flexor profundus digitorum*. It accompanies the anterior interosseous artery along the interosseous membrane, in the interval between the *Flexor longus pollicis* and *Flexor profundus digitorum* muscles, both of which it supplies, and terminates below in the *Pronator quadratus* muscle, sending filaments to the inferior radioulnar articulation and the wrist-joint.

The **palmar cutaneous branch** (*ramus cutaneus palmaris n. mediani*) arises from the median nerve at the lower part of the forearm. It pierces the fascia above the annular ligament, and, descending over that ligament, divides into two branches, of which the **outer branch** supplies the skin over the ball of the thumb, and communicates with the anterior cutaneous branch of the musculocutaneous nerve; and the **inner branch** supplies the integument of the palm of the hand, communicating with the cutaneous branch of the ulnar.

In the palm of the hand the median nerve is covered by the integument and palmar fascia and is crossed by the superficial palmar arch. It rests upon the tendons of the flexor muscles. In this situation it becomes enlarged, somewhat flattened, of a reddish color, and divides into two branches. Of these, the **external branch** supplies a muscular branch to some of the muscles of the thumb and digital branches to the thumb and radial side of the index finger; the **internal branch** supplies digital branches to the contiguous sides of the index and middle and of the middle and ring fingers. The digital branches, before they subdivide, are called **common palmar digital branches of the median nerve** (*nn. digitales volares communes*).

The **branch to the muscles of the thumb** (*ramus muscularis*) is a short nerve which divides to supply the *Abductor*, *Opponens*, and the superficial head of the *Flexor brevis pollicis* muscles, the remaining muscles of this group being supplied by the ulnar nerve.

The **digital branches** (*nn. digitales volares proprii*) are five in number. The **first** and **second** pass along the borders of the thumb, the external branch communicating with branches of the radial nerve. The **third** passes along the radial side of the index finger, and supplies the *First lumbricalis* muscle. The **fourth** subdivides to supply the adjacent sides of the index and middle fingers, and sends a branch to the *Second lumbricalis* muscle. The **fifth** supplies the adjacent sides of the middle and ring fingers, and communicates with a branch from the ulnar nerve.

Each digital nerve, opposite the base of the first phalanx, gives off a dorsal branch, which joins the dorsal digital nerve from the radial nerve and runs along the side of the dorsum of the finger, to end in the integument over the last phalanx. At the end of the finger the digital nerve divides into a palmar and a dorsal branch, the former of which supplies the extremity of the finger, and the latter ramifies around and beneath the nail.

The digital nerves, as they run along the fingers, are placed superficial to the digital arteries. The cutaneous areas supplied by the median nerve are shown in Figs. 762 and 763.

The **Ulnar Nerve** (*n. ulnaris*) (Figs. 758 and 764) is situated along the inner or ulnar side of the upper limb, and is distributed to the muscles and integument of the forearm and hand. It is smaller than the median, behind which it is placed, diverging from it in its course down the arm. It *arises* from the inner cord of the brachial plexus, in common with the inner head of the median and the internal cutaneous nerves, and derives its fibres from the eighth cervical and first thoracic nerves. At its origin it lies to the inner side of the axillary artery, and holds the same relation with the brachial artery to the middle of the arm. Here it pierces the intermuscular septum, runs obliquely across the internal head of the Triceps, and descends to the groove between the internal condyle and the olecranon, accompanied by the inferior profunda artery. **At the elbow** it rests upon the back of the inner condyle, and passes into the forearm between the two heads of the Flexor carpi ulnaris muscle. **In the forearm** it descends in a perfectly straight course along the ulnar side of the extremity, lying upon the Flexor profundus digitorum muscle, its upper half being covered by the Flexor carpi ulnaris muscle, its lower half lying on the outer side of the muscle, being covered by the integument and fascia. In the upper third of its course, it is separated from the ulnar nerve by a considerable interval, but in the rest of its extent the nerve lies to the inner side of the artery. **At the wrist** the ulnar nerve crosses the annular ligament on the outer side of the pisiform bone, to the inner side of and a little behind the ulnar artery, and immediately beyond this bone divides into two branches, the superficial and the deep palmar.

Branches.—The branches of the ulnar nerve are:

In the forearm	{	Articular (elbow).	In the hand	{	Superficial palmar.
		Muscular.			Deep palmar.
		Cutaneous.			
		Dorsal cutaneous.			
		Articular (wrist).			

The **articular branches** to the elbow-joint consist of several small filaments. They *arise* from the nerve as it lies in the groove between the inner condyle of the humerus and the olecranon.

The **muscular branches** (*rami musculares*), two in number, *arise* from the trunk of the nerve near the elbow; one supplies the Flexor carpi ulnaris; the other, the inner half of the Flexor profundus digitorum.

The **cutaneous branches** are two in number, **palmar** and **dorsal**.

The **palmar cutaneous branch** (*ramus cutaneus palmaris*) *arises* from the ulnar nerve at about the middle of the forearm and runs downward on the ulnar artery, giving off some filaments entwining around the vessel. Just above the annular ligament it pierces the deep fascia and ends in the integument of the palm, communicating with the palmar cutaneous branch of the median nerve.

The **dorsal cutaneous branch** (*ramus dorsalis manus*) *arises* about two inches above the wrist; it passes posteriorly beneath the Flexor carpi ulnaris, perforates the deep fascia, and, running along the ulnar side of the back of the wrist and hand, divides into branches (*nn. digitales dorsales*); one of these supplies the inner side of the little finger; a second supplies the adjacent sides of the little and ring fingers; a third joins the branch of the radial nerve which supplies the adjoining sides of the middle and ring fingers, and assists in supplying them; a fourth is distributed to the metacarpal region of the hand, communicating with a branch of the radial nerve.

On the little finger the posterior digital branches extend only as far as the base of the terminal phalanx, and on the ring finger as far as the base of the second phalanx; the more distal parts of these digits are supplied by posterior branches derived from the palmar digital branches of the ulnar.

The **superficial palmar branch** (*ramus superficialis n. ulnaris*) supplies the Palmaris brevis and the integument on the inner side of the hand, and terminates in two digital branches, which are distributed, one to the ulnar side of the little finger, the other to the adjoining sides of the little and ring fingers, the latter communicating with a branch from the median. The digital branches are distributed to the fingers in the same manner as the digital branches of the median.

The **deep palmar branch** (*ramus profundus n. ulnaris*), accompanied by the deep branch of the ulnar artery, passes between the Abductor and Flexor brevis minimi digiti muscles; it then perforates the Opponens minimi digiti and follows the course of the deep palmar arch beneath the flexor tendons. At its origin it supplies the muscles of the little finger. As it crosses the deep part of the hand it sends two branches to each interosseous space, one for the Dorsal and one for the Palmar interosseous muscle, the branches to the Second and Third palmar interossei supplying filaments to the two inner Lumbrical muscles. At its termination between the thumb and index finger it supplies the Adductores transversus et obliquus pollicis and the inner head of the Flexor brevis pollicis. It also sends articular filaments to the wrist-joint.

It will be remembered that the inner part of the Flexor profundus digitorum muscle is supplied by the ulnar nerve; the two inner Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. The outer part of the Flexor profundus is supplied by the median nerve; the two outer Lumbricales, which are connected with the tendons of this part of the muscle, are therefore supplied by the same nerve. Brooks states that in twelve instances out of twenty-one he found that the Third lumbrical received a twig from the median nerve, in addition to its branch from the ulnar. The cutaneous areas supplied by the ulnar nerve are shown in Figs. 762 and 763.

The **Musculospiral Nerve** (*n. radialis*) (Figs. 764 and 765), the largest branch of the brachial plexus, supplies the muscles of the back part of the arm and forearm, and the integument of the same parts, as well as that of the back of the hand (Figs. 762 and 763). It arises from the posterior cord of the brachial plexus, of which it may be regarded as the continuation. Its fibres are derived from the sixth, seventh, and eighth, and sometimes also from the fifth cervical and first thoracic nerves. At its commencement it is placed first behind the axillary artery and then behind the upper part of the brachial artery, passing down in front of the tendons of the Latissimus dorsi and Teres major. It winds around from the inner to the outer side of the humerus in the musculospiral groove with the superior profunda artery, between the internal and external heads of the Triceps muscle (Fig. 765). It pierces the external intermuscular septum, and descends between the Brachialis anticus and Brachioradialis muscles to the front of the external condyle of the humerus, where it divides into the radial and posterior interosseous nerves.

The branches of the musculospiral nerve are:

Muscular.	Radial.
Cutaneous.	Posterior interosseous.

The **muscular branches** (*rami musculares n. radialis*) are derived from the nerve at the inner side, back part, and outer side of the arm respectively; they supply the Triceps, Anconeus, Brachioradialis, Extensor carpi radialis longior, and Brachialis anticus muscles. The **internal muscular branches** supply the inner and middle heads of the Triceps muscle. That to the inner head of the Triceps is a long, slender filament which lies close to the ulnar nerve, as far as the lower third of the arm, and is therefore frequently spoken of as the **ulnar collateral branch**. The **posterior muscular branch**, of large size, arises from the nerve in the groove between the Triceps muscle and the humerus. It divides into branches which

supply the outer and inner heads of the Triceps and Anconeus muscles. The branch for the latter muscle is a long, slender filament which descends in the substance of the Triceps to the Anconeus. The **external muscular branches** supply the Brachioradialis, Extensor carpi radialis longior, and (usually) the outer part of the Brachialis anticus muscles.

The **cutaneous branches** are three in number, one **internal** and two **external**. The **internal cutaneous branch** (*n. cutaneus brachii posterior*) arises in the axillary space with the inner muscular branch. It is of small size, and passes through the axilla to the inner side of the arm, supplying the integument on its posterior aspect nearly as far as the olecranon. In its course it crosses beneath the intercostohumeral nerve, with which it communicates. The **external cutaneous branch** (*n. cutaneus antebrachii dorsalis*) divides into two branches, and each one perforates the outer head of the Triceps muscle at its attachment to the humerus. The **upper** and smaller one passes to the front of the elbow, lying close to the cephalic vein, and supplies the integument of the lower half of the arm on its anterior aspect. The **lower branch** pierces the deep fascia below the insertion of the Deltoid muscle, and passes down along the outer side of the arm and elbow, and then along the back part of the radial side of the forearm to the wrist, supplying the integument in its course, and joining, near its termination, with the posterior cutaneous branch of the musculocutaneous nerve.

The **Radial Nerve** (*ramus superficialis n. radialis*) (Fig. 764), passes along the front of the radial side of the forearm to the commencement of its lower third. It lies at first a little to the outer side of the radial artery, concealed beneath the Brachioradialis. In the middle third of the forearm it lies beneath the same muscle, in close relation with the outer side of the artery. It leaves the artery about three inches above the wrist, passes beneath the tendon of the Brachio-

FIG. 765.—The suprascapular, circumflex, and musculospiral nerves.

radialis, and, piercing the deep fascia at the outer border of the forearm, divides into two branches. The **external branch**, the smaller of the two, supplies the integument of the radial side and ball of the thumb, joining with the **anterior branch** of the musculocutaneous nerve. The **internal branch** communicates, above the wrist, with the posterior cutaneous branch from the musculocutaneous, and on the back of the hand forms an arch with the dorsal cutaneous branch of the ulnar nerve. It then divides into four **digital nerves** (*nn. digitales dorsales*), which are distributed as follows: The first supplies the ulnar side of the thumb; the second, the radial side of the index finger; the third, the adjoining sides of the index and middle fingers; and the fourth, the adjacent borders of the middle and ring fingers.¹ The latter nerve communicates with a filament from the posterior branch of the ulnar nerve.

The **Dorsal or Posterior Interosseous Nerve** (*n. interosseous [antebrachii] dorsalis*) (Figs. 764 and 765) winds to the back of the forearm around the outer side of the radius, passes between the two planes of fibres of the Supinator [*brevis*] muscle, and is prolonged downward, between the superficial and deep layer of muscles, to the middle of the forearm. Considerably diminished in size, it descends on the interosseous membrane, beneath the Extensor longus pollicis muscle, to the back of the carpus, where it presents a gangliform enlargement from which filaments are distributed to the inferior radioulnar articulation, to the wrist-joint, and to the ligaments and articulations of the carpus. It supplies all the muscles of the radial and posterior brachial regions, excepting the Anconeus, Supinator longus, and Extensor carpi radialis longior.

Applied Anatomy.—The brachial plexus may be severed by traction on the limb, leading to complete paralysis. Bristow² has reported three cases of avulsion of the plexus and has described twenty-four cases. In these cases it is generally believed that the lesion is rather a tearing away of the nerves from the spinal cord than a solution of continuity of the nerve fibres themselves. In a case operated upon by Bristow it was found that the plexus had given way where the four cervical nerves and the first thoracic nerve unite to form three trunks. In supra-clavicular division of the brachial plexus, not only will there be motor and sensor paralysis in the limb, but the Serratus magnus muscle will probably be paralyzed, because of injury to the posterior thoracic nerves. In the axilla any of the nerves forming the brachial plexus may be injured by a wound of this part, the median being the one which is most frequently damaged from its exposed position. The musculospiral, on account of its sheltered and deep position, is least often wounded. The brachial plexus in the axilla is often damaged from the pressure of a crutch, producing the condition known as *crutch paralysis*. In these cases the musculospiral is the nerve most frequently implicated; the ulnar nerve being the one that appears to suffer next in frequency.

The *circumflex nerve* is of particular surgical interest. On account of its course around the surgical neck of the humerus, it is liable to be torn in fractures of this part of the bone, and in dislocations of the shoulder-joint, leading to paralysis of the Deltoid, and, according to Erb, inflammation of the shoulder-joint is liable to be followed by a neuritis of this nerve from extension of the inflammation to it.

Hilton takes the circumflex nerve as an illustration of a law which he lays down, that "*the same trunks of nerves whose branches supply the groups of muscles moving a joint furnish also a distribution of nerves to the skin over the insertions of the same muscles, and the interior of the joint receives its nerves from the same source.*" In this way he explains the fact that an inflamed joint becomes rigid, because the same nerves which supply the interior of the joint supply the muscles which move that joint.

The *median nerve* is liable to injury in wounds of the forearm. When paralyzed, there is loss of flexion of the second phalanges of all the fingers and of the terminal phalanges of the index and middle fingers. Flexion of the terminal phalanges of the ring and middle fingers can still be effected by that portion of the Flexor profundus digitorum which is supplied by the ulnar nerve. There is power to flex the proximal phalanges through the Interossei. The thumb cannot be flexed or opposed, and is maintained in a position of extension and adduction. All power of pronation is lost. The wrist can be flexed, if the hand is first adducted, by the action

¹ According to Hutchinson, the digital nerve to the thumb reaches only as high as the root of the nail; the one to the forefinger as high as the middle of the second phalanx, and the one to the middle and ring fingers not higher than the first phalangeal joint (London Hospital Gazette, vol. iii, p. 319).

² Annals of Surgery, September, 1902.

of the *Flexor carpi ulnaris*. There is loss or impairment of sensation on the palmar surface of the thumb, index, middle, and outer half of the ring fingers, and on the dorsal surface of the same fingers over the last two phalanges; except in the thumb, where the loss of sensation is limited to the back of the last phalanx. In order to expose the median nerve for the purpose of *stretching* it an incision should be made along the radial side of the tendon of the *Palmaris longus* muscle, which serves as a guide to the nerve.

The *ulnar nerve* is liable to be injured in wounds of the forearm. When paralyzed, there is loss of power of flexion in the ring and little fingers; there is impaired power of ulnar flexion and adduction of the hand; there is inability to spread out the fingers from paralysis of the *Interossei*; and there is inability to adduct the thumb. The fingers cannot be flexed at the first joints, and cannot be extended at the other joints. A *claw hand* develops, the first phalanges being overextended and the others flexed. Sensation is lost or impaired in the skin of the ulnar side of the hand anteriorly and posteriorly, involving the little finger, the ring finger, and the ulnar half of the middle finger posteriorly, and anteriorly involving the little finger and the ulnar half of the ring finger. In order to expose the nerve in the lower part of the forearm, an incision should be made along the outer border of the tendon of the *Flexor carpi ulnaris*, and the nerve will be found lying on the ulnar side of the ulnar artery.

The *musculospiral nerve* is probably more frequently injured than any other nerve of the upper extremity. In consequence of its close relationship to the humerus as it lies in the musculospiral groove, it is frequently torn or injured in fractures of this bone, or subsequently involved in the callus that may be thrown out around a fracture, and thus pressed upon and its functions interfered with. It is also liable to be squeezed against the bone by kicks or blows; it may be divided by wounds of the arm. When paralyzed, the hand is flexed at the wrist and lies flaccid. This condition is known as *drop wrist*. The fingers are also flexed, and on an attempt being made to extend them the last two phalanges only will be extended through the action of the *Interossei*, the first phalanges remaining flexed. There is no power of extending the wrist. Supination is completely lost when the forearm is extended on the arm, but is possible to a certain extent if the forearm is flexed so as to allow of the action of the *Biceps*. The power of extension of the forearm is lost on account of paralysis of the *Triceps*. Loss of sensation may be considerable or slight. Its area is shown in Fig. 763. The best position in which to expose the nerve for the purpose of stretching is to make an incision along the inner border of the *Brachioradialis* muscle, just above the level of the elbow-joint. The skin and superficial structures are to be divided and the deep fascia exposed. The white line in this structure indicating the border of the muscle is to be defined, and the deep fascia divided in this line. By now raising the *Brachioradialis* the nerve will be found lying beneath it, on the *Brachialis anticus* muscle.

Postanesthetic paralysis. When a person emerges from the influence of a general anesthetic palsy of the arm may be found to exist. The brachial plexus may have been compressed during the operation by drawing the arm strongly from the body or elevating it by the side of the head. In such a case the plexus was compressed by the head of the humerus (Braun).

The median nerve is stretched when the arm is rotated externally and drawn backward and outward. The ulnar nerve is stretched when the forearm is flexed and supinated (Braun). Garriques believes that in most cases of postanesthetic paralysis the brachial plexus was squeezed between the collar bone and the first rib by the head of the patient being drawn to the opposite side or being allowed to fall back.

The Anterior or Ventral Divisions of the Thoracic Nerves (*rami anteriores*).—

The anterior primary divisions of the thoracic nerves are twelve in number on each side. Eleven of them are situated between the ribs, and are therefore termed *intercostal*; the twelfth lies below the last rib. Each nerve is connected with the adjoining ganglion of the sympathetic by one or two filaments (*ramus communicans*). The intercostal nerves are distributed chiefly to the parietes of the thorax and abdomen and differ from the anterior divisions of the other spinal nerves in that there is no plexus formation, each nerve running an independent course. The first two nerves supply fibres to the upper limb in addition to their thoracic branches; the next four are limited in their distribution to the parietes of the thorax; the five lower supply the parietes of the thorax and abdomen; the twelfth thoracic is distributed to the abdominal wall and the skin of the buttock.

The **Anterior Division of the First Thoracic Nerve** divides into two branches; one, the larger, leaves the thorax in front of the neck of the first rib, and enters into the formation of the **brachial plexus**; the other and smaller branch runs along the first intercostal space, forming the **first intercostal nerve** (*n. intercostalis I*),

giving off muscular branches, and terminates on the anterior part of the thorax by forming the **first anterior cutaneous nerve** (*ramus cutaneus anterior n. intercostalis I*) of the thorax. Occasionally this anterior cutaneous branch is **wanting**. The first intercostal nerve, as a rule, gives off no lateral cutaneous branch, but sometimes a small branch is given off which communicates with the intercostohumeral. It frequently receives a connecting twig from the second thoracic nerve, which passes upward over the neck of the second rib.

FIG. 766.—Distribution of cutaneous nerves.

The **Anterior Divisions of the Second, Third, Fourth, Fifth, and Sixth Thoracic Nerves** and the **Small Branch from the First Thoracic Nerve** (*nn. intercostales*) are confined to the parietes of the thorax, and are named **thoracic intercostal nerves**. They pass forward in the intercostal spaces below the intercostal vessels. At the back of the thorax they lie between the pleura and the posterior intercostal membrane, piercing the latter, and course between the two planes of Intercostal muscles as far as the middle of the rib. They then enter the substance of the Internal intercostal muscles, and, running amidst their fibres as far as the costal cartilages, they gain the inner surface of the muscles, and lie between them and the pleura.

Near the sternum, they cross in front of the internal mammary artery and Triangularis sterni muscle, pierce the Internal intercostal muscles, the anterior intercostal membrane, and Pectoralis major muscle, and supply the integument of the anterior wall of the thorax and over the mammary gland, forming the anterior cutaneous nerves of the thorax; the branch from the second nerve is joined with the supraclavicular nerves of the cervical plexus.

Branches.—Numerous slender **muscular filaments** (*rami musculares*) supply the Intercostals, the Infracostales, the Levatores costarum, the Serratus posticus superior, and the Triangularis sterni muscles. At the front of the thorax some of these branches cross the costal cartilages from one intercostal space to another.

FIG. 767.—Plan of a typical intercostal nerve. (W. Keiller.)

The **lateral cutaneous nerves** (*rami cutanei laterales*) are derived from the intercostal nerves, midway between the vertebræ and sternum; they pierce the External intercostal and Serratus magnus muscles, and divide into anterior and posterior branches. The **anterior branches** (*rami anteriores*) are reflected forward to the side and fore part of the thorax, supplying the skin of the thorax and mamma; those of the fifth and sixth nerves supply the upper digitations of the External oblique. The **posterior branches** (*rami posteriores*) are reflected posteriorly to supply the integument over the scapula and over the Latissimus dorsi muscle.

The **lateral cutaneous branch of the second intercostal nerve** (*n. intercostobrachialis*) is of large size, and does not divide, like the other nerves, into an anterior and a posterior branch. It is named, from its origin and distribution, the **intercosto-humeral** or **intercostobrachial nerve** (Figs. 751 and 764). It pierces the External intercostal muscle, crosses the axilla to the inner side of the arm, and joins with a filament from the lesser internal cutaneous nerve of the upper arm (*nerve of Wrisberg*). It then pierces the fascia, and supplies the skin of the upper half of

the inner and back part of the arm (Figs. 762 and 763), communicating with the internal cutaneous branch (*n. cutaneus antebrachii medialis*) of the musculospiral nerve. The size of this nerve is in inverse proportion to the size of the other cutaneous nerves, especially the nerve of Wrisberg. A **second intercostohumeral nerve** is frequently given off from the third intercostal. It supplies filaments to the armpit and inner side of the arm. It may or may not send a branch to the intercostohumeral.

The **Anterior Divisions of the Seventh, Eighth, Ninth, Tenth, and Eleventh Thoracic Nerves** are continued anteriorly from the intercostal spaces into the abdominal wall; hence these nerves are named **thoracoabdominal intercostal nerves**. They have the same arrangement as the upper ones as far as the anterior extremities of the intercostal spaces, where they pass behind the costal cartilages, and between the Internal oblique and Transversalis muscles, to the sheath of the Rectus, which they perforate. They supply the Rectus muscle, and terminate in branches which become subcutaneous near the linea alba. These branches are named the **anterior or ventral cutaneous nerves of the abdomen**. They are directed outward as far as the lateral cutaneous nerves, supplying the integument of the front of the belly. The lower intercostal nerves supply the Intercostals, Serratus posticus inferior, and Abdominal muscles, and, about the middle of their course, give off **lateral cutaneous branches** which pierce the External intercostal and External oblique muscles, in the same line as the lateral cutaneous nerves of the thorax, and divide into **anterior and posterior branches**, which are distributed to the integument of the abdomen and back; the ventral branches supply the digitations of the External oblique and extend downward and forward nearly as far as the margin of the Rectus muscle; the posterior branches pass backward to supply the skin over the Latissimus dorsi.

The **Anterior Division of the Last Thoracic Nerve** is larger than that of the other thoracic nerves; it runs along the lower border of the last rib, and passes under the external arcuate ligament of the Diaphragm. It then runs in front of the Quadratus lumborum muscle, perforates the Transversalis muscle, and passes between it and the Internal oblique muscle, to be distributed in the same manner as the lower intercostal nerves. It communicates with the iliohypogastric branch of the lumbar plexus, and is frequently connected with the first lumbar nerve by a slender branch, the **thoracicolumbar nerve**, which descends in the substance of the Quadratus lumborum muscle. It gives a branch to the Pyramidalis muscle.

The **lateral cutaneous branch of the last thoracic** (*ramus cutaneus lateralis [abdominalis] intercostalis XII*) is remarkable for its large size. It does not divide into an anterior and a posterior branch, like the other lateral cutaneous branches of the intercostal nerves, but perforates the Internal and External oblique muscles, passes over the crest of the ilium in front of the iliac branch of the iliohypogastric, and is distributed to the integument of the front part of the gluteal region, some of its filaments extending as low down as the trochanter major.

Applied Anatomy.—The lower seven intercostal nerves and the iliohypogastric from the first lumbar nerve supply the skin of the abdominal wall. They run downward and inward fairly equidistant from each other. The sixth and seventh supply the skin over the "pit of the stomach;" the eighth corresponds to about the position of the middle linea transversa; the tenth to the umbilicus; and the iliohypogastric supplies the skin over the pubes and external abdominal ring. There are several points of surgical significance about the distribution of these nerves, and it is important to remember their origin and course, for in many diseases affecting the nerve trunks at or near their origin the pain is referred to their peripheral origins. Thus, in *Pott's disease of the spine* children will often be brought to the surgeon suffering from pain in the belly. This is due to the fact that the nerves are irritated at the seat of disease as they issue from the vertebral canal. When the irritation is confined to a single pair of nerves, the sensation complained of is often a feeling of constriction, as if a cord were tied around the abdomen; and in these cases the situation of the sense of constriction may serve to localize the disease in

the spinal column. In other cases, where the bone disease is more extensive and two or more nerves are involved, a more diffused pain in the abdomen is complained of. A similar condition is sometimes present in affections of the cord itself, as in *tuberculous dorsalis*.

Again, it must be borne in mind that the same nerves which supply the skin of the abdomen supply also the muscles which constitute the greater part of the abdominal wall. Hence it follows that any irritation applied to the peripheral terminations of the cutaneous branches in the skin of the abdomen is immediately followed by reflex contraction of the abdominal muscles. A good practical illustration of this may sometimes be seen in watching two surgeons examine the abdomen of the same patient. One, whose hand is cold, causes the muscles of the abdominal wall to contract at once and the belly to become rigid, and thus not nearly so suitable for examination; the other, who has taken the precaution to warm his hand, examines the abdomen without exciting any reflex contraction. The supply of both muscles and skin from the same source is of importance in protecting the abdominal viscera from injury. A blow on the abdomen, even of a severe character, will do no injury to the viscera if the muscles are in a condition of firm contraction; whereas in cases where the muscles have been taken unawares, and the blow has been struck while they were in a state of rest, an injury insufficient to produce any lesion of the abdominal wall has been attended with rupture of some of the abdominal contents. The importance, therefore, of immediate reflex contraction upon the receipt of an injury cannot be overestimated, and the intimate association of the cutaneous and muscular fibres in the same nerve produces a much more immediate response on the part of the muscles to any peripheral stimulation of the cutaneous filaments than would be the case if the two sets of fibres were derived from independent sources.

Again, the nerves supplying the abdominal muscles and skin are derived from the lower intercostal nerves and are intimately connected with the sympathetic supplying the abdominal viscera through the lower thoracic ganglia from which the splanchnic nerves are derived. In consequence of this, in rupture of the abdominal viscera and in acute peritonitis the muscles of the belly wall become firmly contracted, and thus as far as possible preserve the abdominal contents in a condition of rest.

THE LUMBOSACRAL PLEXUS.

The anterior primary divisions of the lumbar, sacral, and coccygeal nerves form the lumbosacral plexus, the first lumbar nerve being frequently joined by a branch from the twelfth thoracic. For descriptive purposes this plexus is usually divided into three parts—the lumbar, sacral, and pudendal plexuses.

The Anterior or Ventral Divisions of the Lumbar Nerves (*rami anteriores*).—The anterior divisions of the lumbar nerves increase in size from above downward. They are joined, near their origins, by gray *rami communicantes* from the lumbar ganglia of the sympathetic cord. These consist of long, slender filaments, which accompany the lumbar arteries around the sides of the bodies of the vertebræ beneath the Psoas magnus muscle. Their arrangement is somewhat irregular; one ganglion may give rami to two lumbar nerves, or one lumbar nerve may receive rami from two ganglia. The first and second and sometimes the third and fourth lumbar nerves are each connected with the lumbar part of the sympathetic cord by a *white ramus communicans*. The nerves pass obliquely outward behind the Psoas magnus, or between its fasciculi, distributing filaments to it and the Quadratus lumborum muscles. The first three and the greater part of the fourth are connected together in this situation by anastomotic loops, and form the **lumbar plexus**. The anterior division of the fifth lumbar, joined with a branch from the fourth, descends across the base of the sacrum to join the anterior division of the first sacral nerve and assists in the formation of the sacral plexus. The cord resulting from the union of the fifth lumbar and the branch from the fourth is called the **lumbosacral cord** (*truncus lumbosacralis*) (Figs. 769 and 774).

The Lumbar Plexus (*plexus lumbalis*) (Figs. 768 and 769).—The lumbar plexus is formed by the loops of communication between the anterior divisions of the four upper lumbar nerves. The plexus is narrow above, and often connected with the last thoracic nerve by a slender branch. The plexus is broad below, where it is joined to the sacral plexus by the lumbosacral cord. The lumbar plexus is situated in the substance of the Psoas magnus muscle near its posterior part, in front of the transverse processes of the lumbar vertebræ.

The mode in which the plexus is arranged varies in different subjects.¹ It differs from the brachial plexus in not forming an intricate interlacement, but the several nerves of distribution arise from one or more of the spinal nerves in the following manner: The first lumbar nerve receives a branch from the last tho-

FIG. 768.—Diagram of the lumbar plexus.

racic, gives off a larger, upper branch, which subdivides into the **iliohypogastric** and **ilioinguinal** nerves; and a smaller lower branch which unites with a branch of the second lumbar, to form the **genitofemoral** nerve. The remainder of the second nerve and the third and fourth lumbar nerves divide into **anterior** and **posterior divisions**. The anterior division of the second unites with the anterior division of the third nerve and a part of the anterior division of the fourth nerve to form the **obturator** nerve. The remainder of the anterior

division of the fourth nerve passes down to communicate with the fifth lumbar nerve. The posterior divisions of the second and third nerves divide into two branches, a smaller branch from each uniting to form the **external** or **lateral cutaneous** nerve, and a larger branch from each, joining with the posterior division of the fourth lumbar nerve to form the **femoral** or **anterior crural** nerve. The **accessory obturator**, when it exists, is formed by the union of two small branches given off from the third and fourth nerves.

The branches of the lumbar plexus may therefore be arranged as follows:

Iliohypogastric	1, L.
Ilioinguinal	1, L.
Genitofemoral	1, 2, L.
Dorsal Divisions.		
External (or lateral) cutaneous	2, 3, L.
Femoral (or anterior crural)	2, 3, 4, L.
Ventral Divisions.		
Obturator	2, 3, 4, L.
Accessory obturator	3, 4, L.

The **Iliohypogastric Nerve** (*n. iliohypogastricus*) (Figs. 768 and 769) arises from the first lumbar nerve. It emerges from the lateral border of the Psoas magnus muscle at its upper part, and crosses obliquely in front of the Quadratus lumborum to the crest of the ilium. It then perforates the Transversalis muscle posteriorly near the crest of the ilium. It gives off **muscular branches** (*rami musculares*) to the abdominal wall, and divides between the Transversalis and the Internal oblique into two cutaneous branches, **iliac** and **hypogastric**.

¹ For statistical studies of the variations encountered in different individuals, see the article by Bardeen, in the American Journal of Anatomy, vol. vi.

The **iliac branch** (*ramus cutaneus lateralis*) pierces the Internal and External oblique muscles immediately above the crest of the ilium, and is distributed to the integument of the gluteal region, behind the lateral cutaneous branch of the last thoracic nerve (Fig. 775). The size of this nerve bears an inverse proportion to that of the lateral cutaneous branch of the last thoracic nerve.

The **hypogastric branch** (*ramus cutaneus anterior*) (Fig. 770) continues onward between the Internal oblique and Transversalis muscles. It then pierces the Internal oblique, and becomes cutaneous by perforating the aponeurosis of the External oblique, about an inch (2.5 cm.) above and a little laterad of the external abdominal ring, and is distributed to the integument of the hypogastric region. The iliohypogastric nerve communicates with the last thoracic and ilioinguinal nerves.

FIG. 769.—The lumbar plexus and its branches.

The **Ilioinguinal Nerve** (*n. ilioinguinalis*) (Figs. 769 and 770), smaller than the preceding, *arises* with it from the first lumbar nerve. It emerges from the lateral border of the Psoas magnus muscle just below the iliohypogastric nerve, and, passing obliquely across the Quadratus lumborum and Iliacus muscles, perforates the Transversalis near the fore part of the crest of the ilium, and communicates with the iliohypogastric nerve between that muscle and the Internal oblique. The nerve then pierces the Internal oblique, distributing **muscular branches** (*rami musculares*) to it, and, accompanying the spermatic cord through the external abdominal ring, is distributed to the integument of the upper and inner part of the thigh, to the skin covering the root of the penis, and to the scrotum in the

male (*nn. scrotales anteriores*) and to the skin covering the mons veneris and labium majus in the female (*nn. labiales anteriores*). The size of this nerve is in inverse proportion to that of the iliohypogastric. Occasionally it is very small, and ends by joining the iliohypogastric; in such cases a branch from the iliohypogastric takes the place of the ilioinguinal, or the ilioinguinal nerve may be altogether absent.

The **genitofemoral or genitocrural nerve** (*n. genitofemoralis*) (Figs. 768 and 769) arises from the first and second lumbar nerves. It passes obliquely through the substance of the Psoas magnus muscle, and emerges from its inner border at a level corresponding to the intervertebral substance between the third and fourth lumbar vertebræ; it then descends on the surface of the Psoas muscle, under cover of the peritoneum, and divides into a **genital** and a **femoral branch**.

The **genital branch or external spermatic nerve** (*n. spermaticus externus*) passes outward on the Psoas magnus, and pierces the fascia transversalis, or passes through the internal abdominal ring; in the male it then descends along the back part of the spermatic cord to the scrotum, and supplies the Cremaster muscle. In the female it accompanies the round ligament, and is lost upon it.

The **femoral branch or lumboinguinal nerve** (*n. lumboinguinalis*) (Fig. 770) descends on the external iliac artery, sending a few filaments around it, and, passing beneath Poupart's ligament to the thigh, enters the sheath of the femoral vessels, lying superficial and a little external to the femoral artery. It pierces the anterior layer of the sheath of the vessels, and, becoming superficial by passing through the fascia lata, it supplies the skin of the anterior aspect of the thigh as far as midway between the pelvis and knee. On the front of the thigh it communicates with the outer branch of the middle cutaneous nerves, derived from the femoral nerve. A few filaments from this nerve may be traced on to the femoral artery; they are derived from the nerve as it passes beneath Poupart's ligament.

The **External or Lateral Cutaneous Nerve** (*n. cutaneus femoris lateralis*) (Figs. 769 and 770) arises from the second and third lumbar nerves. It emerges from the lateral border of the Psoas magnus muscle, about its middle, and crosses the Iliacus muscle obliquely, toward the anterior superior spine of the ilium. It then passes under Poupart's ligament and over the Sartorius muscle into the thigh, where it divides into two branches, **anterior** and **posterior**.

The **anterior branch** descends in an aponeurotic canal formed in the fascia lata, becomes superficial about four inches below Poupart's ligament, and divides into branches which are distributed to the integument along the anterior and outer part of the thigh, as far down as the knee. The terminal filaments of this nerve frequently communicate with the middle and internal cutaneous and with the patellar branch of the long saphenous nerve, forming with them the **patellar plexus**.

The **posterior branch** pierces the fascia lata, and subdivides into branches which pass backward across the outer and posterior surface of the thigh, supplying the integument from the level of the great trochanter to the middle of the thigh.

The **Obturator Nerve** (*n. obturatorius*) (Figs. 769 and 771) supplies the Obturator externus and Adductor muscles of the thigh, the articulations of the hip and knee, and occasionally the integument of the thigh and leg. It arises from the second, the third, and the fourth lumbar nerves. Of these, the branch from the third is the largest, while that from the second is often very small. It descends through the inner fibres of the Psoas magnus muscle, and emerges from its inner border near the brim of the pelvis; it then passes behind the external iliac vessels, which separate it from the ureter, and runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen. Here it enters the thigh, and divides into an anterior and a posterior branch, which are separated by some of the fibres of the Obturator externus muscle, and lower down by the Adductor brevis muscle.

FIG. 770.—Cutaneous nerves of right lower extremity. Front view.

FIG. 771.—Nerves of the right lower extremity.
Front view.

The **anterior branch** (*ramus anterior*) (Fig. 771) passes down in front of the Adductor brevis, being covered by the Pectineus and Adductor longus; at the lower border of the latter muscle, it communicates with the internal cutaneous and internal saphenous nerves, forming a kind of plexus. It then descends upon the femoral artery, upon which it is finally distributed. The nerve, near the obturator foramen, gives off an articular branch to the hip-joint. Behind the Pectineus it distributes muscular branches to the Adductor longus and Gracilis, and usually to the Adductor brevis, and in rare instances to the Pectineus, and receives a communicating branch from the accessory obturator nerve when that nerve is present.

Occasionally the communicating branch to the internal cutaneous and internal saphenous nerves is continued down, as a **cutaneous branch** (*ramus cutaneus*), to the thigh and leg. When this is so, it emerges from beneath the lower border of the Adductor longus, descends along the posterior margin of the Sartorius to the inner side of the knee, where it pierces the deep fascia, communicates with the internal or long saphenous nerve, and is distributed to the integument of the inner side of the leg as low down as its middle. When this communicating branch is small its place is supplied by the internal cutaneous nerve.

The **posterior branch** (*ramus posterior*) pierces the anterior part of the Obturator externus, sending branches to supply this muscle, and passes behind the Adductor brevis on the front of the Adductor magnus, where it divides into numerous muscular branches, which supply the Adductor magnus, and the Adductor brevis when the latter does not receive a branch from the anterior division of the nerve. It also gives off a filament to the knee-joint.

The **articular branch for the knee-joint** is sometimes absent; it either perforates the lower part of the Adductor magnus, or passes through the opening which transmits the femoral artery, and enters the popliteal space; it then descends upon the popliteal artery, as far as the back part of the knee-joint, where it perforates the posterior ligament, and is distributed to the synovial membrane. It gives filaments to the artery in its course.

The **Accessory Obturator Nerve** (*n. obturatorius accessorius*) (Fig. 774) is present in about 29 per cent. of cases. It is of small size, and arises by separate filaments from the third and fourth lumbar nerves. It descends along the inner border of the Psoas magnus muscle, crosses the ascending ramus of the os pubis, and passes under the outer border of the Pectineus muscle, where it divides into numerous branches. One of these supplies the Pectineus, penetrating its deep surface; another is distributed to the hip-joint; while a third communicates with the anterior branch of the obturator nerve. When this nerve is absent the hip-joint receives two branches from the obturator nerve. Occasionally it is very small, and becomes lost in the capsule of the hip-joint.

The **Femoral or Anterior Crural Nerve** (*n. femoralis*) (Figs. 769 and 771) is the largest branch of the lumbar plexus. It supplies muscular branches to the Iliacus, Pectineus, and all the muscles on the front of the thigh, excepting the Tensor fasciae femoris; cutaneous filaments to the front and inner side of the thigh, and to the leg and foot (Fig. 766); and articular branches to the hip- and knee-joint. It arises from the second, third, and fourth lumbar nerves, sometimes from the first or fifth as well. It descends through the fibres of the Psoas magnus, emerging from this muscle at the lower part of its outer border, and passes downward between it and the Iliacus muscle, and beneath Poupart's ligament, into the thigh, where it becomes somewhat flattened, and divides into an anterior and a posterior part. Under Poupart's ligament it is separated from the femoral artery by a portion of the Psoas magnus.

Within the abdomen the femoral nerve gives off from its outer side some small muscular branches to the Iliacus, and a branch to the femoral artery which is

distributed upon the upper part of that vessel. The origin of this branch varies; it occasionally arises higher than usual, or it may arise lower down in the thigh.

In the thigh the following branches are given off:

From the Anterior Division.

Middle cutaneous.
Internal cutaneous.
Muscular.

From the Posterior Division.

Long saphenous.
Muscular.
Articular.

The middle and internal cutaneous branches of the femoral nerve are the **rami cutanei anteriores n. femoralis** of the BNA.

The **middle cutaneous nerve** (Figs. 770 and 771) pierces the fascia lata (and generally the Sartorius) about three inches (8 cm.) below Poupart's ligament, and divides into two branches (Fig. 770), which descends in immediate proximity along the fore part of the thigh, to supply the integument as low as the front of the knee. Here they communicate with the internal cutaneous nerve and the patellar branch of the internal saphenous nerve, to form the **patellar plexus**. In the upper part of the thigh the outer division of the middle cutaneous nerve communicates with the femoral branch of the genitofemoral nerve.

The **internal cutaneous nerve** (Fig. 770) passes obliquely across the upper part of the sheath of the femoral artery, and divides in front or at the inner side of that vessel into two branches, **anterior** and **posterior** or **internal**.

The internal cutaneous nerve, before dividing, gives off a few filaments, which pierce the fascia lata (accompanying the long saphenous vein) to supply the integument of the inner side of the thigh. One of these filaments passes through the saphenous opening; a second becomes subcutaneous about the middle of the thigh (Fig. 770); and a third pierces the fascia at its lower third (Fig. 770).

The **anterior branch** runs downward on the Sartorius, perforates the fascia lata at the lower third of the thigh, and divides into two branches, one of which supplies the integument as low down as the inner side of the knee; the other crosses to the outer side of the patella, communicating in its course with the **nervus cutaneus patellae**, a branch of the long or internal saphenous nerve. The **posterior** or **internal branch** descends along the inner border of the Sartorius muscle to the knee, where it pierces the fascia lata, communicates with the long saphenous nerve, and gives off several cutaneous branches. It then passes down to supply the integument of the inner side of the leg. Beneath the fascia lata, at the lower border of the Adductor longus, it joins with branches of the long saphenous and obturator nerves to form a plexiform network (**subsartorial plexus**) (Fig. 771). When the communicating branch from the obturator nerve is large and continued to the integument of the leg, the internal branch of the internal cutaneous is small and terminates in the plexus, occasionally giving off a few cutaneous filaments.

The **Muscular Branches of the Anterior Division** (**rami musculares**).—The nerve to the **Pectineus** arises from the femoral nerve immediately below Poupart's ligament, and passes inward behind the femoral sheath to enter the anterior surface of the muscle; it is often duplicated. The nerve to the **Sartorius** arises in common with the middle cutaneous.

The **long or internal saphenous nerve** (*n. saphenus*) (Figs. 770 and 771) is the largest of the cutaneous branches of the femoral nerve. It approaches the femoral artery where this vessel passes beneath the Sartorius, and lies in front of it, beneath the aponeurotic covering of Hunter's canal, as far as the opening in the lower part of the Adductor magnus. It then leaves the artery, and proceeds distally along the inner side of the knee, beneath the Sartorius muscle, pierces the fascia lata opposite the interval between the tendons of the Sartorius and Gracilis muscles, and becomes

subcutaneous. The nerve then passes along the inner side of the leg (Fig. 770), accompanied by the internal saphenous vein, descends behind the internal border of the tibia, and at the lower third of the leg divides into two branches; one continues its course along the margin of the tibia, terminating at the inner ankle; the other passes in front of the ankle, and is distributed to the integument along the inner side of the foot, as far as the great toe, communicating with the internal branch of the musculocutaneous nerve.

The long saphenous nerve *about the middle of the thigh* gives off a communicating branch which joins the subsartorial plexus.

At the inner side of the knee it gives off a large **patellar branch** (*ramus infrapatellaris*), which pierces the Sartorius and fascia lata, and is distributed to the integument in front of the patella. This nerve communicates above the knee with the anterior branch of the internal cutaneous and with the middle cutaneous; below the knee, with other branches of the long saphenous; and on the outer side of the joint, with branches of the external cutaneous nerve, forming a plexiform network, the **patellar plexus** (*plexus patellae*). The patellar branch is occasionally small, and terminates by joining the internal cutaneous, which supplies its place in front of the knee.

Below the knee the branches of the long saphenous nerve are distributed to the integument of the front and inner side of the leg, communicating with the cutaneous branches from the internal cutaneous or from the obturator nerve.

The **Muscular Branches of the Posterior Division** supply the four parts of the Quadriceps extensor muscle.

The **branch to the Rectus femoris** enters its under surface high up, sending off a small filament to the hip-joint.

The **branch to the Vastus externus**, of large size, follows the course of the descending branch of the external circumflex artery to the lower part of the muscle. It gives off an articular filament to the knee-joint.

The **branch to the Vastus internus** is a long branch which runs down on the outer side of the femoral vessels in company with the long saphenous nerve. It enters the muscle about its middle, and gives off a filament which can usually be traced downward on the surface of the muscle to the knee-joint.

The **branches to the Crureus** are two or three in number, and enter the muscle on its anterior surface about the middle of the thigh; a filament from one of these descends through the muscle to the Subcrureus and the knee-joint.

The **articular branch to the hip-joint** is derived from the nerve to the Rectus muscle.

The **articular branches to the knee-joint** are three in number. One, a long slender filament, is derived from the nerve to the Vastus externus muscle; it penetrates the capsular ligament of the joint on its anterior aspect. Another is derived from the nerve to the Vastus internus muscle. It can usually be traced downward on the surface of this muscle to near the joint; it then penetrates the muscle and accompanies the deep branch of the anastomotica magna artery, pierces the capsular ligament of the joint on its inner side, and supplies the synovial membrane. The third branch is derived from the nerve to the Crureus.

The Anterior or Ventral Divisions of the Sacral and Coccygeal Nerves (*rami anteriores*) (Fig. 774).—The **anterior primary divisions** of the **sacral and coccygeal nerves** form the **sacral and pudendal plexuses**. The anterior divisions of the upper four sacral nerves enter the pelvis through the anterior sacral foramina, that of the fifth between the sacrum and coccyx, while that of the coccygeal nerve curves forward below the rudimentary transverse process of the first piece of the coccyx. The first and second sacral are large; the third, fourth, and fifth diminish progressively from above downward. Each nerve receives a *gray ramus communicans* from the corresponding ganglion of the sympathetic cord,

FIG. 772.—The posterior sacral nerves.

FIG. 773.—Side view of pelvis, showing sacral nerves.

while from the third, and frequently from the second and fourth anterior sacral divisions, *white rami communicantes* are given to the pelvic plexuses of the sympathetic.

THE SACRAL PLEXUS (PLEXUS SACRALIS) (Fig. 774).

The *sacral plexus* is formed by the lumbosacral cord, the anterior primary division of the first and portions of the anterior primary divisions of the second and third sacral nerves.

The lumbosacral cord comprises the whole of the anterior primary division of the fifth and a part of the anterior primary division of the fourth lumbar nerves; it appears at the inner margin of the Psoas magnus and runs downward (caudad) over the pelvic brim to join the first sacral nerve. The third sacral nerve divides into an upper and a lower branch, the former entering the sacral and the latter the pudendal plexus

FIG. 774.—Plan of sacral plexus with the pudendal plexus. (Gerrish.) (See text for variations in origin of the perforating cutaneous nerve.)

The branches or divisions forming the sacral plexus converge toward the lower part of the great sacrosciatic foramen, and unite to form a flattened band, from the anterior and posterior surfaces of which several branches arise. The band itself is continued as the *great sciatic nerve*, which splits on the back of the thigh into the *internal* and *external popliteal* nerves; these two nerves sometimes arise separately from the plexus, and in all cases their independence can be shown by dissection.

Relations.—The sacral plexus lies on the anterior or ventral surface of the pelvic part of the Pyriformis and is covered in front by the pelvic fascia, which separates it from the internal iliac vessels, the ureter and the pelvic colon. The gluteal vessels run between the lumbosacral cord and the first sacral nerve, and the sciatic vessels between the second and third sacral nerves.

All the nerves entering the plexus, with the exception of the third sacral, split into anterior and posterior divisions, and the nerves arising from these are as follows:

	Anterior or Ventral Divisions.	Posterior or Dorsal Divisions.
Nerve to Quadratus femoris and Gemellus inferior	4, 5, L. 1, S.	
Nerve to Obturator internus and Gemellus superior	5, L. 1, 2, S.	
Nerve to Piriformis		(1), 2, S.
Superior gluteal		4, 5, L. 1, S.
Inferior gluteal		5, L. 1, 2, S.
Small sciatic	2, 3, S.	
Great sciatic { Internal popliteal	4, 5, L. 1, 2, 3, S.	
{ External popliteal		4, 5, L. 1, 2, S.

The nerve to the *Quadratus femoris* and *Gemellus inferior* arises from the anterior divisions of the fourth and fifth lumbar and first sacral nerves; it leaves the pelvis through the great sacrosclatic foramen, below the *Piriformis*, and runs downward beneath the great sciatic nerve, the *Gemelli*, and the tendon of the *Obturator internus*, enters the anterior surface of these muscles; it gives off an articular branch to the hip-joint.

The nerve to the *Obturator internus* arises from the anterior divisions of the fifth lumbar and first and second sacral nerves; it leaves the pelvis through the great sacrosclatic foramen below the *Piriformis* muscle, crosses the ischial spine, reënters the pelvis through the small sacrosclatic foramen, and ends in the *Obturator internus*, after entering the pelvic surface of that muscle. The branch to the *Gemellus superior* enters the upper part of the posterior surface of that muscle.

The nerve to the *Piriformis* arises from the posterior division of the second, or the posterior divisions of the first and second sacral nerves, and enters the anterior surface of the muscle; this nerve may be double.

The **Superior Gluteal Nerve** (*n. gluteus superior*) (Figs. 774 and 776) arises from the posterior divisions of the fourth and fifth lumbar and first sacral nerves; it leaves the pelvis through the great sacrosclatic foramen above the *Piriformis*, accompanied by the gluteal vessels, and divides into a superior and an inferior branch. The superior branch accompanies the upper branch of the deep division of the gluteal artery, and ends in the *Gluteus minimus* after giving off branches to supply a part of the *Gluteus medius*. The inferior branch accompanies the lower branch of the gluteal artery across the *Gluteus minimus*; it gives filaments to the *Gluteus medius* and *Gluteus minimus*, and ends in the *Tensor fasciæ femoris*.

The **Inferior Gluteal Nerve** (*n. gluteus inferior*) (Fig. 774) arises from the posterior divisions of the fifth lumbar and first and second sacral nerves; it leaves the pelvis through the great sacrosclatic foramen, below the *Piriformis* muscle, and divides into branches, which enter the deep surface of the *Gluteus maximus*.

The **Small Sciatic** (*n. cutaneus femoris posterior*) (Figs. 774 and 776), or **post-femoral cutaneous nerve** supplies the integument of the perineum and back part of the thigh and leg. It arises partly from the anterior and partly from the posterior divisions of the first, second, and third sacral nerves, and emerges from the pelvis through the great sacrosclatic foramen below the *Piriformis*. It then descends beneath the *Gluteus maximus* with the sciatic artery, and passes down the back part of the thigh beneath the fascia lata, and over the long head of the *Biceps* to the lower part of the popliteal region, here it pierces the fascia and accompanies the external saphenous vein (*v. saphena parva*) to about the middle of the back of the leg, its terminal filaments communicating with the sural or external saphenous nerve.

The branches of the small sciatic nerve are all cutaneous, and are grouped as follows: **gluteal**, **perineal**, and **femoral**.

The **gluteal cutaneous branches** (*nn. clunium inferiores [laterales]*), two or three in number, turn upward around the lower border of the Gluteus maximus to supply the skin covering the lower and outer part of that muscle.

The **perineal cutaneous branches** (*rami perineales*) are distributed to the skin at the upper and inner side of the thigh, on its posterior aspect. One branch, longer than the rest, the **inferior pudendal or long scrotal nerve** (Fig. 776), curves forward below the ischial tuberosity, pierces the fascia lata, and runs forward beneath the superficial fascia of the perineum to be distributed to the skin of the scrotum in the male and the labium majus in the female, communicating with the superficial perineal and inferior hemorrhoidal nerves.

The **femoral cutaneous branches** consist of numerous descending filaments derived from both sides of the nerve, and are distributed to the back and inner sides of the thigh, to the skin covering the popliteal space, and to the upper part of the leg.

The **Great Sciatic Nerve** (*n. ischiadicus*) (Figs. 774 and 776) supplies nearly the whole of the integument of the leg, the muscles of the back of the thigh, and those of the leg and foot. It is the largest nerve cord in the body, measuring three-quarters of an inch in breadth, and is the continuation of the flattened band of the sacral plexus. It passes out of the pelvis through the great sacrosciatic foramen, below the Piriformis muscle. It descends between the great trochanter of the femur and the tuberosity of the ischium, along the back part of the thigh, to about its lower third, where it divides into two large branches, the **internal popliteal or tibial** and **external popliteal or peroneal nerves** (Fig. 776). This division may take place at any point between the sacral plexus and the lower third of the thigh. When the division occurs at the plexus (in 10 per cent. of cases) the two nerves descend together side by side; or they may be separated, at their commencement, by the interposition of part or the whole of the Piriformis muscle.

As the nerve descends along the back of the thigh, it rests upon the posterior surface of the ischium, the nerve of the Quadratus femoris, and the External rotator muscles of the thigh, in company with the small sciatic nerve and artery, and is covered by the Gluteus maximus; lower down, it lies upon the Adductor magnus, and is covered by the long head of the Biceps.

The **branches** of the nerve, before its division, are **articular** and **muscular**.

The **articular branches** (*rami articulares*) arise from the upper part of the nerve; they supply the hip-joint, perforating the posterior part of its fibrous capsule. These branches are sometimes derived directly from the sacral plexus.

The **muscular branches** (*rami musculares*) are distributed to the flexors of the leg—viz., the Biceps, Semitendinosus, and Semimembranosus, and to the Adductor magnus. The nerve to the short head of the Biceps comes from the external popliteal part of the great sciatic, while the other muscular branches arise from the internal popliteal portion, as may be seen in those cases where the two popliteal nerves emerge separately on the buttock.

The **Internal Popliteal or Tibial Nerve** (*n. tibialis*) (Figs. 774 and 776), the larger of the two terminal branches of the great sciatic, *arises* from the anterior primary branches of the last two lumbar and first three sacral nerves. It descends along the back part of the thigh, through the middle of the popliteal space, to the lower part of the Popliteus muscle, where it passes with the artery beneath the arch of the Soleus and becomes the **posterior tibial**. It is overlapped by the Hamstring muscles above, and then becomes more superficial, and lies to the outer side of, and some distance from, the popliteal vessels; opposite the knee-joint it is in close relation with the vessels, and crosses to the inner side of the artery. Below, it is overlapped by the Gastrocnemius.

The **branches** of this nerve are the **articular** and **muscular**, and a **cutaneous branch**, the **communicans tibialis**.

FIG. 775.—Cutaneous nerves of lower extremity. Posterior view.

FIG. 776.—Nerves of the lower extremity.¹ Posterior view.

¹ N. B.—In this diagram the external saphenous (or sural nerve) and communicans peronei are not in their normal position. They have been displaced by the removal of the superficial muscles.

The articular branches (*rami articulares*), usually three in number, supply the knee-joint; two of these branches accompany the superior and inferior internal articular arteries, and a third, the azygos articular artery.

The **muscular branches** (*rami musculares*), four or five in number, *arise* from the nerve as it lies between the two heads of the Gastrocnemius; they supply that muscle and the Plantaris, Soleus, and Popliteus. The branch which supplies the Popliteus turns around its lower border and is distributed to the deep surface of the muscle.

The **communicans tibialis** (*n. cutaneus surae medialis*) descends between the two heads of the Gastrocnemius, and about the middle of the back of the leg pierces the deep fascia, and joins a communicating branch (*ramus anastomoticus peroneus*) from the external popliteal nerve to form the **short or external saphenous nerve** (Fig. 776). The external saphenous nerve, formed by the communicating branches of the internal and external popliteal nerves, passes downward and outward near the outer margin of the tendo Achillis, lying close to the external saphenous vein, to the interval between the external malleolus and the os calcis. It divides into two branches, the posterior of which breaks up into **lateral calcaneal branches** (*rami calcanei laterales*). The **anterior branch** (*n. cutaneus dorsalis lateralis*) winds around the outer malleolus, and is distributed to the integument along the outer side of the foot and little toe, communicating on the dorsum of the foot with the musculocutaneous nerve. In the leg its branches communicate with those of the small sciatic. The cutaneous area supplied by the external saphenous nerve is indicated in Fig. 778.

The **Posterior Tibial Nerve** (Fig. 776), the direct continuation of the internal popliteal nerve, commences at the lower border of the Popliteus muscle, and passes along the back part of the leg with the posterior tibial vessels to the interval between the inner malleolus and the heel, where it divides into the **external and internal plantar nerves**. It lies upon the deep muscles of the leg, and is covered above by the muscles of the calf, lower down by the skin and fascia. In the upper part of its course it lies to the inner side of the posterior tibial artery, but it soon crosses that vessel, and lies to its outer side as far as the ankle. In the lower third of the leg it is placed parallel with the inner margin of the tendo Achillis.

The branches of the posterior tibial nerve are **muscular, internal calcaneal, and articular**.

The **muscular branches** (*rami musculares*) *arise* either separately or by a common trunk from the upper part of the nerve. They supply the Soleus, Tibialis posterior, Flexor longus digitorum, and Flexor longus hallucis muscles; the branch to the latter muscle accompanies the peroneal artery. The branch to the Soleus enters the deep surface of the muscle, while that from the internal popliteal enters the superficial surface.

The **internal calcaneal branches** (*rami calcanei mediales*) perforate the internal annular ligament, and supply the integument of the heel and inner side of the foot (Fig. 778).

The **articular branch** (*ramus articularis ad articulationem talocruralem*) is given off just above the bifurcation of the nerve and supplies the ankle-joint.

The **Internal Plantar Nerve** (*n. plantaris medialis*) (Fig. 777), the larger of the two terminal branches of the internal popliteal, accompanies the internal plantar artery along the inner side of the foot. From its origin at the inner ankle it passes beneath the Abductor hallucis, and then forward between this muscle and the Flexor brevis digitorum; it divides opposite the bases of the metatarsal bones into **four plantar digital branches** (*nn. digitales plantares communes*) and communicates with the plantar nerve.

Branches.—In its course the internal plantar nerve gives off **cutaneous branches**, which pierce the plantar fascia and supply the integument of the sole of the foot

(Fig. 778); **muscular branches**, which supply the Abductor hallucis and Flexor brevis digitorum; **articular branches**, to the articulations of the tarsus and metatarsus; and **four plantar digital branches** (*nn. digitales plantares proprii*). The first (innermost) branch becomes cutaneous about the middle of the sole, between the Adductor hallucis and Flexor brevis digitorum; the three outer branches pass between the divisions of the plantar fascia in the clefts between the toes. They are distributed in the following manner: The **first** supplies the inner border of the great toe, and sends a filament to the Flexor brevis hallucis muscle; the **second** bifurcates, to supply the adjacent sides of the great and second toes, sending a filament to the First lumbrical muscle; the **third** supplies the adjacent sides of the second and third toes; the **fourth** supplies the corresponding sides of the third and fourth toes, and receives a communicating branch from the external plantar nerve (Fig. 736). Each digital nerve gives off cutaneous and articular filaments; and opposite the last phalanx sends a dorsal branch, which supplies the structures around the nail, the continuation of the nerve being distributed to the ball of the toe. It will be observed that the distribution of these branches is precisely similar to that of the median nerve in the hand.

The **External Plantar Nerve** (*n. plantaris lateralis*) (Fig. 777), the smaller of the two, completes the nerve supply to the structures of the sole of the foot (Fig. 778), being distributed to the little

FIG. 777.—The plantar nerves.

FIG. 778.—Areas of distribution of the cutaneous nerves of the sole (W. Keiller, in Gerrish's Text-book of Anatomy.)

toe and outer half of the fourth, as well as to most of the deep muscles, its distribution being similar to that of the ulnar nerve in the hand. It passes obliquely forward with the external plantar artery to the outer side of the foot, lying between the Flexor brevis digitorum and Flexor accessorius; and in the interval between the former muscle and Abductor minimi digiti, divides into a **superficial** and a **deep branch**. Before its division it supplies the Flexor accessorius and Abductor minimi digiti.

The **superficial branch** (*ramus superficialis*) separates into two digital nerves. One, the smaller of the two, supplies the outer side of the little toe, the Flexor brevis minimi digiti, and the two Interosseous muscles of the fourth metatarsal

space; the other and larger digital branch supplies the adjoining sides of the fourth and fifth toes, and communicates with the internal plantar nerve.

The **deep or muscular branch** (*ramus profundus*) accompanies the external plantar artery into the deep part of the sole of the foot, beneath the tendons of the Flexor muscles, and Adductor obliquus hallucis, and supplies all the Interossei (except those in the fourth metatarsal space), the three outer Lumbricales, the Adductor obliquus hallucis, and the Adductor transversus hallucis.

The **External Popliteal or Peroneal Nerve** (*n. peronaeus communis*) (Figs. 774 and 776), about one-half the size of the internal popliteal, is derived from the posterior branches of the last two lumbar and first two sacral nerves. It descends obliquely along the outer sides of the popliteal space to the head of the fibula, close to the inner margin of the Biceps muscle. It is easily felt beneath the skin behind the head of the fibula at the inner side of the tendon of the Biceps. It passes between the tendon of the Biceps and outer head of the Gastrocnemius, winds around the neck of the fibula, between the Peroneus longus and the bone, and divides beneath the muscle into the **anterior tibial** and **musculocutaneous nerves**.

The **branches** of the external popliteal nerve, previous to its division, are **articular** and **cutaneous**.

The **articular branches** (*rami articulares*) are three in number: two of these accompany the superior and inferior external articular arteries to the outer side of the knee. The upper one occasionally *arises* from the great sciatic nerve before its bifurcation. The third (*recurrent*) articular nerve is given off at the point of division of the external popliteal nerve; it ascends with the anterior recurrent tibial artery through the Tibialis anticus muscle to the front of the knee, which it supplies.

The **Lateral Cutaneous Branch** (*n. cutaneous surae lateralis*).—There may be two or three of these branches. They supply the integument along the back part and outer side of the leg. The largest **cutaneous** branch of the peroneal is the **peroneal communicating** (*ramus anastomaticus peronaeus* or *communicans fibularis*), which *arises* near the head of the fibula, crosses the external head of the Gastrocnemius to the middle of the leg, and joins with the *communicans tibialis* to form the external saphenous nerve. This nerve occasionally exists as a separate branch, which is continued as far down as the heel.

The **Anterior Tibial Nerve or Deep Peroneal** (*n. peronaeus profundus*) (Fig. 771) commences at the bifurcation of the peroneal nerve, between the fibula and upper part of the Peroneus longus, passes obliquely downward beneath the Extensor longus digitorum muscle to the fore part of the interosseous membrane, and gets into relation with the anterior tibial artery above the middle of the leg; it then descends with the artery to the front of the ankle-joint, where it divides into an **external** and an **internal branch**. This nerve lies at first on the outer side of the anterior tibial artery, then in front of it, and again at its outer side at the ankle-joint.

The **branches** of the anterior tibial nerve in its course through the leg are the **muscular branches** (*rami musculares*) to the Tibialis anticus, Extensor longus digitorum, Peroneus tertius, and Extensor proprius hallucis muscles, and an **articular branch** to the ankle-joint.

The **external or tarsal branch** of the anterior tibial nerve passes outward across the tarsus, beneath the Extensor brevis digitorum, and, having become enlarged like the posterior interosseous nerve at the wrist, supplies the Extensor brevis digitorum muscle. From the enlargement three minute **interosseous branches** are given off which supply the tarsal joints and the metatarsophalangeal joints of the second, third, and fourth toes. The first of these sends a filament to the Second dorsal interosseous muscle.

The **internal branch**, the continuation of the nerve, accompanies the dorsalis pedis artery along the inner side of the dorsum of the foot, and at the first interosseous space divides into two **dorsal digital branches** (*nn. digitales dorsales hallucis lateralis et digiti secundi medialis*), which supply the adjacent sides of the great and second toes, communicating with the internal branch of the musculocutaneous nerve. Before it divides it gives off to the first space an **interosseous branch** which supplies the metatarsophalangeal joint of the great toe and sends a branch to the First dorsal interosseous muscle.

The **Musculocutaneous Nerve** (*n. peroneus superficialis*) (Fig. 771) supplies the muscles on the fibular side of the leg and the integument over the greater part of the dorsum of the foot. It passes forward between the Peronei muscles and the Extensor longus digitorum, pierces the deep fascia at the lower third of the leg on its front and outer side, and divides into two branches. This nerve in its course between the muscles gives off **muscular branches** to the Peroneus longus and brevis, and **cutaneous branches** to the integument of the lower part of the leg.

The **internal dorsal cutaneous branch** (*n. cutaneus dorsalis medialis*) of the musculocutaneous nerve passes in front of the ankle-joint, and divides into three **dorsal digital branches** (*nn. digitales dorsales pedis*). The internal branch supplies the skin of the dorsum of the foot and the inner side of the great toe, and communicates with the internal saphenous nerve. The intermediate branch runs to the space between the great and second toes, supplies the adjacent sides of these, and communicates with the anterior tibial nerve. The external branch passes to the space between the second and third toes and supplies the adjacent sides of these.

The **external dorsal cutaneous branch** (*n. cutaneus dorsalis intermedius*), the smaller, passes along the outer side of the dorsum of the foot, and divides into two **dorsal digital branches**, the inner being distributed to the adjacent sides of the third and fourth toes, the outer to the adjacent sides of the fourth and fifth toes. It also supplies the integument of the outer ankle and outer side of the foot and communicates with the external saphenous nerve.

The branches of the musculocutaneous nerve supply all the toes excepting the outer side of the little toe, which is supplied by the small saphenous nerve. The adjoining sides of the great and second toes are also supplied by the internal branch of the anterior tibial. It frequently happens that some of the outer branches of the musculocutaneous are absent, their place being then taken by branches of the external saphenous nerve.

THE PUDENDAL PLEXUS (PLEXUS PUDENDUS).

The **pudendal plexus** (Fig. 774) is not sharply marked off from the sacral plexus, some of the branches which spring from it may arise in conjunction with those of the sacral plexus. It lies on the posterior wall of the pelvis and is usually formed by branches from the ventral primary divisions of the second and third sacral nerves the whole of the anterior primary divisions of the fourth and fifth sacral nerves, and the coccygeal nerve.

It gives off the following branches:

Perforating cutaneous (variable)	(2, 3, S.) (3, 4, S.) (4, 5, S.)
Pudic	2, 3, 4, S.
Visceral	3, 4, S.
Muscular	4, S.
Anococcygeal	4, 5, S, and Cocc.

The **Perforating Cutaneous Nerve** (*n. clunium inferior medialis*) (Fig. 774) is not always present. It sometimes arises from the second and third sacral

nerves, or from the third and fourth or even fourth and fifth sacral nerves, and is of small size. When present, it pierces the lower part of the great sacrosciatic ligament, and, winding around the lower border of the Gluteus maximus, supplies the integument covering the inner and lower part of that muscle. When absent, its place is taken either by a cutaneous branch of the small sciatic, or by the *greater coccygeal perforating nerve* of Eisler.

The **Pudic Nerve** (*n. pudendus*) (Figs. 774 and 776) derives its fibres from the anterior branches of the second, third, and fourth sacral nerves. It leaves the pelvis below the Piriformis through the great sacrosciatic foramen. It then crosses the spine of the ischium, and enters the pelvis through the lesser sacrosciatic foramen. It accompanies the pudic vessels upward and forward along the outer wall of the ischiorectal fossa, being contained in a sheath of the obturator fascia, termed **Alcock's canal**, and divides into two terminal branches, the **perineal nerve**, and the **dorsal nerve of the penis or clitoris**. Before its division it gives off the **inferior hemorrhoidal nerve**.

The **inferior hemorrhoidal nerve** (*n. hemorrhoidalis inferior*) is occasionally derived separately from the sacral plexus (3d S.). It passes across the ischio-rectal fossa, with its accompanying vessels, toward the lower end of the rectum, and is distributed to the Sphincter ani externus and to the integument around the anus. Branches of this nerve communicate with the inferior pudendal and superficial perineal nerves at the fore part of the perineum.

The **perineal nerve** (*n. perinei*), the inferior and larger of the two terminal branches of the pudic, is situated below the pudic artery. It accompanies the superficial perineal artery in the perineum, dividing into **cutaneous** and **muscular branches**.

The **cutaneous branches** (*superficial perineal*) are two in number, **posterior** and **anterior**. The **posterior** or **external branch** pierces the base of the triangular ligament of the urethra, and passes forward along the outer side of the urethral triangle in company with the superficial perineal artery; it is distributed to the skin of the scrotum (*nn. scrotales posteriores*). It communicates with the inferior hemorrhoidal, the inferior pudendal, and the other superficial perineal nerve. The **anterior** or **internal branch** also pierces the base of the triangular ligament, and passes forward nearer to the middle line, to be distributed to the inner and back part of the scrotum. Both these nerves supply the labium majus in the female.

The **muscular branches** are distributed to the Transversus perinaei, Accelerator urinae, Erector penis, and Compressor urethrae. A distinct branch is given off from the nerve to the Accelerator urinae, pierces this muscle, and supplies the corpus spongiosum, ending in the mucous membrane of the urethra. This is the **nerve to the bulb**.

The **Dorsal Nerve of the Penis** (*n. dorsalis penis*) is the deepest division of the pudic nerve; it accompanies the pudic artery along the ramus of the ischium; it then runs forward along the inner margin of the ramus of the os pubis, between the superficial and deep layers of the triangular ligament. Piercing the superficial layer, it gives a branch to the corpus cavernosum, and passes forward, in company with the dorsal artery of the penis, between the layers of the suspensory ligament, on to the dorsum of the penis, along which it is carried as far as the glans on which it ends.

In the female the dorsal nerve is very small, and supplies the **clitoris** (*n. dorsalis clitoridis*).

The **visceral branches** arise from the third and fourth, and sometimes the second, sacral nerves and are distributed to the bladder and rectum, and, in the female, to the vagina; they communicate with the pelvic plexuses of the sympathetic.

The **muscular branches** are derived from the fourth sacral, and supply the Levator ani, Coccygeus, and Sphincter ani externus. The branches to the Levator ani

and Coccygeus enter their pelvic surfaces; that to the Sphincter ani externus (*perineal branch*) reaches the ischiorectal fossa by piercing the Coccygeus or by passing between it and the Levator ani. Cutaneous branches from this branch supply the skin between the anus and the coccyx.

Anococcygeal Branches (*nn. anococcygei*).—The fifth sacral nerve receives a communicating branch from the fourth, and unites with the coccygeal nerve to form the **coccygeal plexus** (*plexus coccygeus*). From this plexus the anococcygeal nerves take origin; they consist of a few fine filaments which pierce the great sacrosciatic ligament to supply the skin in the region of the coccyx.

Applied Anatomy.—The lumbar plexus is formed in the Psoas magnus, and, therefore, in *Psoas abscess* any or all of its branches may be irritated, causing severe pain in the parts to which the irritated nerves are distributed. The *genitofemoral nerve* is the one which is most frequently implicated. The nerve is also of importance, as it is concerned in one of the *reflexes* employed in the investigation of diseases of the spine. If the skin over the inner side of the thigh just below Poupert's ligament, the part supplied by the femoral branch of the genitofemoral nerve, be gently tickled in a male child, the testicle will be noticed to be drawn upward through the action of the Cremaster, which is supplied by the genital branch of the same nerve. The same result may sometimes be noticed in adults, and can almost always be produced by severe stimulation. This reflex, when present, shows that the portion of the cord from which the first and second lumbar nerves are derived is in a normal condition.

The *femoral or anterior crural nerve* is in danger of being injured in *fractures of the true pelvis*, since the fracture most commonly takes place through the ascending ramus of the os pubis, at or near the point where this nerve crosses the bone. It is also liable to be injured in *fractures and dislocations of the femur*, and in some *tumors* growing in the pelvis is likely to be pressed upon, and its functions impaired. Moreover, on account of its superficial position, it is exposed to injury in *wounds and stabs in the groin*. When this nerve is *paralyzed*, the patient is unable to flex his hip completely, on account of the loss of motion in the Iliacus; or to extend the knee on the thigh, on account of paralysis of the Quadriceps extensor cruris; there are complete paralysis of the Sartorius and partial paralysis of the Pectineus. There is loss of sensation down the front and inner side of the thigh, except in that part supplied by the femoral branch of the genitofemoral nerve, and by the ilioinguinal nerve. There is also loss of sensation down the inner side of the leg and foot as far as the ball of the great toe.

The *obturator nerve* is of special surgical interest. It is rarely *paralyzed* alone, but occasionally is paralyzed in association with the femoral (anterior crural). The principal interest attached to it is in connection with its supply to the knee; pain in the knee being symptomatic of many diseases in which the trunk of this nerve, or one of its branches, is irritated. Thus, it is well known that in the earlier stages of *hip-joint disease* the patient does not complain of pain in that articulation, but on the inner side of the knee, or in the knee-joint itself, both these articulations being supplied by the obturator nerve, the final distribution of the nerve being to the knee-joint. Again, the same thing occurs in *sacroiliac disease*: pain is complained of in the knee-joint or on its inner side. The obturator nerve is in close relationship with the sacroiliac articulation, passing over it, and, according to some anatomists, distributing filaments to it. Again, in *cancer of the sigmoid flexure*, and even in cases where masses of hardened feces are impacted in this portion of the gut, pain is complained of in the knee. The left obturator nerve lies beneath the sigmoid flexure, and is readily pressed upon and irritated when disease exists in this part of the intestine. Finally, pain in the knee forms an important diagnostic sign in *obturator hernia*. The hernial protrusion as it passes through the opening in the obturator membrane presses upon the nerve and causes pain in the parts supplied by its peripheral filaments. When the obturator nerve is *paralyzed*, the patient is unable to press his knees together or to cross one leg over the other, on account of paralysis of the Adductor muscles. Rotation outward of the thigh is impaired from paralysis of the Obturator externus. Sometimes there is loss of sensation in the upper half of the inner side of the thigh.

The *great sciatic nerve* is liable to be pressed upon by various *pelvic tumors*, giving rise to pain along its trunk, to which the term *sciatica* is applied. Tumors growing from the pelvic viscera, or bones, *aneurisms* of some of the branches of the internal iliac artery, *calculus in the bladder*, when of large size, accumulation of feces in the rectum, may all cause pressure on the nerve inside the pelvis, and give rise to sciatica. Outside the pelvis exposure to cold, violent movements of the hip-joint, *exostoses* or other tumors, growing from the margin of the sacrosiatic foramen, may also give rise to the same condition. When paralyzed there is loss of motion in all the muscles below the knee, and loss of sensation in the same situation, except the upper half of the back of the leg, supplied by the small sciatic and the upper half of the inner side of the leg, when the communicating branch of the obturator is large.

The great sciatic nerve has been frequently cut down upon and *stretched*, or has been acu-

punctured for the relief of sciatica. The nerve has also been stretched in cases of locomotor ataxia, the anesthesia of leprosy, etc. In order to define it on the surface, a point is taken at the junction of the middle and lower third of a line stretching from the posterior superior spine of the ilium to the outer part of the tuber ischii, and a line is drawn from this point to the middle of the upper part of the popliteal space. The line must be slightly curved with its convexity outward, and as it passes downward to the lower border of the *Gluteus maximus* is slightly nearer the tuberosity of the ischium than to the great trochanter, as it crosses a line drawn between these two points. The operation of stretching the sciatic nerve is performed by making an incision over the course of the nerve about the centre of the thigh. The skin, superficial structures, and deep fascia having been divided, the interval between the inner and outer Hamstrings is to be defined, and these muscles respectively pulled inward and outward with retractors. The nerve will be found a little to the inner side of the Biceps. It is to be separated from the surrounding structures, hooked up with the finger, and stretched by steady and continuous traction for two or three minutes. The sciatic nerve may also be stretched by what is known as the "dry" method. The patient is laid on his back, the foot is extended, the leg flexed on the thigh, and the thigh strongly flexed on the abdomen. While the thigh is maintained in this position the leg is forcibly extended to its full extent, and the foot as fully flexed on the leg. This last-named method is uncertain.

The position of the external popliteal nerve, close behind the tendon of the Biceps on the outer side of the ham, should be remembered in *subcutaneous division of the tendon*. After it is divided, a cord often rises up close beside it, which might be mistaken for a small undivided portion of the tendon, and the surgeon might be tempted to reintroduce his knife and divide it. This must never be done, as the cord is the external popliteal nerve, which becomes prominent as soon as the tendon is divided. (See also page 527.)

THE SYMPATHETIC NERVE SYSTEM (SYMPATHICUS) (Fig. 779).

The distinction of the sympathetic nerve system from the cerebrospinal system is made merely for reasons of convenience. The two systems are intimately connected and the sympathetic is morphologically a derivative of the central axis disseminated in connection with the nutritive apparatus and establishing relationships among the vegetative organs.

The sympathetic nerve system consists of (1) a series of **central ganglia** (*ganglia trunci sympathici*) connected by a great ganglionic cord, the **gangliated cord** (*truncus sympathicus*), extending from the base of the skull to the coccyx, one gangliated cord on each side of the middle line of the body, ventrolaterad of the vertebral column; (2) of three **great gangliated plexuses** (*plexus sympathici*) or aggregations of nerves and ganglia, situated ventrolaterad of the spine in the thoracic, abdominal, and pelvic cavities respectively; (3) of **smaller or terminal ganglia**, situated in relation with the abdominal viscera;¹ and (4) of numerous **nerve fibres**. These latter are of two kinds—**communicating**, by which the ganglia communicate with each other and with the cerebrospinal nerves; and **distributory**, supplying the internal viscera and the coats of the bloodvessels.

Each gangliated cord may be traced upward from the base of the skull into the cranial cavity by an ascending branch, which passes through the carotid canal, forms a plexus on the internal carotid artery and in the cavernous sinus (Fig. 782), and communicates with certain cranial nerves (p. 1070); the lower ends of the two cords converge and end in a single ganglion, the **ganglion impar** (*ganglion coccygeum impar*), situated ventrad of the coccyx. The ganglia of the cord are distinguished as **cervical**, **thoracic**, **lumbar**, and **sacral**, and except in the neck they closely correspond in number to the vertebræ against which they lie. They are arranged thus:

Cervical portion	3 pairs of ganglia.
Thoracic	"	10 to 12 "
Lumbar	"	4 "
Sacral	"	4 or 5 "

¹ The ciliary, sphenopalatine, otic, and submaxillary ganglia, already described in connection with the trigeminal nerve, may be regarded as belonging to the sympathetic system.

In the neck the ganglia are situated in front of the transverse processes of the vertebræ; in the thoracic region, in front of the heads of the ribs; in the lumbar region, on the sides of the bodies of the vertebræ; and in the sacral region, in front of the sacrum.

Connections with the Spinal Nerves.—Communications are established between the sympathetic and spinal nerves through what are known as **gray and white rami communicantes** (Fig. 779), the gray rami conveying sympathetic fibres into the spinal nerves, and the white rami transmitting afferent and efferent fibres to the sympathetic. Each spinal nerve receives a gray ramus communicans from the gangliated cord of the sympathetic, but white rami are not supplied by all the spinal nerves. The white rami are derived from the first thoracic to the first lumbar, inclusive, while the visceral branches which run from the second, third and fourth sacral nerves directly to the pelvic plexuses of the sympathetic belong to this category. The majority of the fibres which spring from the sympathetic ganglia are amyelinic (*fibres of Remak*); the fibres which reach the sympathetic through the white ramus communicans are myelinated.

The **branches of distribution, or sympathetic nerves**, derived from the gangliated cords from the prevertebral plexuses, and also from the smaller ganglia, are principally destined for the bloodvessels and thoracic and abdominal viscera, supplying the involuntary muscle fibres of the coats of the vessels and the hollow viscera, and the secreting cells, as well as the muscular coats of the vessels in the glandular viscera. They consist of efferent and afferent fibres, for the origin and course of which see pages 1017 and 1018.

The **three great gangliated plexuses (collateral ganglia)** are situated in front of the spine in the thoracic, abdominal, and pelvic regions, and are named, respec-

FIG. 779.—Anterior surface of the spinal cord, showing the spinal nerves and their connections with the sympathetic trunk on one side. (Testut.)

tively, the **cardiac**, the **solar** or **cœliac**, and the **hypogastric plexus**. They consist of collections of nerves and ganglia, the nerves being derived from the gangliated cords and from the cerebrospinal nerves. They distribute branches to the viscera.

FIG. 780.—The sympathetic nerve system.

THE GANGLIATED CORD (TRUNCUS SYMPATHETICUS).

Cervicocephalic Portion of the Gangliated Cord (Figs. 781, 782).

The cervicocephalic portion of each gangliated cord (*pars cephalica et cervicalis s. sympathici*) consists of three ganglia, distinguished, according to their position, as the superior, middle, and inferior cervical, connected by intervening cords. This portion of the sympathetic cord receives no white rami communicantes from the cervical spinal nerves, its spinal fibres being derived from the white rami of the upper thoracic nerves which enter the corresponding thoracic ganglia of the sympathetic and through these ascend into the cervical portion.

The **superior cervical ganglion** (*ganglion cervicale superius*) (Figs. 780 and 781), the largest of the three, is about three-quarters of an inch in length. It is placed opposite the second and third cervical vertebræ. It is of a reddish-gray color, is usually fusiform in shape, is sometimes broad and flattened, and is occasionally constricted at intervals; it is believed that it is formed by the coalescence of the four ganglia corresponding to the four upper cervical nerves. It is in relation, in front, with the sheath of the internal carotid artery and internal jugular vein; behind, it lies on the Rectus capitis anticus major.

Its branches may be divided into **superior, inferior, external, internal, and anterior.**

The **superior branch** (*n. caroticus internus*) (Fig. 739) appears to be a direct prolongation of the ganglion. It is soft in texture and of a reddish color. It ascends by the side of the internal carotid artery, and, entering the carotid canal in the temporal bone, divides into two branches, which lie, one on the outer, and the other on the inner, side of that vessel.

The **outer branch**, the larger of the two, distributes filaments to the internal carotid artery and forms the **carotid plexus**.

The **inner branch** also distributes filaments to the internal carotid artery, and, continuing onward, forms the **cavernous plexus**.

The **Carotid Plexus** (*plexus caroticus internus*) (Figs. 780 and 781) is situated on the outer side of the internal carotid artery. Filaments from this plexus occasionally form a small gangliform swelling, the **carotid ganglion**, on the under surface of the artery. The carotid plexus communicates with the Gasserian ganglion, the abducent nerve, and the sphenopalatine ganglion; it distributes filaments to the wall of the carotid artery, and also communicates with Jacobson's nerve (the tympanic branch of the glossopharyngeal).

The **communicating branches to the abducent nerve** consist of one or two filaments which join that nerve as it lies upon the outer side of the internal carotid artery. The communication with the sphenopalatine ganglion is effected by a branch, the **large deep petrosal nerve** (Fig. 740), given off from the plexus on the outer side of the artery; this branch passes through the cartilage filling up the foramen lacerum medium, and joins the large superficial petrosal from the facial to form the **Vidian nerve** (Figs. 735 and 740). The Vidian nerve then proceeds through the Vidian canal to the sphenopalatine ganglion. The communication with Jacobson's nerve is effected by two branches, one of which is called the **deep petrosal nerve**, and the other the **caroticotympanic nerve**; the latter may consist of two or three delicate filaments.

The **Cavernous Plexus** (*plexus cavernosus*) (Fig. 781) is situated below and internal to that part of the internal carotid which is placed by the side of the sella turcica, in the cavernous sinus, and is formed chiefly by the internal division of the ascending branch from the superior cervical ganglion. It communicates with the oculomotor, the trochlear, the ophthalmic division of the trigeminal,

and the abducent nerves, and with the ciliary or lenticular ganglion, and distributes filaments to the wall of the internal carotid artery, and to the hypophysis. The branch of communication with the oculomotor nerve joins it at its point of division; the branch to the trochlear nerve joins it as it lies on the outer wall of the cavernous sinus; other filaments are connected with the under surface of the trunk of the ophthalmic nerve; and a second filament of communication joins the abducent nerve.

FIG. 781.—The cephalic portion of the sympathetic nerve system, seen obliquely from above and behind. (Toldt.)

The filaments of connection with the ciliary ganglion (Fig. 730) arise from the anterior part of the cavernous plexus and enter the orbit through the sphenoidal fissure; they may join the nasal branch of the ophthalmic nerve or be continued forward as a separate branch.

The terminal filaments from the carotid and cavernous plexuses are prolonged along the internal carotid artery, forming plexuses which entwine around the anterior and middle cerebral arteries and the ophthalmic artery; along the former vessels they may be traced on to the pia; along the latter, into the orbit, where they accompany each of the branches of the vessel. The filaments prolonged to the anterior communicating artery connect the sympathetic nerves of the right and left sides.

The so-called inferior branch of the superior cervical ganglion communicates with the middle cervical ganglion.

The external branches are communicating, and consist of gray rami communicantes to the upper four cervical nerves and to certain of the cranial nerves. Sometimes the branch to the fourth cervical nerve may come from the cord connecting the superior and middle cervical ganglia. The branches to the cranial nerves consist of delicate filaments, which run to the ganglion of the trunk of

the vagus, and to the hypoglossal nerve. A separate filament (*nervus jugularis*) passes upward to the base of the skull, and subdivides to join the petrous ganglion of the glossopharyngeal, and the ganglion of the root of the vagus in the jugular foramen.

The internal branches are peripheral, and consist of the pharyngeal and laryngeal branches, and the superior cardiac nerve.

The pharyngeal branches (*rami pharyngei*) (Fig. 780) pass inward to the side of the pharynx, where they join with branches from the glossopharyngeal, vagus, and external laryngeal nerves to form the pharyngeal plexus.

The laryngeal branches join the superior laryngeal nerve and its branches.

The superior cardiac nerve (*n. cardiacus superior*) (Figs. 780) arises by two or more branches from the superior cervical ganglion, and occasionally receives a filament from the cord of communication between the first and second cervical ganglia. It runs down the neck behind the common carotid artery, lying upon the Longus colli, and crosses in front of the inferior thyroid artery and recurrent laryngeal nerve.

The course of the nerves on the two sides then differs. The right superior cardiac nerve, at the root of the neck, passes either in front of or behind the subclavian artery, and along the innominate artery, to the back part of the arch of the aorta, where it joins the deep cardiac plexus. It is connected with other branches of the sympathetic; about the middle of the neck it receives filaments from the external laryngeal nerve; lower down it obtains one or two twigs from the vagus, and as it enters the thorax it is joined by a filament from the recurrent laryngeal. Filaments from the nerve communicate with the thyroid branches from the middle cervical ganglion.

The left superior cardiac nerve, in the thorax, runs by the side of the left common carotid artery, and in front of the arch of the aorta to the superficial cardiac plexus.

The anterior branches (*nn. carotici externi*) (Fig. 782) ramify upon the external carotid artery and its branches, forming around each a delicate plexus, on the

FIG. 782.—Diagram of the cervical sympathetic cord. (Testut.)

FIG. 783.—The subclavian loop passing from the middle to the inferior cervical ganglia.

nerves composing which small ganglia are occasionally found. The plexuses accompanying some of these arteries have important communications with other nerves. That surrounding the external carotid artery (*plexus caroticus externus*) is connected with the branch of the facial nerve to the Stylohyoid muscle; that surrounding the facial artery communicates with the submaxillary ganglion by one or two filaments; and that accompanying the middle meningeal artery sends an offshoot which passes to the otic ganglion and a second, the external superficial petrosal nerve (Fig. 740), to the geniculate ganglion of the facial nerve.

The **middle cervical ganglion** (*ganglion cervicale medium*) (Figs. 780 and 782) is the smallest of the three cervical ganglia, and is occasionally altogether wanting. It is placed opposite the sixth cervical vertebra, usually upon, or close to, the inferior thyroid artery. It is probably formed by the coalescence of two ganglia corresponding to the fifth and sixth cervical nerves.

It is joined by gray rami communicantes to the fifth and sixth cervical nerves.

It gives off the thyroid and middle cardiac nerves.

The **thyroid branches** are small filaments which accompany the inferior thyroid artery to the thyroid gland, forming the **inferior thyroid plexus** (*plexus thyroideus inferior*); they communicate, on the artery, with the superior cardiac nerve, and, in the gland, with branches from the recurrent and external laryngeal nerves.

The **middle or great cardiac nerve** (*n. cardiacus medius*) (Fig. 780), the largest of the three cardiac nerves, *arises* from the middle cervical ganglion or from the cord between the middle and inferior ganglia. On the right side it descends behind the common carotid artery, and at the root of the neck passes either in front of or behind the subclavian artery; it then descends on the trachea, receives a few filaments from the recurrent laryngeal nerve, and joins the right side of the deep cardiac plexus. In the neck it communicates with the superior cardiac and recurrent laryngeal nerves. On the left side the middle cardiac nerve enters the thorax between the left carotid and subclavian arteries, and joins the left side of the deep cardiac plexus. If the middle cervical ganglion is absent, the above-named branches arise from the gangliated cord.

The **inferior cervical ganglion** (*ganglion cervicale inferius*) (Figs. 780 and 782) is situated between the base of the transverse process of the last cervical vertebra and the neck of the first rib on the inner side of the superior intercostal artery. Its form is irregular; it is larger in size than the preceding, and is frequently joined to the first thoracic ganglion. It is probably formed by the coalescence of two ganglia which correspond to the last two cervical nerves. It is connected to the middle ganglion by two or more cords, one of which forms a loop around the subclavian artery and supplies offshoots to it. This loop is named the *ansa subclavii* (Vieussensii).

The ganglion is joined to the seventh and eighth cervical nerves by gray rami communicantes.

It gives off the inferior cardiac nerve and offshoots to bloodvessels.

The **inferior cardiac nerve** (*n. cardiacus inferior*) *arises* from the inferior cervical or first thoracic ganglion. It passes down behind the subclavian artery and along the front of the trachea to join the deep cardiac plexus. It communicates freely behind the subclavian artery with the recurrent laryngeal and middle cardiac nerves.

The *offshoots to bloodvessels* accompany the vertebral artery, and form a plexus around it; this plexus (*plexus vertebralis*) supplies filaments to the vessel, and is continued up the vertebral and basilar arteries to the cerebral and cerebellar arteries.

Applied Anatomy.—The situation of the cervical sympathetic makes wounds of it rare. Thirteen cases of traumatic injury to the cervical sympathetics were collected by Seeligmüller. In ten cases paralysis existed; in three, irritation. Tumors of the neck may cause irritation or

paralysis. In *irritation* of the sympathetic the corresponding side of the face becomes pale, the pupil dilates, the palpebral fissure widens, and the eyeball protrudes. In many cases there is acceleration of the heart beats. In *paralysis* of the sympathetic the pupil contracts, the palpebral fissure is narrowed by partial ptosis, the corresponding side of the face reddens, there is an increase in the flow of tears, and recession of the eyeball.

The surgeon occasionally resects the sympathetic. Jonnesco recommends bilateral removal of the superior cervical ganglia for glaucoma, and bilateral removal of all the cervical sympathetic ganglia for epilepsy and for exophthalmic goitre. The results of resection do not appear to justify the operation.

The Thoracic Portion (Pars Thoracalis) of the Gangliated Cord (Fig. 784).

The thoracic portion of the gangliated cord consists of a series of ganglia which usually correspond in number to that of the vertebræ; but, from the occa-

FIG. 784.—Plan of the right sympathetic cord and splanchnic nerves. (Testut.)

sional coalescence of two, their number is uncertain. The ganglia are placed on each side of the spine, resting against the heads of the ribs, and are covered by

the costal pleura; the last two ganglia are, however, anterior to the rest, being placed on the side of the bodies of the eleventh and twelfth thoracic vertebræ. The ganglia are small in size and of a grayish color. The first ganglion, larger than the others, is of an elongated form and is frequently blended with the last cervical ganglion. They are connected by the intervening portions of the cord.

Two rami communicantes, one white and the other gray, connect each ganglion with its corresponding spinal nerve.

The *branches from the upper five ganglia* are very small; they supply filaments to the thoracic aorta and its branches, and to the bodies of the vertebræ and their ligaments. Branches from the second, third, and fourth ganglia enter the posterior pulmonary plexus.

The *branches from the lower seven ganglia* are large, and white in color; they distribute filaments to the aorta, and unite to form the three splanchnic nerves. These are named the **great**, the **lesser**, and the **smallest**, or **renal splanchnic**.

The **great splanchnic nerve** (*n. splanchnicus major*) is white in color, firm in texture, and is *formed* by branches from the thoracic ganglia between the fifth or sixth and the ninth or tenth; but the fibres in the higher roots may be traced upward in the sympathetic cord as far as the first or second thoracic ganglion. These roots unite to form a cord of considerable size. It descends obliquely inward in front of the bodies of the vertebræ along the posterior mediastinum, perforates the crus of the Diaphragm, and terminates in the **semilunar ganglion of the solar plexus** (Fig. 784), distributing filaments to the **renal** and **suprarenal plexuses**. A ganglion (*ganglion splanchnicum*) exists on this nerve opposite the eleventh or twelfth thoracic vertebra.

The **lesser splanchnic nerve** (*n. splanchnicus minor*) is *formed* by filaments from the tenth and eleventh ganglia, and from the cord between them. It pierces the Diaphragm near or with the preceding nerve, and joins the aorticorenal ganglion of the **solar plexus** (Fig. 784). It communicates in the thorax with the great splanchnic nerve, and ends in the solar plexus.

The **least splanchnic nerve** (*n. splanchnicus imus*) *arises* from the last thoracic ganglion, and, piercing the Diaphragm, terminates in the **renal plexus**. It occasionally communicates with the preceding nerve.

A striking analogy appears to exist between the splanchnic and the cardiac nerves. The cardiac nerves are three in number, they *arise* from the three cervical ganglia, and are distributed to a large and important organ in the thoracic cavity. The splanchnic nerves, also three in number, are connected probably with all the thoracic ganglia, and are distributed to important organs in the abdominal cavity.

The Lumbar Portion (Pars Lumbalis) of the Gangliated Cord (Fig. 780).

The lumbar portion of the gangliated cord is situated in front of the vertebral column along the inner margin of the Psoas magnus. It consists usually of four ganglia, connected together by interganglionic cords. It is continuous above with the thoracic portion beneath the internal arcuate ligament of the Diaphragm, and below with the sacral portion behind the common iliac artery. The ganglia are of small size, and placed much nearer the median line than the thoracic ganglia.

Gray rami communicantes connect all the ganglia with the lumbar spinal nerves. There may be two from each ganglion, but the arrangement is not so uniform as in other regions. The first and second, and sometimes the third, lumbar nerves send white rami communicantes to the upper two or three ganglia.

From the situation of the lumbar ganglia these branches are longer than in the other regions. They accompany the lumbar arteries around the sides of the bodies

of the vertebræ, passing beneath the fibrous arches from which some of the fibres of the *Psoas magnus* arise.

Of the **branches of distribution** some branches pass inward, in front of the aorta, and help to form the **abdominal aortic plexus** (*plexus aorticus abdominalis*) (Fig. 780). Other branches descend in front of the common iliac arteries, and, joining over the promontory of the sacrum, assist in forming the **hypogastric plexus** (*plexus hypogastricus*) (Fig. 780). Numerous delicate filaments are also distributed to the bodies of the vertebræ and the ligaments connecting them.

Pelvic Portion (Pars Pelvina) of the Gangliated Cord (Fig. 780).

The pelvic portion of the gangliated cord is situated in front of the sacrum along the inner side of the anterior sacral foramina. It consists of four or five small ganglia on each side, connected by interganglionic cords. Below, these cords converge and unite on the front of the coccyx by means of a small ganglion, the **coccygeal ganglion** or **ganglion impar** (*ganglion coccygeum impar*) (Fig. 780).

Gray rami communicantes pass from the ganglia to the sacral and coccygeal nerves. No white rami communicantes join this part of the gangliated cord, but the visceral branches which arise from the third and fourth, and sometimes from the second, sacral are regarded as homologous with white rami communicantes.

The **branches of distribution** communicate on the front of the sacrum with the corresponding branches from the opposite side; some, from the first two ganglia, pass to join the pelvic plexus, while others form a plexus which accompanies the middle sacral artery, from which plexus filaments pass to the coccygeal gland.

THE GREAT PLEXUSES OF THE SYMPATHETIC SYSTEM.

The great plexuses of the sympathetic are the large aggregations of nerves and ganglia, previously alluded to, situated in the thoracic, abdominal, and pelvic cavities respectively, and named the cardiac, pulmonary, œsophageal, celiac, and hypogastric plexuses respectively. They consist not only of sympathetic fibres derived from the ganglia, but also of fibres from the central nerve system which are conveyed through the white rami communicantes. From them are derived the branches which supply the viscera.

The Cardiac Plexus (Plexus Cardiacus) (Fig. 780).

The cardiac plexus is situated at the base of the heart, and is divided into a **superficial part**, which lies in the concavity of the arch of the aorta, and a **deep part**, which lies between the trachea and aorta. The two plexuses are, however, closely connected.

The **superficial cardiac plexus** lies beneath the arch of the aorta, in front of the right pulmonary artery. It is formed by the left superior cardiac nerve, the left (and occasionally also the right) inferior cervical cardiac branches of the vagus, and filaments from the deep cardiac plexus. A small ganglion, the **cardiac ganglion of Wrisberg** (*ganglion cardiacum* [*Wrisbergi*]) is occasionally found connected with these nerves at their point of junction. This ganglion, when present, is situated immediately beneath the arch of the aorta on the right side of the ductus arteriosus. The superficial cardiac plexus gives branches to the deep cardiac plexus beneath the arch of the aorta to the right or anterior coronary plexus and to the left anterior pulmonary plexus.

The **deep cardiac plexus** is situated in front of the trachea at its bifurcation.

above the point of division of the pulmonary artery and behind the arch of the aorta. It is formed by the cardiac nerves derived from the cervical ganglia of the sympathetic and the cardiac branches of the recurrent laryngeal and vagus. The only cardiac nerves which do not enter into the formation of this plexus are the left superior cardiac nerve and the inferior cervical cardiac branch from the left vagus.

The branches from the **right side** of this plexus pass, some in front of, and others behind, the right pulmonary artery; the former, the more numerous, transmit a few filaments to the anterior pulmonary plexus, and are then continued onward to form part of the **right coronary plexus**; those behind the pulmonary artery distribute a few filaments to the right auricle, and are then continued onward to form a part of the **left coronary plexus**.

The **left side** of the plexus is connected with the superficial cardiac plexus and gives filaments to the left auricle of the heart, and to the anterior pulmonary plexus, and is then continued to form the greater part of the **left coronary plexus**.

The **left coronary plexus** (*plexus coronarius posterior*) is larger than the right, and accompanies the left coronary artery; it is chiefly formed by filaments prolonged from the left side of the deep cardiac plexus, and by a few from the right side. It gives branches to the left auricle and ventricle.

The **right coronary plexus** (*plexus coronarius anterior*) is formed partly from the superficial and partly from the deep cardiac plexus. It accompanies the right coronary artery, and gives branches to the right auricle and ventricle.

Although sympathetic filaments enter into the formation of the **anterior** and **posterior pulmonary** and the **oesophageal plexuses**, these are usually regarded as portions of the vagus nerve (p. 1010).

The Cœliac or Solar Plexus (*Plexus Coeliacus*) (Figs. 780, 785).

The cœliac or solar plexus supplies the viscera in the abdominal cavity. It consists of a great network of nerves and ganglia, situated behind the pancreas and the lesser peritoneal cavity and in front of the aorta and crura of the Diaphragm. It surrounds the cœliac axis and root of the superior mesenteric artery, extending downward as low as the pancreas and outward to the suprarenal glands. This plexus, and the ganglia connected with it, receive the **great**, the **small**, and the **least splanchnic nerves** of both sides, and some filaments from the **right vagus nerve**. It distributes filaments which accompany, under the name of plexuses, all the branches from the front of the abdominal aorta.

Of the ganglia of which the solar plexus is partly composed the principal are the two **semilunar ganglia** (*ganglia coeliaca*) (Figs. 785 and 786), which are situated one on each side of the plexus, and are the largest ganglia in the body. They are large, irregular, gangliform masses formed by the aggregation of smaller ganglia, having interspaces between them. They are situated in front of the crura of the Diaphragm, close to the suprarenal glands; the one on the right side lies beneath the inferior vena cava. The upper part of each ganglion is joined by the great splanchnic nerve, and to the inner side of each the branches of the solar plexus are connected. The lower portion of each semilunar ganglion is detached, and is named the **aorticorenal ganglion**.

From the cœliac plexus are derived the following:

Phrenic or Diaphragmatic plexus.
Suprarenal plexus.
Renal plexus.
Spermatic } plexus.
Ovarian }

Gastric plexus.
Splenic plexus.
Hepatic plexus.
Superior mesenteric plexus.
Aortic plexus.

The **Phrenic Plexus** (*plexus phrenicus*) (Fig. 785) accompanies the inferior phrenic artery to the Diaphragm, some filaments passing to the suprarenal gland. It *arises* from the upper part of the semilunar ganglion, and is larger on the right than on the left side. It receives one or two branches from the phrenic nerve. At the point of junction with the phrenic nerve is a small ganglion, the **phrenic ganglion** (*ganglion phrenicum*) (Fig. 786), which lies on the under surface of the Diaphragm, near the right suprarenal. Its branches are distributed to the inferior vena cava, suprarenal, and hepatic plexus. There is no phrenic ganglion on the left side.

FIG. 785.—The semilunar ganglia with the sympathetic plexuses of the abdominal viscera radiating from the ganglia. (Toldt.)

The **Suprarenal Plexus** (*plexus suprarenalis*) (Fig. 785) is formed by branches from the celiac plexus, from the semilunar ganglion, and from the phrenic and great splanchnic nerves, a ganglion being formed at the point of junction of the latter nerve. It supplies the suprarenal gland, being chiefly distributed to its medullary portion. The branches of this plexus are remarkable for their large size in comparison with the size of the organ they supply.

The **Renal Plexus** (*plexus renalis*) (Figs. 785 and 786) is formed by filaments from the coeliac plexus, the lower part of the semilunar ganglion (aorticorenal ganglion) and the aortic plexus. It is also joined by the least splanchnic

FIG. 786.—Lumbar portion of the gangliated cord, with the coeliac and hypogastric plexuses. (After Henle.)

nerve. The nerves from these sources, fifteen or twenty in number, have numerous ganglia developed upon them. They accompany the branches of the renal artery into the kidney, some filaments on the right side being distributed to the inferior vena cava, and others, on both sides, to the spermatic plexuses.

The **Spermatic Plexus** (*plexus spermaticus*) (Fig. 785) is derived from the renal plexus, receiving branches from the aortic plexus. It accompanies the spermatic vessels to the testis.

In the female the **ovarian plexus** (*plexus arteriae ovaricae*) arises like the spermatic plexus, and is distributed to the ovaries, Fallopian tubes, and fundus of the uterus.

The **Gastric or Coronary Plexus** (*plexus gastricus superior*) (Fig. 785) accompanies the gastric artery along the lesser curvature of the stomach, and joins with branches from the left vagus nerve.

The **Splenic Plexus** (*plexus lienalis*) (Fig. 785) is formed by branches from the celiac plexus, the left semilunar ganglia, and from the right vagus nerve. It accompanies the splenic artery and its branches to the substance of the spleen, giving off, in its course, filaments to the pancreas, the **pancreatic plexus**, and the **left gastroepiploic plexus**, which accompanies the left gastroepiploic artery along the greater curvature of the stomach.

The **Hepatic Plexus** (*plexus hepaticus*) (Fig. 785), the largest offshoot from the celiac plexus, receives filaments from the left vagus and right phrenic nerves. It accompanies the hepatic artery, ramifying in the substance of the liver upon the branches of the portal vein within the substance of the liver.

Branches from this plexus accompany all the divisions of the hepatic artery. Thus, there is a **pyloric plexus** accompanying the pyloric branch of the hepatic, which joins with the gastric plexus and vagi nerves. There is also a **gastro-duodenal plexus**, which subdivides into the **pancreaticoduodenal plexus**, which accompanies the pancreaticoduodenal artery, to supply the pancreas and duodenum, joining with branches from the mesenteric plexus. The **gastroepiploic plexus**, which accompanies the right gastroepiploic artery along the greater curvature of the stomach, and which is said to anastomose with branches from the splenic plexus, is in reality derived from the splenic plexus. A **cystic plexus**, which supplies the gall-bladder, also arises from the hepatic plexus near the liver.

The **Superior Mesenteric Plexus** (*plexus mesentericus superior*) (Fig. 785) is a continuation of the lower part of the great solar plexus, receiving a branch from the junction of the right vagus nerve with the celiac plexus. It surrounds the superior mesenteric artery, which it accompanies into the mesentery, and divides into a number of secondary plexuses, which are distributed to all parts supplied by the artery—viz., **pancreatic branches** to the pancreas; **intestinal branches**, which supply the whole of the small intestine; and **ileocolic, right colic, and middle colic branches**, which supply the corresponding parts of the large intestine. The nerves composing this plexus are white in color and firm in texture; in the upper part of the plexus close to the origin of the superior mesenteric artery is a ganglion (*ganglion mesentericum superius*).

The **Abdominal Aortic Plexus** (*plexus aorticus abdominalis*) (Figs. 785 and 786) is formed by branches derived, on either side, from the celiac plexus, receiving filaments from some of the lumbar ganglia. It is situated upon the sides and front of the aorta, between the origins of the superior and inferior mesenteric arteries. From this plexus arise part of the spermatic, the inferior mesenteric, and the hypogastric plexuses; it also distributes filaments to the inferior vena cava.

The **Inferior Mesenteric Plexus** (*plexus mesentericus inferior*) (Fig. 785) is derived chiefly from the left side of the aortic plexus. It surrounds the inferior mesenteric artery, and divides into a number of secondary plexuses, which are distributed to all the parts supplied by the artery—viz., the **left colic** and **sigmoid plexuses**, which

supply the descending and sigmoid flexure of the colon; and the **superior hemorrhoidal plexus** (*plexus hemorrhoidalis superior*), which supplies the upper part of the rectum and joins in the pelvis with branches from the pelvic plexus.

The Hypogastric Plexus (*Plexus Hypogastricus*) (Figs. 780, 786).

The hypogastric plexus supplies the viscera of the pelvic cavity. It is situated in front of the promontory of the sacrum, between the two common iliac arteries, and is formed by the union of numerous filaments, which descend on each side from the abdominal aortic plexus and from the lumbar ganglia. This plexus contains no evident ganglia; it bifurcates, below, into two lateral portions, right and left, which form the **pelvic plexuses**.

The Pelvic Plexuses.

The pelvic plexuses supply the viscera of the pelvic cavity, and are situated at the side of the rectum in the male, and at the sides of the rectum and vagina in the female. They are formed by a continuation of the hypogastric plexus, by the visceral branches from the second, third, and fourth sacral nerves, and by a few filaments from the first two sacral ganglia. At the points of junction of these nerves small ganglia are found. From these plexuses numerous branches are distributed to the rectum and bladder in the male, and to the rectum, bladder, uterus, and vagina in the female. They accompany the branches of the internal iliac artery. These secondary plexuses are (1) the **inferior hemorrhoidal**, (2) **vesical**, (3) **prostatic**, (4) **vaginal**, and (5) **uterine plexuses**.

The **Inferior Hemorrhoidal Plexus** (*plexus haemorrhoidalis inferior*) arises from the upper part of the pelvic plexus. It supplies the rectum, joining with branches of the superior hemorrhoidal plexus.

The **Vesical Plexus** (*plexus vesicalis*) arises from the fore part of the pelvic plexus. The nerves composing it are numerous, and contain a large proportion of spinal nerve fibres. They accompany the vesical arteries, and are distributed to the side and base of the bladder. Numerous filaments also pass to the vesiculae seminales and vasa deferentia; those accompanying the vas deferens join, on the spermatic cord, with branches from the spermatic plexus.

The **Prostatic Plexus** (*plexus prostaticus*) is continued from the lower part of the pelvic plexus. The nerves composing it are of large size. They are distributed to the prostate gland, seminal vesicles, and erectile tissue of the penis. The nerves supplying the erectile tissue of the penis consist of two sets, the **small** and **large cavernous nerves**. They are slender filaments, which arise from the fore part of the prostatic plexus, and, after joining with branches from the internal pudic nerve, pass forward beneath the pubic arch.

The **small cavernous nerves** (*nn. cavernosi penis minores*) perforate the fibrous covering of the penis, near its root.

The **large cavernous nerve** (*n. cavernosus penis major*) passes forward along the dorsum of the penis, joins with the dorsal nerve of the penis, and is distributed to the corpora cavernosa and corpus spongiosum.

The uterine and vaginal plexuses in reality constitute one plexus, the **utero-vaginal plexus** (*plexus uterovaginalis*).

The **Vaginal Plexus** arises from the lower part of the pelvic plexus. It is distributed to the walls of the vagina, to the erectile tissue of the vestibule, and to the clitoris. The nerves composing this plexus contain, like the vesical, a large proportion of spinal nerve fibres.

The **Uterine Plexus** accompanies the uterine artery to the side of the uterus between the layers of the broad ligament; it communicates with the ovarian plexus.

THE ORGANS OF SPECIAL SENSE.

THE organs of the senses (*organa sensuum*) are five in number—those of smell, sight, hearing, taste, and touch.

THE NOSE.

The nose is the peripheral portion of the organ of smell (*organon olfactus*); by means of the peculiar properties of its nerves it protects the lungs from the inhalation of deleterious gases and assists the organ of taste in discriminating the properties of food. The organ of smell consists of two parts—one external, the **outer nose**, which projects from the centre of the face, and an internal, the **cavum nasi**, which is divided by a septum into the **right** and **left nasal fossæ**.

THE OUTER NOSE (*NASUS EXTERNUS*).

The outer nose is the more anterior and prominent part of the organ of smell. Of a pyramidal form, it is directed downward, and projects from the centre of the face immediately above the upper lip. Its **root** (*radix nasi*) is connected directly with the forehead. Its **base** (*basis nasi*) presents two elliptical orifices, the **nostrils** or **anterior nares** (*nares*), separated from each other by an antero-posterior septum, the **columna** (*septum mobile nasi*). The margins of the nostrils are provided with a number of stiff hairs or **vibrissæ**, which arrest the passage of foreign substances carried with the current of air intended for respiration. The **point** (*apex nasi*) is the free extremity of the nose. The **lateral surfaces** of the nose form, by their union in the middle line, the **dorsum** (*dorsum nasi*), the direction of which varies considerably in different individuals. The portion of the dorsum over the nasal bones is the **bridge**. Each lateral surface terminates below in a rounded eminence, the **wing** or **ala nasi**, which, by its lower margin (*margo nasi*), forms the outer boundary of the corresponding nostril. Above the ala is a depression, the **alar sulcus**.

Structure.—The nose is composed of a framework of **bones** and **cartilages**, the latter being slightly acted upon by certain muscles. It is covered externally by the integument, internally by mucous membrane, and is supplied with vessels and nerves.

The **bony framework** occupies the upper part of the organ; it consists of the **nasal bones** and the **nasal processes of the maxillæ** (pp. 99 and 104).

The **cartilaginous framework** (*cartilaginee nasi*) (Figs. 787 and 788) consists of five pieces—the **two upper** and the **two lower lateral cartilages** and the **cartilage of the septum**.

The **upper lateral cartilage** (*cartilago nasi lateralis*) of each side is situated below the free margin of the nasal bone and is flat and triangular in shape. Its anterior margin is thicker than the posterior, and continuous above with the cartilage of the septum. Its posterior margin is attached to the nasal process of the maxilla. Its inferior margin is connected by fibrous tissue with the lower lateral cartilage; one surface is turned outward, the other inward toward the nasal cavity.

The **lower lateral cartilage** (*cartilago alaris major*) is a thin, flexible plate situated immediately below the preceding, and bent upon itself in such a manner as to form the inner and outer walls

of the orifice of the nostril. The portion which forms the **inner wall** (*crus mediale*), thicker than the rest, is loosely connected with the corresponding portion of the opposite cartilage to form a small part of the columnna. Its inferior border, free, rounded, and projecting, forms, with the thickened integument and subjacent tissue and the corresponding parts of the opposite side, the mobile septum. The part of the cartilage which forms the **outer wall** (*crus laterale*) is

FIGS. 787 and 788.—Cartilages of the nose.

curved to correspond with the ala of the nose; it is oval and flattened, narrow behind, where it is connected with the nasal process of the maxilla by a tough fibrous membrane, in which are found three or four small cartilaginous plates, the **sesamoid or lesser alar cartilages** (*cartilaginee alares minores*). Above, it is connected by fibrous tissue to the upper lateral cartilage and front part of the cartilage of the septum; below, it falls short of the margin of the nostril; the ala being completed by dense cellular tissue covered by skin. In front the lower lateral cartilages are separated by a notch which corresponds with the point of the nose.

The **cartilage of the septum** (*cartilago septi nasi*) (Figs. 787 and 789) is somewhat quadrilateral in form, thicker at its margins than at its centre, and completes the separation between the nasal fossæ in front. Its **anterior margin**, thickest above, is connected with the nasal bones, and is continuous with the anterior margins of the two upper lateral cartilages. Below, it is connected to the inner portions of the lower lateral cartilages by fibrous tissue. Its **posterior margin** is connected with the perpendicular lamella of the ethmoid; its inferior margin with the vomer and the palate processes of the maxillæ (Fig. 789).

It may be prolonged backward (especially in children) for some distance between the vomer and perpendicular plate of the ethmoid, forming what is termed the **sphenoidal process** (*processus sphenoidalis septi cartilaginei*). The septal cartilage does not reach as far as the lower part of the nasal septum. This is formed by the thinnest portions of the

FIG. 789.—Bones and cartilage of septum of the nose. Right side.

lower lateral cartilages and by the skin; it is freely movable, and hence is termed the **mobile septum**.

Along the lower margin of the anterior half of the cartilage of the septum is another cartilage which is attached to the vomer and is known as the **vomerine cartilage**, or **cartilage of Jacobson** (*cartilago vomeronasalis*).

These various cartilages are connected to each other and to the bones by a tough fibrous membrane, which allows the utmost facility of movement between them.

The **muscles of the nose** are situated beneath the integument; they are (on each side) the *Pyramidalis nasi*, the *Levator labii superiores alaeque nasi*, the *Dilatator naris*, anterior and posterior, the *Compressor nasi*, the *Compressor narium minor*, and the *Depressor alae nasi*. They have been previously described (p. 372).

The **integument** covering the dorsum and the sides of the nose is thin, and loosely connected with the subjacent parts; but the integument of the tip and the alæ of the nose is thicker and more firmly adherent, and is furnished with a large number of sebaceous follicles, the orifices of which are usually very distinct.

The **mucous membrane** lining the interior of the nose is continuous with the skin externally and with the mucous membrane which lines the nasal fossæ within.

The **arteries of the nose** are the **lateralis nasi from the facial**, and the **inferior artery of the septum from the superior coronary**, which supply the alæ and septum, the sides and dorsum being supplied from the **nasal branch of the ophthalmic** and the **infraorbital**. The **veins of the nose** terminate in the **facial and ophthalmic**. The **lymphatics of the outer nose** are shown in Fig. 557. They empty chiefly into the **submaxillary lymph nodes**. The **nerves** for the muscles of the nose are derived from the **facial**, while the skin receives its branches from the **infraorbital, infratrochlear, and nasal branches of the ophthalmic**.

THE NASAL FOSSÆ (CAVUM NASI).

The nasal fossæ are two irregular cavities situated in the middle of the face, one on each side of the mesal plane. They open in front, when the soft parts are in place, by the two **nostrils or anterior nares**, and terminate, behind, in the nasopharynx by the **posterior nares**.

FIG. 790 —Outer wall of nasal fossa

The **anterior nares** (*nares*) are somewhat pear-shaped apertures, each measuring about one inch (2.5 cm.) antero-posteriorly and half an inch (1.2 cm.) trans-

versely at their widest part. The nasal fossæ in the dry skull open in front by the anterior nasal aperture (*apertura pyriformis*).

The **posterior nares** (*choanae*) are two oval openings, which are smaller in the living or recent subject than in the skeleton, because they are narrowed by the mucous membrane. Each measures an inch (2.5 cm.) in the vertical and half an inch (1.2 cm.) in the transverse direction in a well-developed adult skull.

For the description of the bony boundaries of the nasal fossæ see page 138.

Inside the aperture of the nostril is a slight dilatation, the **vestibule** (*vestibulum nasi*), which extends as a small pouch, the **ventricle**, toward the point of the nose. Above and behind the vestibule is surrounded by a prominence (*limen nasi*). Below the prominence the vestibule is lined with skin; above and behind it the fossa is lined with mucous membrane. The fossa, above and behind the vestibule, has been divided into two parts—an **olfactory portion** (*regio olfactoria*), a slit-

FIG. 791.—External wall of right nasal fossa, parts of the turbinates having been cut away to show the orifices of the sinuses which open into the meatuses. (Testut.)

like cavity, comprising the upper and central part of the septum and the superior turbinated process, and a **respiratory portion** (*regio respiratoria*), which comprises the rest of the fossa.

The Outer Wall (Figs. 790 and 791).—The **superior, middle, and inferior meatus** (*meatus nasi superior, medius, and inferior*) are described on page 141. The **sphenoidal air sinus** opens into the **sphenoethmoidal recess** (*recessus sphenoethmoidalis*), a narrow recess above the superior turbinated process (Fig. 791). The **posterior ethmoidal cells** open into the front and upper part of the **superior meatus** (Fig. 790). On raising or cutting away the middle turbinated process the outer wall of the middle meatus is fully exposed (Figs. 791 and 792) and presents (1) a rounded elevation, termed the **bullæ ethmoidalis**, opening on or immediately above which are the orifices of the middle ethmoidal cells; (2) a deep, narrow, curved groove, in front of the bullæ ethmoidalis, termed the **hiatus semilunaris**, into which the **anterior ethmoidal cells** and the maxillary sinus open, the orifice of the latter being placed near the level of its roof. The middle meatus is pre-

longed, above and in front, into the **infundibulum**, which leads into the **frontal sinus**. The anterior extremity of the meatus is continued into a depressed area which lies above the vestibule and is named the **atrium** (*atrium meatus medii nasi*). The **nasal duct** opens into the anterior part of the inferior meatus, the opening being frequently overlapped by a fold of mucous membrane.

The Inner Wall (Fig. 792).—The inner wall or septum is frequently more or less deflected from the mesal plane (Figs. 104 and 792), thus limiting the size of one fossa and increasing that of the other. Ridges or spurs of bone growing outward from the septum are also sometimes present. Immediately over the incisive foramen at the lower edge of the cartilage of the septum a depression, the **naso-palatine recess** (*recessus nasopalatinus*), may be seen. In the septum close to this

FIG. 792.—Transverse vertical section of the nasal fossæ. The section is made anterior to the superior turbinated processes. (Cryer.)

recess a minute orifice may be discerned; it leads into a blind pouch, the rudimentary organ of Jacobson (*organon vomeronasale*), which is well developed in some of the lower animals, but is rudimentary in man. The organ is supported by a plate of cartilage, distinct from the cartilage of the septum, the **cartilage of Jacobson** (p. 1082). The cartilage of Jacobson is to the outer side of the lower edge of the cartilage of the septum. Just below the opening of the blind pouch is an elevation, the **eminence of Jacobson**.

The Mucous Membrane (*membrana mucosa nasi*).—The mucous membrane lining the nasal fossæ is sometimes called the **Schneiderian membrane**.¹ It is intimately adherent to the periosteum or perichondrium, upon which it lies. It is continuous

¹ After Conrad Victor Schneider (1614–1680), Professor of Anatomy at Wittemberg.

externally with the skin through the anterior nares, and with the mucous membrane of the nasopharynx through the posterior nares. From the nasal fossæ its continuity may be traced with the conjunctiva through the nasal duct and lacrimal canals; with the lining membrane of the tympanum and mastoid cells through the Eustachian tube; and with the frontal, ethmoidal, and sphenoidal sinuses, and the maxillary sinus through the several openings in the meatuses. The mucous membrane is thickest and most vascular over the turbinated bones. It is also thick over the septum, but in the intervals between the spongy bones and on the floor of the nasal fossæ it is very thin. Where it lines the various sinuses it is thin and pale.

Owing to the great thickness of this membrane, the nasal fossæ are much narrower, and the turbinated bones, especially the lower ones, appear larger and more prominent than in the dried skull. From the same circumstance, also, the various apertures communicating with the meatuses are considerably narrowed.

FIG. 793.—Section of the olfactory mucous membrane. (Cadiat.)

Structure of the Mucous Membrane (Fig. 793).—The epithelium covering the mucous membrane differs in its character according to the functions of the part of the nose in which it is found. In the respiratory portion of the nasal cavity the epithelium is columnar and ciliated, which is also the type found in the accessory sinuses, with the exception of the maxillary, where the epithelium is of the simple polygonal variety. Interspersed among the columnar ciliated cells are goblet or mucin cells, while between their bases are found smaller pyramidal cells. In this region, beneath the epithelium and its basement membrane, is a fibrous layer infiltrated with leukocytes, so as to form in many parts diffuse lymphoid tissue, which is particularly plentiful in children; beneath this is a nearly continuous layer of smaller and larger glands, some mucous and some serous, the ducts of which open upon the surface. In the respiratory portion of the mucous membrane there is an extensive anastomosing plexus of veins, which in some regions forms a distinct **cavernous tissue** (*plexus cavernosus concharum*). The cavernous tissue is particularly distinct over the inferior turbinated bones. In the olfactory region the mucous membrane is yellowish in color and the epithelial cells are columnar and non-ciliated; they are of two kinds, **supporting cells** and **olfactory cells**.

The **supporting cells** are irregular pigmented elements that contain oval nuclei, situated in the deeper parts of the cells; the free surface of each cell presents a sharp outline, and its deep extremity is prolonged into a process which runs inward, branching to communicate with similar processes from neighboring cells, so as to form a network in the deep part of the mucous membrane. Lying between these central processes of the supporting cells are a large number of spindle-shaped cells, the **olfactory cells**, which consist of a large-spherical nucleus surrounded by a small amount of granular protoplasm, and possessing two processes, of which one runs outward between the columnar epithelial cells, and projects on the surface of the mucous membrane as a fine, hair-like process, the **olfactory hair**; the other or deep process runs inward, is frequently beaded, and is continuous with one of the filaments of the olfactory nerves. Beneath the epithelium, extending through the thickness of the mucous membrane, is a layer of tubular,

often branched, glands, the **glands of Bowman** (*glandulae olfactoriae*), identical in structure with serous glands.

The **arteries** of the nasal fossæ are the *anterior* and *posterior ethmoidal*, from the ophthalmic, which supply the ethmoidal cells, frontal sinuses, and roof of the nose; the *sphenopalatine*, from the internal maxillary, which supplies the mucous membrane covering the spongy bones, the meatuses, and septum; the *inferior artery of the septum*, from the superior coronary of the facial; and the *infraorbital* and *alveolar branches* of the internal maxillary, which supply the lining membrane of the antrum. The ramifications of these vessels form a close, plexiform network, beneath and in the substance of the mucous membrane.

The **veins** of the nasal fossæ form a close, cavernous-like network beneath the mucous membrane. This cavernous appearance is especially well marked over the lower part of the septum and over the middle turbinated process and inferior turbinated bones. Some of the veins pass, with those accompanying the sphenopalatine artery, through the sphenopalatine foramen; and others, through the alveolar branch, to join the *facial vein*; some accompany the ethmoidal arteries, and terminate in the *ophthalmic vein*; and, lastly, a few communicate with the veins in the interior of the skull, through the foramina in the cribriform plate of the ethmoid bone, and the foramen cecum.

The **lymphatics** have already been described (p. 780).

The **nerves** of ordinary sensation are the nasal branch of the ophthalmic, filaments from the anterior dental branch of the superior maxillary, the Vidian, the nasopalatine, the large or anterior palatine, and nasal branches of the sphenopalatine ganglion. The *nasal branch of the ophthalmic division of the trigeminal nerve* distributes filaments to the fore part of the septum and outer wall of the nasal fossæ. *Filaments from the anterior dental branch of the superior maxillary* supply the inferior meatus and inferior turbinated bone. The *Vidian nerve* supplies the upper and back part of the septum and superior turbinated process, and the *upper anterior nasal branches* from the *sphenopalatine ganglion* have a similar distribution. The *nasopalatine nerve* supplies the middle of the septum. The *larger or anterior palatine nerve* supplies the lower nasal branches to the middle turbinated process and the turbinated bone. The *olfactory nerves*, the special nerves of the sense of smell, are distributed to the olfactory region, and have been already referred to (p. 976).

Applied Anatomy.—Instances of *congenital deformity* of the nose are occasionally met with, such as complete absence of the nose, an aperture only being present; or perfect development on one side, and suppression or malformation on the other; or there may be imperfect apposition of the nasal bones, so that the nose presents a median cleft or furrow. Deformities which have been acquired are much more common, such as *flattening of the nose* (*saddle nose*), the result of *syphilitic necrosis*, imperfect development of the nasal bones in cases of *congenital syphilis*, or a lateral deviation of the nose may result from *fracture*.

The skin over the alæ and tip of the nose is thick and closely adherent to subjacent parts. *Inflammation* of this part is therefore very painful, on account of the tension. The skin is largely supplied with blood, and the circulation here being terminal, vascular engorgement is liable to occur, especially in women at the menopause and in both sexes from disorders of digestion, exposure to cold, etc. The skin of the nose also contains a large number of sebaceous follicles, and these, as a result of intemperance, are apt to become affected, and the nose becomes reddened, congested, and irregularly swollen. To this condition the term *grog blossom* is popularly applied. In some of these cases there is enormous hypertrophy of the skin and subcutaneous tissues, producing pendulous masses, termed *lipomata nasi*. *Ordinary epithelioma* and *rodent ulcer* may attack the nose, the latter being the more common of the two. *Lupus* and *syphilitic ulceration* frequently attack the nose, and may destroy the whole of the cartilaginous portion. In fact, *lupus vulgaris* begins more frequently on the ala of the nose than in any other situation.

Cases of congenital occlusion of one or both nostrils, or adhesion between the ala and septum may occur, and may require immediate operation, since the obstruction much interferes with sucking. Bony closure of the posterior nares may also occur.

To *examine the nasal cavities*, the head should be thrown back and the nose drawn upward, the parts being dilated by some form of speculum. The posterior nares can be explored by the aid of reflected light from the mouth, by which the posterior nares can be illuminated. The examination is very difficult to carry out, and, as a rule, sufficient information regarding the presence of foreign bodies or tumors in the nasopharynx can be obtained by the introduction of the finger behind the soft palate through the mouth. The *septum of the nose* is sometimes displaced or *deviates* from the middle line; this may be the result of an injury or some congenital defect in its development; in the latter case the deviation usually occurs along the line of union of the vomer and mesethmoid, and rarely occurs before the seventh year. Sometimes the deviation may be so great that the septum may come in contact with the outer wall of the nasal fossa, and may even become adherent to it, thus producing complete obstruction. *Perforation of the septum* is not an uncommon affection and may arise from several causes—syphilitic or tuberculous ulceration, blood tumor or abscess of the septum, and especially in workmen exposed to the vapor of bichromate of potash, from the irritating and corrosive action of its fumes. When

small, the perforation may cause a peculiar whistling sound during respiration. When large, it may lead to the falling in of the bridge of the nose.

Epistaxis is a very common affection in children. It is rarely of much consequence, and will almost always subside, but in the more violent hemorrhages of later life it may be necessary to plug the posterior nares. In performing this operation it is desirable to remember the size of the posterior nares. A ready method of regulating the size of the plug to fit the opening is to make it of the same size as the terminal phalanx of the thumb of the patient to be operated on.

Foreign bodies, such as boot buttons, are frequently inserted into the nostrils by children, and require some care in their removal, as unskilled attempts only result in pushing the foreign body farther into the nasal fossa. Bodies which remain in the nose any length of time are apt to set up an ulceration of the mucosa, which may spread to the bone; a unilateral nasal discharge in a child is always suggestive of the presence of a foreign body. A foreign body is best removed under anesthesia, placing the left forefinger in the nasopharynx to prevent the passage of the body into the air-passages, and then removing the foreign body through the anterior naris by a suitable scoop or forceps manipulated by the right hand.

Nasal polypus is a very common disease, and presents itself in three forms—the gelatinous, the fibrous, and the malignant. The first is by far the most common. It grows from the mucous membrane of the outer wall of the nasal fossa, where there is an abundant layer of highly vascular submucous tissue; rarely from the septum, where the mucous membrane is closely adherent to the cartilage and bone, without the intervention of much, if any, submucous tissue. The most common seat of gelatinous polyps is probably the middle turbinated process. The fibrous polypus generally grows from the base of the skull behind the posterior nares or from the roof of the nasal fossæ. The malignant polypi, both sarcomatous and carcinomatous, may arise in the nasal cavities and the nasopharynx; or they may originate in the antrum, and protrude through its inner wall into the nasal fossa.

Rhinoliths or nose-stones may sometimes be found in the nasal cavities. They arise from the deposition of phosphate of lime upon either a foreign body or a piece of inspissated secretion.

The nasal passages furnish a secretion of their own and receive secretion from other parts (tears and secretions of the accessory sinuses). The nasal cavities contain the ethmoidal labyrinths, the lateral masses of the ethmoid (which form the superior and middle turbinated processes), and the inferior turbinated bones. The nasal cavity is surrounded by three pairs of pneumatic spaces, the **accessory sinuses**. These are the maxillary sinuses (p. 103), the frontal sinuses (p. 79), and the cells of the ethmoidal labyrinth (p. 99). The lacrimal duct opens into the inferior meatus. Inflammation of the air-cells may follow inflammation of the nasal mucous membrane or bone disease. One set of cells or many may suffer. Suppuration may occur; pus may be retained; death of bone may ensue. The most serious conditions may follow (abscess of brain, sinus thrombosis, septicemia), and an operation is necessary to obtain relief.

THE EYE.

The **eyeball** or **globe** (*bulbus oculi*) (Figs. 794 and 796) is contained in the anterior part of the cavity of the orbit. In this situation it is securely protected from injury, while its position is such as to insure the most extensive range of sight. It is acted upon by numerous muscles, by which it is capable of being directed to different parts; it is supplied by vessels and nerves, and is additionally protected in front by the orbital margins, eyelids, etc.

The eyeball is embedded in the fat of the orbit, but is partly surrounded by a thin membranous sac, the **capsule of Ténon**, which isolates it, so as to allow of free movement.

The **Capsule of Ténon** (*fascia bulbi* [*Tenoni*]) (Figs. 794 and 795) consists of a thin membrane which envelops the eyeball from the optic nerve to the ciliary region, separating it from the orbital fat and forming a socket in which it plays. Its inner surface is smooth, and is in contact with the outer surface of the sclera, the **periscleral** or **suprascleral lymph space** only intervening. This lymph space is continuous with the subdural and subarachnoid spaces, and is traversed by delicate bands of connective tissue which extend between the capsule and the sclera. This lymph space forms a flexible pocket, in which the globe rotates. The capsule is perforated behind by the **ciliary vessels** and **nerves** and by the **optic nerve**, being continuous with the sheath of the latter. In front it blends with the ocular conjunctiva, and with it is attached to the ciliary region of the eyeball.

It is perforated by the ocular muscles, and is reflected backward on each as a tubular sheath. The sheath of the Superior oblique is carried as far as the fibrous

FIG. 794.—The right eye in sagittal section, showing the capsule of Ténon (semidiagrammatic). (Testut.)

pulley of that muscle; that on the Inferior oblique reaches as far as the floor of the orbit, to which it gives off a slip. The sheaths on the Recti are gradually lost in the epimysium, but they give off important expansions. The expansion from the Superior rectus blends with the tendon of the Levator palpebrae; that of the Inferior rectus is attached to the inferior tarsal plate. These two Recti, therefore, will exercise some influence on the movements of the eyelids. The expansions from the sheaths of the Internal and External recti are strong, especially the one from the latter muscle, and are attached to the lacrimal and malar bones respectively. As they probably check the action of these two Recti, they have been named the **internal** and **external check ligaments**.

Lockwood has also described a thickening of the lower part of the capsule of Ténon which he has named the **suspensory ligament of the eye**. It is slung like a

FIG. 795.—The capsule of Ténon. The aponeurosis is seen from behind forward on the posterior hemisphere of the globe. *a*. Cellulofibrous intermuscular lamina. *b*. Deep leaf of the sheath incised at the point where it leaves the muscle to fold itself on the posterior hemisphere when it forms the posterior capsule. *d*. Partly incised. *c*. Serosus membrane. (Poirier and Charpy.)

hammock below the eyeball, being expanded in the centre, and narrow at its extremities, which are attached to the malar and lacrimal bones respectively.¹

The anterior one-third of the globe is covered by the **conjunctiva**, or mucous membrane, reflected from the inner surfaces of the lids (Fig. 797). A lateral view of the globe shows that it is composed of **segments of two spheres** of different sizes (Figs. 796 and 797). The **anterior segment** is one of a small sphere, and forms about one-sixth of the eyeball. It is more prominent than the **posterior segment**, which is one of a much larger sphere, and forms about five-sixths of the globe. Between the small, anterior or corneal segment and the large, posterior or scleral segment is a shallow and narrow groove, the **scleral sulcus** (*sulcus sclerae*). The **anterior pole** is the centre of the anterior portion of the cornea. The **posterior pole** is the centre of the posterior portion of the sclera. A straight line joining

FIG. 796.—The right eye in horizontal section. (Toldt.)

these two poles is the **sagittal or optic axis** (*axis optica*) (Fig. 796). A line drawn around the eyeball equally distant at all points from the two poles is called the **equator** (Fig. 796). The plane of the equator divides the globe in an **anterior** and a **posterior hemisphere**. The **visual axis** (*linea visus*) (Fig. 796) passes in a straight line from the first nodal point on the cornea to the fovea centralis of the yellow spot on the retina. A **nodal point** is the point of intersection of convergent rays with the visual axis. The first nodal point is 6.9685 mm. behind the summit of the cornea. The axes of the eyeballs are nearly parallel to the mesal plane, and therefore do not correspond to the axes of the orbits, which are inclined to this plane, forming with it an anterior angle of about 30 degrees. The optic nerves

¹ See a paper by C. B. Lockwood, *Journal of Anatomy and Physiology*, vol. xx, part i, p. 1.

follow the direction of the axes of the orbits and are therefore not parallel; each nerve either leaves or connects with its eyeball about 1 mm. below and 3 mm. to the inner or nasal side of the posterior pole (Fig. 796). The eyeball measures rather more in its transverse and antero-posterior diameters than in its vertical diameter, the former amounting to about 24 mm. (nearly an inch), the latter to about 23.5 mm. (nine-tenths of an inch). The diameters in the female are somewhat less than in the male. At birth the eyeball has a transverse diameter of about 17.5 mm., while at puberty it measures from 20 to 21 mm.

The eyeball is composed of three **investing tunics** and of three main **refracting media**.

FIG. 797.—Diagram of a horizontal section of the right eye, showing the upper surface of the lower segment. (Testut.)

THE TUNICS OF THE EYE.

From without inward the three tunics are:

- I. Sclera and Cornea.
- II. Choroid, Ciliary Body, and Iris.
- III. Retina.

I. The Sclera and Cornea (*Tunica Fibrosa Oculi*).

The sclera and cornea (Figs. 797 and 798) form the external tunic of the eyeball; they are essentially fibrous in structure, the sclera being opaque, and forming the posterior five-sixths of the globe; the cornea, which forms the remaining sixth, is transparent.

The Sclera (*σκληρός*, hard).—The sclera has received its name from its extreme density and hardness; it is a firm, unyielding, opaque, fibrous membrane serving to maintain the form of the globe. It is much thicker behind than in front. Its *external surface* is of a white color, and is in contact with the inner surface of the capsule of Ténon, a lymph space intervening; it is quite smooth, except one-quarter of an inch back of the sclerocorneal junction, at the points where the Recti and Obliqui muscles are attached to it, and its anterior part is covered by the **conjunctival membrane** (Fig. 820); hence the whiteness and brilliancy of the front of the eyeball. Its *inner surface* is stained a brown color, marked by grooves, in which are lodged the **ciliary nerves** and **vessels** (Figs. 806 and 807); the inner surface of the sclera is loosely connected with the outer surface of the choroid by a layer of exceedingly fine cellular pigmented tissue (*lamina fusca*), which traverses an extensive lymph space, the **perichoroidal space** (*spatium perichoroideale*) (Figs. 806 and 820) intervening between the sclera and choroid. Behind, the sclera is pierced by the **optic nerve** and is continuous with the fibrous sheath of the nerve, which is derived from the dura (Fig. 801). At the point where the optic nerve passes through the sclera, the lamina fusca is represented by an arrangement of the fibrous tissue which forms a thin network, the **cribriform lamina** (*lamina cribrosa sclerae*) (Fig. 811); the minute orifices in this lamina serve for the transmission of nerve filaments, and the fibrous septa dividing them from one another are continuous with the membranous processes which separate the bundles of nerve fibres. One of these openings (*porus opticus*), larger than the rest, occupies the centre of the lamella; it transmits the **arteria centralis retinae** to the interior of the eyeball (Fig. 811). Around the cribriform lamella are numerous small apertures for the transmission of the **ciliary nerves** and the **short ciliary arteries**, and about midway between the margin of the cornea and the entrance of the optic nerve are four or five large apertures, for the transmission of **veins** (*venae vorticosae*) (Fig. 820). In front, the fibrous tissue of the sclera is continuous with the substantia propria of the cornea (Fig. 820), but the opaque sclera slightly overlaps the outer surface of the transparent cornea.

Structure.—The sclera is formed of white fibrous tissue intermixed with fine elastic fibres, and of flattened connective-tissue cells, some of which are pigmented, contained in cell spaces between the fibres (Fig. 811). These fibres are aggregated into bundles, some of which are arranged in layers having an equatorial direction, but most of which are arranged in layers lying in meridian lines. Its vessels (Figs. 801 and 802) are not numerous, the capillaries being of small size and uniting at long and wide intervals. It obtains arterial blood from the *short posterior ciliary* and the *anterior ciliary arteries*. The venous blood is removed by the *venae vorticosae* and the *anterior ciliary veins*. There are lymph spaces between the cells which empty into the *periscleral* (Fig. 794 and p. 1088) and *perichoroidal lymph spaces* (Fig. 806). Its nerves are derived from the *ciliary nerves* (Fig. 800). They lose their myelin sheaths and enter among the bundles of fibrous tissue, but it is not known how they terminate.

The Cornea (Figs. 796 and 801).—The cornea is the projecting transparent part of the external tunic of the eyeball, and forms the anterior sixth of the surface of the globe. It is almost, but not quite, circular in shape, occasionally a little broader in the transverse than in the vertical direction. It is convex anteriorly, and projects forward from the sclera in the same manner that a watch-glass does from the case. Its degree of curvature varies in different individuals, and in the same individual at different periods of life, it being more prominent in youth than in advanced life. Usually the curvature is slightly greater in the vertical plane than in the horizontal plane; at its centre than at its periphery, and at its temporal than at its nasal side. The cornea is dense and of uniform thickness throughout; its *posterior surface* is perfectly circular in outline, and exceeds the anterior surface slightly in extent, from the latter being overlapped by the sclera. The *anterior surface* is covered with conjunctival epithelium (Fig. 806).

Structure (Fig. 798).—The cornea consists of five layers—namely: (1) the anterior or epithelial layer; (2) the anterior elastic layer; (3) the substantia propria; (4) the posterior elastic layer; (5) the posterior or endothelial layer.

1. The **anterior layer** (*epithelium corneae*) is composed of stratified epithelium and is continuous with the cells of the conjunctiva at the borders of the cornea. There are from five to eight strata of nucleated cells in the anterior layer. The deepest cells are columnar. Above the columnar cells are several layers of polygonal cells, most of which have finger-like processes and are called *prickle cells*. At the surface the cells and nuclei become flat.

2. The **anterior elastic or anterior limiting layer**, or **Bowman's membrane** (*lamina elastica anterior*), is less than half the thickness of the layer of stratified epithelium. It resembles in some respects, but is not, elastic tissue. It shows evidences of fibrillary structure, and does not display a tendency to curl inward or to undergo fracture when detached from the other layers of the cornea. It consists of extremely close interwoven fibrils, similar to those found in the rest of the cornea proper, but contains no corneal corpuscles. It ought, therefore, to be regarded as a part of the proper tissue of the cornea, apparently representing a basement membrane.

3. The **substantia propria** or proper substance of the cornea forms the main thickness of that structure. It is fibrous, tough, unyielding, perfectly transparent, and continuous with the sclera. It is composed of about sixty flattened lamellæ, superimposed one on another. These lamellæ are made up of bundles of modified connective tissue, the fibres of which are directly continuous with the fibres of the sclera. The fibres of each lamella are for the most part parallel with each other; those of alternating lamellæ at right angles to each other. Fibres, however, frequently pass obliquely from one lamella to the next (*fibræ arcuatae*).

The lamellæ are connected with each other by an interstitial cement

substance, in which are spaces, the **corneal spaces** (Fig. 799). The spaces are stellate in shape, and have numerous offshoots or **canaliculi** (Fig. 799), by which they communicate with each other. Each space contains a cell, the **corneal corpuscle** (Fig. 799), which resembles in form the space in which it is lodged, but it does not entirely fill it, the remainder of the space containing lymph. In the aged the margin of the cornea becomes opaque gray. This rim is called the **arcus senilis**, and is due to fat deposit in the lamellæ and corneal corpuscles.

4. The **posterior elastic lamina**, the **membrane of Descemet**, or of **Demours** (*lamina elastica posterior*), which covers the posterior surface of the substantia propria of the cornea, presents no structure recognizable under the microscope. It consists of an elastic, and perfectly transparent homogeneous membrane, of extreme thinness, which is not rendered opaque by either water, alcohol, or acids. It is very brittle, but its most remarkable property is its extreme elasticity and the tendency which it presents to curl up, or roll upon itself, with the attached surface

FIG. 798.—Vertical section through the cornea of a newborn child.
× 200. (Szymonowicz.)

innermost, when separated from the proper substance of the cornea. Its use appears to be "to preserve the requisite permanent correct curvature of the flaccid cornea proper" (Jacob).

At the margin of the cornea this posterior elastic membrane breaks up into fibres to form a reticular structure at the outer angle of the anterior chamber, the intervals between the fibres

forming small cavernous spaces, the spaces of Fontana (*spatia anguli iridis*) (Fig. 764). These little spaces communicate with a circular canal in the deeper parts of the corneoscleral junction.

This is the canal of Schlemm (*sinus venosus sclerae*) (Figs. 760 and 764); it communicates internally with the anterior chamber through the spaces of Fontana, and externally with the scleral veins. Some of the fibres of this reticulated structure are continued into the front of the iris, forming the *ligamentum pectinatum iridis*; while others are connected with the fore part of the sclera and choroid.

5. The posterior layer or the corneal endothelium (*endothelium camerae anterioris*) lines the aqueous chamber and prevents the absorption of the aqueous

humor. It covers the posterior surface of the elastic lamina, is reflected upon the front of the iris, and also lines the spaces of Fontana. It consists of a single layer of polygonal, flattened, transparent, nucleated cells, similar to those lining other serous cavities.

Arteries and Nerves.—The fetal cornea contains bloodvessels which pass from the margin almost to the centre. The adult cornea contains no bloodvessels, except at its margin. The capillaries from the sclera and conjunctiva form loops at the corneal margin, and many of these loops enter the cornea for a distance of 1 mm. (Fig. 802). The balance of the cornea is non-vascular and obtains its nourishment from the lymph in the *lacunae* and *canaliculi*. Lymphatic vessels have not as yet been demonstrated in it, but are represented by the channels in which the bundles of nerves run; these channels are lined by endothelium and are continuous with the cell spaces. The nerves are numerous, and they are derived from the ciliary nerves; they form the *annular plexus* (*plexus annularis*), at the corneal margin, and enter the laminated tissue of the cornea, lose their myelin sheaths, and ramify throughout the substantia propria as the *plexus of the stroma*. From this deep plexus come *perforating fibres* (*fibrae perforantes*), which pass through the anterior elastic lamina and form the *subepithelial plexus*, and from it fibres are given off which ramify between the epithelial cells, forming a network which is termed the *intra-epithelial plexus*. Nerve fibres from the annular plexus and from the plexus of the stroma come into close relation with the corneal corpuscles.

Dissection.—In order to separate the sclera and cornea, so as to expose the second tunic, the eyeball should be immersed in a small vessel of water and held between the finger and thumb. The sclera is then carefully incised, in the equator of the globe, till the choroid is exposed. One blade of a pair of probe-pointed scissors is now introduced through the opening thus made, and the sclera divided around its entire circumference, and removed in separate portions. The front segment being then drawn forward, the handle of the scalpel should be pressed gently against it at its connection with the iris, and, these being separated, a quantity of perfectly transparent fluid will escape; this is the aqueous humor. In the course of the dissection the ciliary nerves (Fig. 800) may be seen lying in the loose cellular tissue between the choroid and sclera or continued in delicate grooves on the inner surface of the latter membrane.

II. The Choroid, Ciliary Body, and Iris (Tunica Vasculosa Oculi) (Figs. 800, 820).

The middle tunic of the eye is formed from behind forward by the choroid, the ciliary body, and the iris.

The choroid invests the posterior five-sixths of the globe, and extends as far forward as the *ora serrata* of the retina; the ciliary body connects the choroid

FIG. 799.—From a horizontal section of an ox's cornea. Positive picture of the canal system demonstrated by the gold chloride method. $\times 450$. (Szymonowicz.)

to the circumference of the iris. The iris is the circular septum, which hangs vertically behind the cornea, presenting in its centre a large rounded aperture, the pupil.

The **Choroid** (*chorioidea*) is a thin, highly vascular membrane, of a dark-brown or chocolate color, which invests the posterior five-sixths of the globe, and is pierced behind by the optic nerve, and in this situation is firmly adherent to the sclera. It is thicker behind than in front. Externally, it is loosely connected by the **lamina fusca** with the inner surface of the sclera (p. 1092). Its inner surface is attached to the retina.

Structure.—The choroid consists of a dense capillary plexus and of small arteries and veins, carrying the blood to and returning it from this plexus (Fig. 802), and of branched and pigmented cells which lie in connective tissue. There are three layers in the choroid. Named from without inward, they are the **lamina suprachoroidea**, the **choroid proper**, and **lamina basalis**.

1. The **lamina suprachoroidea** is on the external surface, that is, the surface next to the sclera. It resembles the lamina fusca of the sclera. It is composed of delicate nonvascular lamellæ, each lamella consisting of a network of fine elastic fibres, among which are branched pigment cells. The spaces between the lamellæ are lined by endothelium, and open freely into the perichoroidal lymph space, which, in its turn, communicates with the periscleral space by the perforations in the sclera through which the vessels and nerves are transmitted.

2. The **choroid proper** is internal to the lamina suprachoroidea. In consequence of the small arteries and veins of the choroid proper being arranged on the outer surface of the capillary network, it is customary to describe this as consisting of two layers—the **outer** (*lamina vasculosa*), composed of small arteries and veins, with pigment cells interspersed between them, and the **inner** (*lamina choriocapillaris*), consisting of a capillary plexus. The **external layer of the choroid proper** or the **lamina vasculosa** consists, in part, of the larger branches of the **short posterior ciliary arteries** (Figs. 801 and 804), which run forward between the veins, before they bend inward to terminate in the capillaries; but this layer is formed principally of veins, which have a whorl-like arrangement and empty into four or five large equidistant trunks, the **venae vorticosæ** (Figs. 801 and 802), which pierce the sclera midway between the margin of the cornea and the attachment of the optic nerve. Interspersed between the vessels are dark star-shaped pigment-cells, the processes of which, communicating with similar branchings from neighboring cells, form a delicate network of stroma, which toward the inner surface of the choroid loses its pigmentary character. The **inner layer of the choroid proper** consists of an exceedingly fine capillary plexus, formed by the short ciliary vessels (Fig. 802), and is known as the **membrane of Ruysh** (*lamina choriocapillaris*). The network is close, and finer at the hinder part of the choroid than in front. About 1.2 cm. behind the cornea its meshes become larger, and are continuous with those of the ciliary processes. These two laminae are connected by an **intermediate stratum**, which is destitute of pigment cells and consists of fine elastic fibres. On the inner surface of the lamina choriocapillaris is a very thin, structureless, or faintly fibrous membrane, called the **lamina basalis** (**membrane of Bruch**); it is closely connected with the stroma of the choroid, and separates it from the pigmentary layer of the retina; the cells of the latter are found attached to this membrane.

Dissection.—The ciliary body should now be examined. It may be exposed, either by detaching the iris from its connection with the Ciliary muscle, or by making a transverse section of the globe, and examining it from behind.

FIG. 800.—The choroid and iris. (Enlarged.)

The **Ciliary Body** (*corpus ciliare*) (Fig. 805) joins the choroid to the margin of the iris. It is in reality a process of the choroid and comprises the **orbiculus ciliaris**, the **ciliary processes**, and the **Ciliary muscle**.

The **orbiculus ciliaris** (*annulus ciliaris*) (Figs. 803 and 804) is a zone of about 4 mm. (one-sixth of an inch) in width, directly continuous with the anterior part of the choroid; it presents numerous ridges arranged in a radial manner. The depressions between the ridges are filled with retinal pigment epithelium (Szymonowicz). The orbiculus contains no lamina choriocapillaris.

FIG. 801.—Vessels and nerves of the choroid and iris, seen from above. The sclera and cornea have been largely removed. (Testut.)

The **ciliary processes** (*processus ciliares*) (Figs. 805 and 820) are formed by the plaiting and folding inward of the various layers of the choroid (*i. e.*, the choroid proper and the lamina basalis) at its anterior margin, and are received between corresponding foldings of the suspensory ligament of the lens, thus establishing a connection between the choroid and inner tunic of the eye. They are arranged in a circle, and form a sort of plaited frill, the **corona ciliaris**, behind the iris, round the margin of the lens (Figs. 805 and 820). They vary between sixty and eighty in number, lie side by side, and may be divided into large and small; the latter, consisting of about one-third of the entire number, are situated in the spaces between the former, but without regular alternation. The larger processes are each about 2.5 mm. (one-tenth of an inch) in length, and are attached by their periphery to three or four of the ridges of the orbiculus ciliaris, and are continuous with the layers of the choroid; the opposite margin is free, and rests upon the circumference of the lens. Their anterior surface is turned toward the back of the iris, with the circumference of which they are continuous. The posterior surface is connected with the suspensory ligament of the lens.

Structure.—The ciliary processes are similar in structure to the choroid, but the vessels are larger, and have chiefly a longitudinal direction. They constitute the most vascular portion of the eyeball. The processes are covered on their inner surface by two strata of black pigment cells, which are continued forward from the retina, and are named the *pars ciliaris retinae* (Fig. 806). In the stroma of the ciliary processes there are also stellate pigment cells, which, however, are not so numerous as in the choroid itself.

FIG. 802.—Diagram of the bloodvessels of the eye, as seen in a horizontal section. (Leber, after Stöhr.)

The **Ciliary muscle** (Bowman's muscle) (*m. ciliaris*) (Figs. 806 and 808) consists of unstriped fibres; it forms a grayish, semitransparent, circular band, about 3 mm. (one-eighth of an inch) broad, on the outer surface of the fore part of the choroid, between the choroid and the iris and back of the sclerocorneal junction. It is thickest in front and gradually becomes thinner behind. It consists of two sets of fibres, **radial** and **circular**. The **radial fibres** (*fibrae meridiales*) (Figs.

806 and 820), the more numerous, arise at the point of junction of the cornea and sclera, and partly also from the ligamentum pectinatum iridis, and, passing backward, are attached to the choroid opposite to the ciliary processes. One bundle, according to Waldeyer, is continued backward to be inserted into the sclera. The **circular fibres** (*fibræ circulares* [Muller]) (Figs. 806 and 820) are

FIG. 803.—The middle or vascular coat of the eye-ball exposed from without. Left eye, seen obliquely from above and before. (Toldt.)

it is again checked by the tension of the slightly contracted.

The **Iris** (*iris*, a rainbow) (Figs. 807 and 809) has received its name from its various colors in different individuals. It is a thin, circular contractile curtain, suspended in the aqueous humor between the cornea and the lens, being perforated a little to the nasal side of its centre by a circular aperture, the **pupil** (*pupilla*) (Fig. 809), for the transmission of light. The pupil of a living person varies in size under the influence of light and in efforts at accommodation. In looking at a near object the pupil is small; in looking at a distant object it is large. In light the pupil contracts, in darkness it dilates; hence the pupil is a window which permits light to pass into the interior of the eye. The size of this window depends on the contraction or relaxation of the iris. The iris divides the **aqueous chamber** (the space between the cornea and lens) into an **anterior chamber** and a **posterior chamber** which communicate through the pupil (Fig. 796). By its **circumference** or **ciliary margin** (*margo ciliaris*) (Figs. 806 and 807) the iris is continuous with the ciliary body, and it is also connected with the posterior elastic lamina of the cornea by means of the **pectinate ligament** (*ligamentum pectinatum iridis*) (Fig. 820). The pectinate ligament of the iris is derived from the posterior

internal to the radial ones and to some extent unconnected with them, and have a circular course around the attachment of the iris. They are sometimes called the "**ring muscle**" of Müller, and were formerly described as the **ciliary ligament**. They are well developed in hypermetropic, but are rudimentary or absent in myopic eyes. The Ciliary muscle is admitted to be the chief agent in accommodation—*i. e.*, in adjusting the eye to the vision of near objects. When the Ciliary muscle contracts, it draws the choroid forward, and relaxes the suspensory ligament. The elasticity of the lens at once allows it to bulge forward until capsule;¹ the pupil is at the same time

¹ Stewart, Manual of Physiology.

elastic layer of the cornea. In this ligament are numerous lymph spaces, the **spaces of Fontana** (*spatia anguli iridis*) [*Fontanae*] (Fig. 806), and they join the canal of

FIG. 805.—A portion of the corona ciliaris magnified. The ciliary processes and the ciliary folds. (Toldt.)

Schlemm to the anterior chamber of the eye. The inner or free edge of the iris forms the margin of the pupil, and is called the **pupillary margin** (*margo pupillaris*) (Fig. 807). The surfaces of the iris are flattened, and look forward and backward, the anterior toward the cornea, the posterior toward the ciliary processes and lens.

FIG. 806.—Section of the eye, showing the relations of the cornea, sclera, and iris, together with the Ciliary muscle and the cavernous spaces near the angle of the anterior chamber. (Waldeyer.)

The iris is pigmented and the color of an individual's eyes depends upon this pigment. The anterior surface (*facies anterior*) (Figs. 807 and 820) of the iris

is variously colored in different individuals, and is marked by lines which converge toward the pupil. The **posterior surface** (*facies posterior*) (Figs. 805 and 820) is of a deep purple tint, from being covered by two layers of pigmented, columnar epithelium, which layers are continuous posteriorly with the *pars ciliaris retinae*. This pigmented epithelium is termed the *pars iridica retinae*, though it is sometimes named *uvea*, from its resemblance in color to a ripe grape.

FIG. 807.—Section of the iris. Anterior surface magnified. (Toldt.)

Structure.—The iris is composed of the following structures:

1. In front is a layer of flattened endothelial cells placed on a delicate hyaline basement membrane. This layer is continuous with the endothelial layer covering the membrane of Descemet, and in men with dark-colored irides the cells contain pigment granules.

FIG. 808.—The ciliary ganglionic plexus and the ciliary nerves entering the plexus. Outer surface of the middle or vascular coat of the eyeball. (Toldt.)

2. The **stroma** (*stroma iridis*) consists of fibres and cells. The former are made up of fine, delicate bundles of fibrous tissue, of which some few fibres have a circular direction at the circumference of the iris, but the chief mass consists of fibres radiating toward the pupil. They form, by their interlacement, delicate meshes, in which the vessels and nerves are contained. Interspersed between the bundles of connective tissue are numerous stellate cells with fine processes.

Many of them in dark eyes contain pigment granules, but in blue eyes and the pink eyes of albinos they are unpigmented. The **muscle fibres** are unstriated and consist of **circular** and **radial fibres**. The **circular fibres** (*m. sphincter pupillae*) surround the margin of the pupil on the posterior surface of the iris, like a sphincter, forming a narrow band about one-thirtieth of an inch (0.8 mm.) in width, those near the free margin being closely aggregated; those more external somewhat separated, and forming less complete circles. The **radial fibres** (*m. dilator pupillae*) converge from the circumference toward the centre, and blend with the circular fibres near the margin of the pupil. These fibres are regarded by some as elastic, not muscular.

3. **Pigmented epithelium** (*pars iridica retinae*). This is a continuation of the pars ciliaris retinae, and consists of two layers of pigmented, columnar epithelial cells. The situation of the pigment differs in different irides. In the various shades of blue eyes the only pigmentation is that of the pigmented epithelium. The color of the eye in these individuals is due to this coloring matter showing more or less through the texture of the iris. In the albino even this pigment is absent. In the gray, brown, and black eye there are, as mentioned above, pigment granules to be found in the connective tissue cells of the stroma and in the endothelial layers on the front of the iris; to these the dark color of the eye is due.

FIG. 809.—Iris, front view. (Testut.)

The **arteries** of the Choroid and Iris (Figs. 804 and 809).—The **short posterior ciliary arteries**, from six to twelve in number, arise from the ophthalmic, or some of its branches; they pass forward around the optic nerve to the posterior part of the eyeball, pierce the sclera around the entrance of the nerve, and supply the choroid coat and ciliary processes. The arteries of the iris are derived from the **long posterior ciliary** and **anterior ciliary arteries** and from the vessels of the ciliary processes (see p. 616). The **long posterior ciliary arteries** (Figs. 801 and 802), two in number, pass through the sclera, one on the inner and one on the outer side of the optic nerve, and pass forward between the sclera and choroid, and, having reached the attached margin of the iris (Figs. 801 and 809), divide into an upper and a lower branch, and, encircling the iris, anastomose with corresponding branches from the opposite side; into this vascular zone (*circulus iridis major*) (Fig. 820) the **anterior ciliary arteries** (Fig. 820), from the **lacrimal** and **anterior ciliary** from the muscular branches of the **ophthalmic**, pour their blood. From this zone vessels converge to the free margin of the iris, and these communicate by branches from one to another and thus form a second zone (*circulus iridis minor*) in this situation. The **veins** pass toward the ciliary margin and communicate with the veins of the ciliary processes and of the canal of Schlemm (Figs. 801 and 802).

The **nerves** of the Choroid and Iris (Fig. 800) are the **short ciliary**, the **ciliary branches of the lenticular ganglion**, and the **long ciliary** from the **nasal branch of the ophthalmic division of the trigeminal**. They pierce the sclera around the entrance of the optic nerve, and run for-

ward in the perichoroidal lymph space, in which they form a plexus, from which plexus filaments pass to supply the bloodvessels of the choroid. After reaching the iris they form a plexus around its attached margin; from this are derived amyelinic fibres which terminate in the circular and radial muscular fibres. Their exact mode of termination has not been ascertained. Other fibres from the plexus terminate in a network on the anterior surface of the iris. The fibres derived from the motor root of the lenticular ganglion (oculomotor nerve) supply the circular fibres, while those derived from the sympathetic supply the radial fibres.

Membrana Pupillaris.—In the fetus the pupil is closed by a delicate transparent vascular membrane, the **membrana pupillaris**, which divides the space into which the iris is suspended into two distinct chambers. This membrane contains numerous minute vessels, continued from the margin of the iris to those on the front part of the capsule of the lens. These vessels have a looped arrangement, and converge toward each other without anastomosing. Between the seventh and eighth months the membrane begins to disappear, by gradual absorption from the centre toward the circumference, and at birth only a few fragments remain. It is said sometimes to remain permanent and produce blindness.

III. The Retina, or Tunica Interna (Figs. 800, 801).

The retina is a delicate nerve membrane, in which the fibres of the optic nerve are spread out and upon the surface of which the images of external objects are received. Its outer surface is in contact with the choroid; its inner with the vitreous body. Behind, it is continuous with the optic nerve; it gradually diminishes in thickness from behind forward; and, in front, extends nearly as far as the ciliary body, where it appears to terminate in a jagged margin, the **ora serrata** (Figs. 802 and 820). Here the nerve tissues of the retina end, but a thin prolongation of the membrane extends forward over the back of the ciliary processes and iris, forming the **pars ciliaris retinae** and **pars iridicae retinae**, already referred to. This forward prolongation consists of the pigmentary layer of the retina, together with a stratum of columnar epithelium. The retina is soft, semi-transparent, and of a purple tint in the fresh state, owing to the presence

FIG. 810.—The arteria centralis retinae, yellow spot, etc., the anterior half of the eyeball being removed. (Enlarged.)

of a coloring material named **rhodopsin** or **visual purple**; but it soon becomes clouded, opaque, and bleached when exposed to sunlight. Exactly in the centre of the front surface of the posterior part of the retina, corresponding to the visual axis, and at a point in which the sense of vision is most perfect, is an oval yellowish spot, called the **yellow spot** (*macula lutea*) (Figs. 799 and 810), having a central depression, the **fovea centralis**. The retina in the situation of the fovea centralis is exceedingly thin, and the dark color of the choroid is distinctly seen through it. It exists only in man, the quadrumana, and some saurian reptiles. About 3 mm. (one eighth of an inch) to the nasal side of the yellow spot, and about 1 mm. below it, is the point of attachment of the optic nerve, the **optic disk** (*porus opticus*) (Figs. 810 and 811), the circumference of which is slightly raised so as to form

an eminence, the **optic papilla** (*colliculus nervi optici*); the central portion is depressed and is called the **optic cup** (*excavatio papillae nervi optici*). The *arteria centralis retinae* pierces its centre. This is the only part of the surface of the retina from which the power of vision is absent, and is termed the **blind spot**.

FIG. 811.—The terminal portion of the optic nerve and its entrance into the eyeball, in horizontal section. (Toldt.)

Structure.—The retina is an exceedingly complex structure, and, when examined microscopically by means of sections made perpendicularly to its surface, is found to consist of many layers of nerve elements bound together and supported by the **sustentacular fibres**. The layers of the retina are:

1. *Membrana limitans interna*.
2. Layer of nerve fibres (*stratum opticum*).
3. Ganglionic layer, consisting of nerve cells.
4. Inner plexiform layer.
5. Inner nuclear layer, or layer of inner granules.
6. Outer plexiform layer.
7. Outer nuclear layer, or layer of outer granules.
8. *Membrana limitans externa*.
9. Jacob's membrane (layer of rods and cones).
10. Pigmentary layer (*tapetum nigrum*).

1. The **membrana limitans interna** is the most internal layer of the retina, and is in contact with the hyaloid membrane of the vitreous humor. It is derived from the supporting framework of the retina, with which tissue it will be described.

2. The **layer of nerve fibres** is formed by the expansion of the optic nerve. This nerve passes through all the other layers of the retina, except the *membrana limitans interna*, to reach its destination. As the nerve passes through the lamina cribrosa of the scleral coat, the fibres of which it is composed lose their myelin sheaths and are continued onward, through the choroid and retina, as simple axones. When these amyelinic axones reach the internal surface of the retina, they radiate from their point of entrance over the surface of the retina, become grouped in bundles, and in many places arranged in plexuses. Most of the axones in this layer are **centripetal**, and are the direct continuations of the axones of the cells of the next layer, but a few of the axones are **centrifugal**, being axones of ganglion cells within the brain. The centrifugal fibres in the layer of nerve fibres pass through it and the next succeeding layer to ramify in the inner plexiform and inner nuclear layers, where they terminate in enlarged extremities. The layer of nerve fibres is thickest at the optic nerve entrance, and gradually diminishes in thickness toward the *ora serrata*.

3. The **ganglionic layer** consists of a single layer of large ganglion cells, except in the macula lutea, where there are several strata. The cells are somewhat flask-shaped, the rounded internal

surface of each cell resting on the preceding layer and sending off an axone which is prolonged as a nerve fibre into the fibre layer. From the opposite extremity numerous dendrites extend into the inner plexiform layer, where they branch out into flattened arborizations at different levels (Fig. 812). The ganglion cells vary much in size, and the dendrites of the smaller ones, as a rule, arborize in the inner plexiform layer as soon as they enter it; while the processes of the larger cells ramify close to the inner nuclear layer.

4. The **inner plexiform layer** is made up of a dense reticulum of minute fibrils, formed by the interlacement of the dendrites of the ganglion cells with those of the cells contained in the next layer, immediately to be described. Within the reticulum formed by these fibrils, a few branched spongioblasts are sometimes embedded.

FIG. 812.—Plan of retinal neurones. (After Cajal.)

5. The **inner nuclear or inner granular layer** consists of a number of closely packed cells, of which there are three varieties—viz.: (1) A large number of oval cells, which are commonly regarded as **bipolar nerve cells**, and are much more numerous than either of the other kind. They each consist of a large oval body placed vertically to the surface, and containing a distinct nucleus. The protoplasm is prolonged into two processes; one of these passes inward into the inner plexiform layer, is varicose in appearance, and ends in a terminal ramification, which is often in close proximity to the ganglion cells. The outer process passes outward into the outer plexiform layer, and there breaks up into a number of branches. There are two varieties of these bipolar cells—one in which the outer process arborizes around the knobbed ends of the rod fibres, and the inner around the cells of the ganglionic layer; these are called **rod bipolars** (Fig. 812); the others are those in which the outer process breaks up in a horizontal ramification, in contact with the end of a cone fibre; these are the **cone bipolars**, and their inner process breaks up into its terminal ramification in the inner molecular layer. (2) At the innermost part of this inner nuclear layer is a stratum of cells, which are named **amacrine cells (of Cajal)**, from the fact that they have no axis-cylinder process, but they give a number of short protoplasmic processes which extend into the inner plexiform layer and there ramify (Fig. 812). There are also at the outermost part of this layer some cells, the processes of which extend into and ramify in the outer molecular layer. These are the **horizontal cells (of Cajal)**. (3) Some few cells are also found in this layer, connected with the fibres of Müller, and will be described with those structures.

6. The **outer plexiform layer** is much thinner than the inner plexiform layer; but, like it, consists of a dense network of minute fibrils, derived from the processes of the horizontal cells of the preceding layer and the outer processes of the bipolar cells, which ramify in it, forming

arborizations around the ends of the rod fibres and with the branched foot plates of the cone fibres. In the neighborhood of the macula lutea, elongations from the inner segments of rod fibres and cone fibres form the so-called **Henle's fibre layer**.

7. The **outer nuclear or outer granular layer**, like the inner nuclear layer, contains several strata of clear oval nuclear bodies; they are of two kinds, and on account of their being respectively connected with the rods and cones of Jacob's membrane (rod fibres and cone fibres) are named **rod granules** and **cone granules**. The **rod granules** are much the more numerous, and are placed at different levels throughout the layer. Their nuclei present a peculiar cross-stripped appearance, and prolonged from either extremity of the granule is a fine process; the outer process is continuous with a single rod of Jacob's membrane; the inner passes inward toward the outer molecular layer and terminates in an enlarged extremity, and is embedded in the tuft into which the outer process of the rod bipolars break up. In its course it presents numerous varicosities. The **cone granules**, fewer in number than the rod granules, are placed close to the membrana limitans externa, through which they are continuous with the cones of Jacob's membrane. They do not present any cross-stripping, but contain a pyriform nucleus which almost completely fills the cell. From their inner extremity a thick process passes inward to the outer plexiform layer, upon which it rests by a somewhat pyramidal enlargement, from which are given

off numerous fine fibrils, which enter the outer plexiform layer, where they come in contact with the outer processes of the cone-bipolars.

8. The **membrana limitans externa**, like the membrana limitans interna, is derived from the fibres of Müller, with which structures it will be described.

9. **Jacob's membrane**, or the **layer of rods and cones**, consists of **visual cells**, and the elements which compose it are of two kinds, **rod cells** and **cone cells**, the former being much more numerous than the latter. The **rod cells** (Fig. 813) are of nearly uniform size, and arranged perpendicularly to the surface. A rod cell consists of a **rod** and a **rod fibre**, and the fibre contains the nucleus. The rods are cylindrical and each consists of two portions, an **outer segment** and an **inner segment**, which are of about equal length. The segments differ from each other as regards refraction and in their behavior with coloring reagents, the inner portion becoming

stained by carmine, iodine, etc., the outer portion remaining unstained with these reagents, but staining yellowish brown with osmic acid. The outer portion of each rod is marked by transverse striæ, and is made up of a number of thin disks superimposed on one another. It also exhibits faint longitudinal markings. The inner portion of each rod, at its deeper part where it is joined to the outer process of the rod granule, is indistinctly granular; its more superficial part presents a longitudinal striation, being composed of fine, bright, highly refracting fibres. The visual purple, or *rhodopsin*, is found only in the outer segments of the rods. At its inner end each rod is prolonged into a very fine fibre, the *rod fibre*, which contains a nucleus, and which terminates in the outer nuclear layer, being somewhat enlarged at its termination.

The *cone cells* (Fig. 813) are conical, or flask-shaped, their broad ends resting upon the *membrana limitans externa*, the narrow pointed extremity being turned to the choroid. Each cone cell consists of two parts, the *cone* and the *cone fibre*. The *outer segment* or cone is a short conical process, which, like the outer segment of a rod, presents transverse striæ. The *inner segment (cone fibre)* resembles the inner portion of the rods in structure, but differs from it in size, being shorter and bulged out laterally in a flask-shaped manner, and at the junction of the cone with the fibre is the nucleus of the cone cell. The cone fibre passes to the outer nuclear layer, and terminates as an expansion from which very minute fibrils are given off. The chemical and optical characters of the rod cells and cone cells are identical.

10. The *pigmentary layer* or *tapetum nigrum*, the most external layer of the retina, formerly regarded as a part of the choroid, consists of a single layer of hexagonal epithelial cells, loaded with pigment granules. Each cell contains a flattened nucleus in the outer portion of the cell which is free from pigment at this point. These cells are smooth externally, where they are in contact with the choroid, but internally they are prolonged into fine, straight processes, which extend between the rods, this being especially the case when the eye is exposed to light. The pigment changes its position under the influence of light, and is distributed through the entire cell. In the eyes of albinos, the cells of the pigmentary layer are present, but they contain no coloring matter.

Supporting Framework of the Retina.—Almost all these layers of the retina are connected by a supporting framework, formed by the *supporting cells* or *supporting fibres of Müller* or *radiating fibres*, from which the *membrana limitans interna et externa* are derived. These fibres are found stretched between the two limiting layers, "like columns between a floor and a roof," and they pass through all the neural layers except Jacob's membrane. Each commences on the inner surface of the retina by a conical hollow base, which sometimes contains a spheroidal body which stains deeply with hematoxylin, the edges of the bases of adjoining fibres being united and thus forming a boundary line, which is the *membrana limitans interna*. As they pass through the nerve fibre and ganglionic layers they give off few lateral branches; in the inner nuclear layer they give off numerous lateral processes for the support of the inner granules, while in the outer nuclear layer they form a network, the *fibre baskets*, around the rod and cone fibrils, and unite to form the external limiting membrane at the bases of the rods and cones. In the inner nuclear layer each fibre of Müller presents a clear oval nucleus, which is sometimes situated at the side of, sometimes altogether within, the fibre. The supporting framework of the retina contains neuroglia cells.

The Path of Light Stimuli.—The stimulus is supposed to be first received by the rod and cone cells (the visual cells), and is transmitted to the bipolar cells of the inner nuclear layer and then to the cells of the ganglionic layer, which send fibres by way of the optic nerve and tract to the brain (see p. 911).

Macula Lutea and Fovea Centralis.—The structure of the retina at the yellow spot presents some modifications. In the macula lutea (1) the nerve fibres are wanting as a continuous layer; (2) the ganglionic layer consists of several strata of cells, instead of a single layer; (3) in Jacob's membrane there are no rods, but only cones, and these are longer and narrower than in other parts; and (4) in the outer nuclear layer there are only cone fibres, which are very long and arranged in curved lines. At the fovea centralis the only parts which exist are the cones of Jacob's membrane, the outer nuclear layer, the cone fibres of which are almost horizontal in direction, and an exceedingly thin inner granular layer, the pigmentary layer, which is thicker and its pigment more pronounced than elsewhere. The color of the macula seems to imbue all the layers except Jacob's membrane; it is of a rich yellow, deepest toward the centre, and does not appear to consist of pigment cells, but simply a staining of the constituent parts.

At the *ora serrata* (Fig. 802) the nerve layers of the retina terminate abruptly, and the retina is continued onward as a single layer of elongated columnar cells covered by the pigmentary layer. This prolongation is known as the *pars ciliaris retinae* (Fig. 806), and can be traced forward from the ciliary processes on to the back of the iris, where it is termed the *pars iridica retinae* or *uvea*.

From the description given of the nerve elements of the retina it will be seen that there is no direct continuity between the structures which form its different layers except between the ganglionic and nerve fibre layers, the majority of the nerve fibres being formed of the axones of the ganglionic cells. In the inner molecular layer the dendrites of the ganglionic layer inter-

lace with those of the cells of the inner nuclear layer, while in the outer molecular layer a like synopsis occurs between the processes of the inner granules and the rod and cone elements.

The *arteria centralis retinae* (Fig. 802) and its accompanying vein, *vena centralis retinae*, pierce the optic nerve, and enter the globe of the eye through the porus opticus. They bifurcate on the surface of the papilla or just beneath it into an upper and a lower branch, and each of these again divides into an inner or nasal, and an outer or temporal branch; these at first run between the hyaloid membrane and the nerve layer; but they soon enter the latter, and pass forward, dividing dichotomously. From these branches a minute capillary plexus is given off, which does not extend beyond the inner nuclear layer. The macula receives small twigs from the temporal branches and others directly from the central artery; these do not, however, reach as far as the fovea centralis, which has no bloodvessels. The branches of the *arteria centralis retinae* do not anastomose with each other—in other words, they are “terminal arteries.” In the fetus, a small vessel passes forward, through the *hyaloid canal* in the vitreous body, to the posterior surface of the capsule of the lens (Fig. 797).

THE REFRACTING MEDIA.

The Refracting media are three—viz.:

Aqueous humor.

Vitreous body.

Crystalline lens.

I. The Aqueous Humor (*Humor Aqueus*).

The aqueous humor completely fills the lymph space known as the **aqueous chamber**, the space which is bounded in front by the cornea and behind by the lens and its suspensory ligament and the ciliary body (Fig. 820). The aqueous chamber is partly divided by the iris into two communicating parts, the **anterior** and **posterior chambers** (Figs. 797 and 820). The **posterior chamber** (*camera oculi posterior*) is only a narrow chink between the peripheral part of the iris, the suspensory ligament of the lens, and the ciliary processes. The **anterior chamber** (*camera oculi anterior*) is bounded in front by the cornea and behind by the iris. The external angle of the anterior chamber is bounded by the periphery of the cornea and of the iris. It is called the **angle** or the **filtration angle** (*angulus iridis*). It is by way of the filtration angle that any excess of aqueous humor passes by way of the spaces of Fontana and the canal of Schlemm (Fig. 806) to the anterior ciliary veins and relieves tension. The aqueous humor is small in quantity, has an alkaline reaction, in composition is little more than water, less than 2 per cent. of its weight being solid matter, chiefly sodium chloride.

FIG. 815.—The vitreous body removed from the eye in the fresh state, with the saucer-shaped hollow in which the lens lies. Seen obliquely from the side and before. (Toldt.)

II. The Vitreous Body (*Corpus Vitreum*) (Figs. 797, 817).

The **vitreous body** occupies about four-fifths of the entire globe. It is composed of a jelly-like tissue containing 98 per cent. water, some salts, and a little albumin, and called the **vitreous humor** (*humor vitreus*), connective-tissue fibres, and connective-tissue cells. It fills the concavity of the retina, and is hollowed in front, forming a deep concavity, **fossa hyaloidea** (Fig. 815), for the reception of the lens. It is perfectly transparent, of the consistence of thin jelly, and is composed of an albuminous fluid enclosed in a delicate transparent membrane, the **hyaloid membrane** (*membrana hyaloidea*), the outside of which is in contact with the *membrana limitans interna* of the retina. In the fetus a peculiar fibrous texture pervades the mass, the fibres joining at the numerous points, and presenting minute nuclear

granules at their point of junction. In the centre of the vitreous humor, running from the entrance of the optic nerve to the posterior surface of the lens, is a canal, filled with fluid and lined by a prolongation of the hyaloid membrane. This is the **hyaloid canal** (*canalis hyaloideus*) (Fig. 797), which in the embryonic vitreous humor conveyed the minute vessel from the central artery of the retina to the back of the lens.

The **hyaloid membrane** encloses the whole of the vitreous humor. In front of the ora serrata it is thickened by the accession of radial fibres and is termed the **zonule of Zinn** (*zonula ciliaris*) (Figs. 816 and 820). Here it presents a series of radially arranged furrows, in which the ciliary processes are accommodated and to which they are adherent, as evidenced by the fact that when removed some of their pigment remains attached to the zonule. The zonule of Zinn splits into two

FIG. 816.—The zonule of Zinn or the suspensory ligament of the lens viewed from behind in connection with the lens and the ciliary body. (Toldt.)

layers, one of which is thin and lines the fossa hyaloidea; the other is named the **suspensory ligament of the lens**; it is thicker, and passes over the ciliary body to be attached to the capsule of the lens a short distance in front of its equator. Scattered and delicate fibres are also attached to the region of the equator itself. This ligament retains the lens in position, and is relaxed by the contraction of the radial fibres of the Ciliary muscle, so that the lens is allowed to become more convex. Behind the suspensory ligament there is a sacculated canal, the **canal of Petit** (*spatia zonularia*), which encircles the margin of the lens and which can be easily inflated through a fine blowpipe inserted through the suspensory ligament. It is bounded in front by the anterior layer of the suspensory ligament of the lens, behind by the membrana hyaloidea, and internally by the capsule of the lens. The canal of Petit is a lymph space. All of the spaces of the canal of Petit communicate with the posterior chamber of the eye.

No vessels penetrate the vitreous body, although a lymph channel remains; so that its nutrition must be carried on by the vessels of the retina and ciliary processes, situated upon its exterior.

III. The Crystalline Lens (*Lens Crystallina*) (Figs. 817, 818).

The **crystalline lens**, enclosed in its *capsule*, is situated immediately behind the pupil, in front of the vitreous body, and is encircled by the ciliary processes, which slightly overlap its margin.

The **capsule of the lens** (*capsula lentis*) (Fig. 778) is a transparent, highly elastic, and brittle membrane, which closely surrounds the lens, and is composed in part of cuticular and in part of connective tissues. It is not white fibrous tissue, and is not true elastic tissue (Szymonowicz). Its outer surface is composed of lamellæ and possesses transverse striations. It rests, *behind*, in the fossa hyaloidea in the fore part of the vitreous body (Fig. 815); in *front*, it is in contact with the free border of the iris, this latter receding from it at the circumference, thus forming the **posterior chamber of the eye** (Fig. 820); and it is retained in its position chiefly by the suspensory ligament of the lens, already described (Fig. 820). The capsule is much thicker in front than behind, and when ruptured the edges roll up with the outer surface innermost, like the elastic lamina of the cornea.

FIG. 817.—The crystalline lens, hardened and divided. (Enlarged.)

FIG. 818.—The terms used in the orientation of the lens. (Toldt.)

The *lens* is a transparent, biconvex body, the convexity of the posterior surface being greater than that of the anterior. The central points of these surfaces are termed respectively the **anterior** and **posterior poles** (*polus anterior et polus posterior lentis*). A line connecting the poles constitutes the **axis** of the lens (*axis lentis*), while the marginal circumference is termed the **equator** (*aequator lentis*). The lens measures from 9 to 10 mm. in the transverse and vertical diameters and about 4 mm. from anterior to posterior pole.

FIG. 819.—Diagram to show the direction and arrangement of the radiating lines on the front and back of the fetal lens. A. From the front. B. From the back.

Structure.—The lens consists of an outer, soft part, easily detached (*substantia corticalis*), and a central, firm part (*nucleus lentis*) (Fig. 817). Faint lines (*radii lentis*) radiate from the poles to the equator. In the adult there may be six or more of these lines, but in the fetus they are only three in number and diverge from each other at angles of 120 degrees (Fig. 819). On the anterior surface one line ascends vertically and the other two diverge downward and outward. On the posterior surface one ray descends vertically and the other two diverge upward. They correspond with the free edges of an equal number of **septa** composed of an amorphous substance, which dip into the substance of the lens. When the lens has been hardened (as in alcohol), it is seen to consist of concentric layers, or **laminae**, each of which is interrupted at the septa. Each lamina is built up of a number of parallel, hexagonal **lens fibres** (*fibræ lentis*), the edges of which are serrated to fit similar serrations of adjacent lens fibres, while the ends of the fibres

come into apposition with the septa. The fibres run in a curved manner from the *septa* on the anterior surface to those on the posterior surface. No fibres pass from pole to pole, but they are arranged in such a way that fibres which commence near the pole on the one aspect of the lens terminate near the peripheral extremity of the plane on the other, and *vice versa*. Each fibre of the outer layers of the lens contains a nucleus, and these nuclei form a layer, the **nuclear layer**, on the surface of the lens. The nuclear layer is most distinct toward the circumference of the lens. The anterior surface of the lens is covered by a single layer of transparent, columnar, nucleated epithelial cells (*epithelium lentis*). At the equator these cells become elongated and their gradual transition into lens fibres can be traced.

FIG. 820.—The upper half of a sagittal section through the front of the eyeball. (Toldt.)

The *changes produced in the lens by age* are the following:

In the **fetus** its form is nearly spherical, its color of a slightly reddish tint, it is not perfectly transparent, and is so soft as to break down readily on the slightest pressure. A small branch from the arteria centralis retinae runs forward, as already mentioned, through the vitreous humor to the posterior part of the capsule of the lens, where its branches radiate and form a plexiform network, which covers its surface, and they are continuous around the margin of the capsule with the vessels of the pupillary membrane and with those of the iris.

In the **adult** the posterior surface is more convex than the anterior; it is colorless, transparent, firm in texture, and devoid of bloodvessels.

In **old age** it becomes flattened on both surfaces, slightly opaque, of an amber tint, and increases in density.

Vessels and Nerves of the Globe of the Eye.—The arteries of the globe of the eye are the short posterior ciliary, long posterior ciliary, and anterior ciliary arteries, and the arteria centralis retinae. They have been already described (p. 616).

The *ciliary veins* are seen on the outer surface of the choroid, and are named from their arrangement, the *venae vorticosae* (p. 1095). They converge to four or five equidistant trunks, which pierce the sclera midway between the margin of the cornea and the porus opticus. Another set of veins accompanies the anterior ciliary arteries and opens into the ophthalmic vein.

The Lymphatic Passages of the Eyeball.—The conjunctiva contains lymph vessels. The eyeball contains lymph spaces, but no lymph vessels. There are two sets of lymph spaces in the eyeball, the anterior and posterior. The **anterior lymph spaces** are the spaces of the cornea, of the iris, of the anterior chamber, and of the posterior chamber. The lymph from the intralamellar lymph spaces of the cornea enters the conjunctival lymphatics at the margin of the cornea. The lymph spaces of the iris open into the anterior chamber by the crypts of the iris, and at the margin of the iris join the spaces of Fontana. The aqueous humor fills the anterior and posterior chambers, but is furnished by the vessels in the posterior chamber; in part by the vessels of the ciliary body, and in part by the vessels of the posterior surface of the iris. The lymph passes by way of the pupil into the anterior chamber, and then is taken up by the spaces of Fontana, the canal of Schlemm, and the anterior ciliary veins.

The **posterior lymph spaces** are the hyaloid canal, the perichoroidal lymph space, the space of Ténon, the intervaginal space of the optic nerve, and the supravaginal space.

The **hyaloid canal** (Figs. 794 and 797) passes between the posterior surface of the lens and the optic disk. The hyaloid canal opens into the intervaginal space of the optic nerve. Between the sclera and the choroid is the **perichoroidal lymph space** (Fig. 820). It is around the choroid vessels and the *venae vorticosae*, and empties into Ténon's space by means of openings through the sclera about the *venae vorticosae*. **Ténon's space** (Figs. 794 and 795) is between the sclera and the capsule of Ténon. It receives lymph from the perichoroidal space, and empties into the supravaginal space.

The optic nerve (Fig. 811) has a sheath of dura and a sheath of pia, and between these sheaths is the **intervaginal lymph space**. It is divided by a prolongation of the cerebral arachnoid into a **subdural space** and a **subarachnoid space**, which empty into the corresponding spaces of the membranes of the brain. The **supravaginal space** is between the dural portion of the sheath of the optic nerve and a posterior prolongation of Ténon's capsule.¹

The Nerves of the Globe of the Eye.—The **long ciliary nerves** (*nn. ciliares longi*), two in number, are derived from the nasal branch of the ophthalmic, and the **short ciliary nerves** (*nn. ciliares breves*), twelve to fifteen in number, are derived from the ciliary or ophthalmic ganglion. Both the long and short ciliary nerves perforate the sclera in the neighborhood of the optic nerve (Fig. 801). They pass along the perichoroidal lymph space, forming a plexus which sends filaments to the choroidal vessels. In front of the Ciliary muscle they form a second plexus, and from it come branches which go to the Ciliary muscle and the muscle fibres and vessels of the iris, sclera, choroid, ciliary body, and iris (Fig. 808). The ciliary nerves supply the cornea. The circular fibres of the iris are innervated by the oculomotor nerve and the radial fibres by the sympathetic.

Applied Anatomy.—From a surgical point of view the cornea may be regarded as consisting of three layers: (1) Of an external epithelial layer, developed from the ectoderm, and continuous with the external epithelial covering of the rest of the body, and therefore its lesions resemble those of the epidermis; (2) of the cornea proper, derived from the mesoderm, and associated in its diseases with the fibrovascular structures of the body; and (3) the posterior elastic layer with its endothelium, also derived from the mesoderm and having the characters of a serous membrane, so that inflammation of it resembles inflammation of the other serous and synovial membranes of the body.

The *cornea* contains no bloodvessels, except at its periphery, where numerous delicate loops, derived from the anterior ciliary arteries, may be demonstrated on the anterior surface of the cornea. The rest of the cornea is nourished by lymph, which gains access to the proper substance of the cornea and the posterior layer through the spaces of Fontana (*spatia anguli iridis*). This lack of direct blood supply renders the cornea very apt to become inflamed in the cachectic and ill-nourished. In spite of the absence of bloodvessels, wounds of the cornea usually heal rapidly. A wound which penetrates the cornea opens the anterior chamber, and aqueous humor escapes. An ulcer may also open the anterior chamber. Through a wound or a perforated ulcer the papillary margin of the iris may prolapse. A trivial injury of the cornea is repaired by transparent tissue. A severe injury is repaired by fibrous tissue, and *opacity* results. A slight opacity resembling a cloud of gray smoke is called *nebula*; a more marked white opacity is called *leucoma*. In *abscess of the cornea* pus gravitates between the layers to the lower part of the cornea and the purulent collection assumes a crescentic shape (*onyx*). The *arcus senilis*, seen in the aged, is a condition of haziness or opacity at the corneal margin due to fatty degeneration of the tissues of the cornea. It signifies interference with the blood supply, because of senile degeneration of adjacent vessels. In cases of *trachoma* there is a peculiar affection of the cornea, called *pannus*, in which the anterior layers of the cornea become vascularized, and a rich network

¹ For the lymphatic channels of the eyeball see Deaver's Surgical Anatomy, vol. ii, p. 392.

of bloodvessels may be seen on the cornea; and in *interstitial keratitis* new vessels extend into the cornea, giving it a pinkish hue, to which the term *salmon patch* is applied. The cornea is richly supplied with nerves, derived from the ciliary nerves, which enter the cornea through the fore part of the sclera and form plexuses in the stroma, terminating between the epithelial cells by free ends or in corpuscles. In cases of *glaucoma* the ciliary nerves may be pressed upon as they course between the choroid and sclera (Fig. 800), and in consequence of the pressure upon them, the cornea, to which they are distributed, becomes anesthetic. When a scar forms on the cornea and the iris becomes adherent, the scar and the iris, and sometimes even the lens, may bulge forward from intraocular tension. This condition is *staphyloma of the cornea*. In conditions of impaired nutrition the cornea may be bulged forward by intraocular pressure. The line of least resistance is a little below the centre of the cornea, and it is bulged forward and strongly curved. This condition is known as *conical cornea*.

The sclera has very few bloodvessels and nerves. The bloodvessels are derived from the anterior ciliary, and form an open plexus in its substance. As they approach the corneal margin this arrangement is peculiar. Some branches pass through the sclera to the ciliary body; others become superficial and lie in the episcleral tissue, and form arches, by anastomosing with each other, some little distance behind the corneal margin. From these arches numerous straight vessels are given off, which run forward to the cornea, forming its marginal plexus. In *inflammation of the sclera and episcleral tissue* these vessels become conspicuous, and form a pinkish zone of straight vessels radiating from the corneal margin, commonly known as the *zone of ciliary injection*. In *inflammation of the iris and ciliary body*, this zone is present, since the sclera speedily becomes involved when these structures are inflamed. But in *inflammation of the cornea* the sclera is seldom much affected, though the cornea and sclera are structurally continuous. This would appear to be due to the fact that the nutrition of the cornea is derived from a different source from that of the sclera. The sclera may be *ruptured subcutaneously* without any laceration of the conjunctiva, and the rupture usually occurs near the corneal margin, where the tunic is thinnest. It may be complicated with lesions of adjacent parts—laceration of the choroid, retina, iris, or suspensory ligament of the lens—and is then often attended with hemorrhage into the anterior chamber, which masks the nature of the injury. In some cases the lens has escaped through the rent in the sclera, and has been found under the conjunctiva. *Wounds of the sclera*, if they do not perforate, usually heal readily. If they extend through the sclera they cause diminished tension, are always dangerous, and are often followed by inflammation, suppuration, and by sympathetic ophthalmia. The sclera may be weakened by injury, inflammation, etc., and the weakened portion may bulge from intraocular pressure, and even a healthy sclera may bulge from excessive intraocular pressure. According to its situation the lesion is known as *ciliary staphyloma*, *equatorial staphyloma*, or *posterior staphyloma*.

One of the functions of the *choroid* is to provide nutrition for the retina and to convey vessels and nerves to the ciliary body and iris. *Inflammation of the choroid* is therefore followed by grave disturbance in the nutrition of the retina, and is attended with early interference with vision. *Purulent choroiditis* is not confined to the choroid; the retina, the vitreous, and the entire uveal tract become involved, and even other structures may suffer. In its diseases it bears a considerable analogy to those which affect the skin, and, like it, is one of the places from which *melanotic sarcomata* may grow. These tumors contain a large amount of pigment in their cells, and grow only from those parts where pigment is naturally present. The *choroid* may be *ruptured* without injury to the other tunics, as well as participating in general injuries of the eyeball. In cases of uncomplicated rupture the injury is usually at its posterior part, and is the result of a blow on the front of the eye. It is attended by considerable hemorrhage, which for a time may obscure vision, but in most cases this is restored as soon as the blood is absorbed.

The *iris* is the seat of a malformation, termed *coloboma*, which consists in a deficiency or cleft, which in a great number of cases is clearly due to an arrest in development. In these cases it is found at the lower aspect, extending directly downward from the pupil, and the gap frequently extends through the choroid to the attachment of the optic nerve. In some rarer cases the gap is round in other parts of the iris, and is then not associated with any deficiency of the choroid. The *iris* is abundantly supplied with bloodvessels and nerves, and is therefore very prone to become *inflamed*. When inflamed, in consequence of the fact that the iris and ciliary body are continuous, and that their vessels communicate, *iritis* is usually associated with *cyclitis*, the disease being called *iridocyclitis*. And, in addition, inflammation of adjacent structures, the cornea and sclera, is apt to spread into the iris. The iris is covered with endothelium, and partakes of the character of a serous membrane, and, like these structures, is liable to pour out a plastic exudation when inflamed, and contract adhesions, either to the cornea in front (*synechia anterior*), or to the capsule of the lens behind (*synechia posterior*). In *iritis* the lens may become involved, and the condition known as *secondary cataract* may be set up. *Tumors* occasionally commence in the iris; of these, *cysts*, which are usually congenital and *sarcomatous tumors*, are the most common and require removal. *Gummata* are not infrequently found in this situation. In some forms of injury of the eyeball, as the impact of a spent shot, a flying cork, the rebound of a twig, or a blow with a whip, the iris may be *detached* from the Ciliary muscle, the amount of detach-

ment varying from the slightest degree to the separation of the whole iris from its ciliary connection.

The *Argyll-Robertson pupil* shows no reaction to light, but retains reaction to accommodation and vision remains good.

The *retina*, with the exception of its pigment layer, and its vessels is perfectly transparent, and is invisible when examined by the ophthalmoscope, so that its diseased conditions are recognized by its loss of transparency. In *retinitis*, for instance, there is more or less dense and extensive opacity of its structure, and not infrequently extravasations of blood into its substance. Hemorrhages may also take place into the retina from rupture of a bloodvessel without inflammation. In *optic neuritis*, *papillitis*, or *choked disk*, the ophthalmoscope shows increase in vascularity, and swelling and opacity of the nerve, which extend beyond the disk margins. Optic atrophy is apt to follow. (Fig. 821 shows a normal optic disk.) The *retina* may become displaced from effusion of serum between it and the choroid or by blows on the eyeball, or may occur without apparent cause in *progressive myopia*, and in this case the ophthalmoscope shows an opaque, tremulous cloud. *Glioma*, a form of sarcoma, and essentially a disease of early life, is occasionally met with in connection with the retina.

The *lens* has no bloodvessels, nerves, or connective tissue in its structure, and therefore is not subject to those morbid changes to which tissues containing these structures are liable. It does, however, present certain morbid or abnormal conditions of various kinds. Thus, variation in shape, absence of the whole or a part of the lens, and displacements are among its *congenital defects*. *Opacities* may occur from injury, senile changes, malnutrition, or errors in growth or development. An opacity of the capsule, of the lens, or of both, is known as a *cataract*. *Senile changes* may take place in the lens, impairing its elasticity and rendering it harder than in youth,

so that its curvature can only be altered to a limited extent by the Ciliary muscle. And, finally, the lens may be *dislocated* or displaced by blows upon the eyeball, and its relations to surrounding structures altered by adhesions or the pressure of newgrowths.

There are two particular regions of the eye which require special notice; one of these is known as the "filtration area," and the other as the "dangerous area." The *filtration area* is the circumcorneal zone immediately in front of the iris. Here are situated the cavernous spaces of Fontana, which communicate with the canal of Schlemm, through which the chief transudation of fluid from the eye is now believed to take place. The *dangerous area of the eye* is the region in the neighborhood of the ciliary body, and wounds or injuries in this situation are peculiarly dangerous; for inflammation of the ciliary body is liable to spread to many of the other structures of the eye, especially to the iris and choroid, which are intimately connected by nerve and vascular supplies. Moreover, wounds which involve the ciliary region are especially liable to be followed by sympathetic ophthalmia, in which destructive inflammation of one eye is excited by some irritation in the other.

Emmetropia is normal vision. In normal vision the practically parallel light rays from distant objects focus on the retina without effort; divergent rays from near objects are focussed on the retina by an effort of accommodation.

Hyperopia or *hypermetropia* is far-sightedness. In this condition the retina is in front of the principal focus when the eye is at rest. The patient endeavors to correct the failure by constant

and tiresome efforts at accommodation. The condition is usually due to inordinate shortness of the axis of the eye, but may be due to loss of the lens, decreased convexity of the refractive surfaces, or lessened refractive power in the refractive media of the eye. It is corrected by the use of convex glasses.

Myopia is near-sightedness. In this condition the rays of light come to a focus in front of the retina, and the patient is subjected to continued eye-strain. It is usually due to too great length of the axis of the eye, but may result from increase in refractive power of refractive media. It is corrected by concave glasses. Sometimes, as a person with hyperopia begins to age, an increased refractive power of the lens causes myopia. The occurrence of myopia in a hyperopic eye is called *second sight*, and it enables the individual to cease wearing convex glasses.

Exenteration of the contents of the orbit means removal of all the contents except those at the orbital apex. Even the periosteum is taken away. It is performed for malignant disease.

Evisceration of the eyeball is performed by making a circular incision at the corneal margin and removing the internal and middle coats and the contents of the globe. The sclera is not removed. A glass ball is inserted into the scleral sheath, and the sclera is closed over the ball by vertical stitches, and the conjunctiva is closed over it by transverse stitches. The operation is performed for leucoma or staphyloma of the cornea. An artificial eye (a shell) is placed over the stump when healing is complete.

Enucleation, or excision of the eyeball, differs from *exenteration of the orbital contents* in the fact that only the eyeball is removed. A circular incision through the ocular conjunctiva is carried around and near to the corneal margin. The conjunctiva and capsule of Ténon are pushed back and the Rectus muscles are clamped and divided back of the clamp. Traction is made upon the globe in a forward and inward direction, and the optic nerve and adjacent structures are cut with scissors from the outer aspect of the globe. The eye is then pulled out of the orbit, and all structures which tend to retain it are divided. The stumps of the Recti muscles are sewed together.

THE APPENDAGES OF THE EYE (ORGANA OCULI ACCESSORIA).

The appendages of the eye include the **eyebrows**, the **eyelids**, the **conjunctiva**, and the **lacrimal apparatus**—viz., the **lacrimal gland**, the **lacrimal sac**, and the **nasal duct**.

The **Eyebrows** (*supercilia*) are two arched eminences of integument which surmount the upper circumference of the orbit on each side, and support numerous short, thick hairs, directed obliquely on the surface. The hairs may entangle foreign bodies and lessen somewhat the force of blows. In structure the eyebrows consist of thickened integument, connected beneath with the Orbicularis palpebrarum, Corrugator supercilii, and Occipitofrontalis muscles. These muscles serve, by their action on this part, to control to a certain extent the amount of light admitted into the eye.

The **Eyelids** (*palpebrae*) (Figs. 823 and 824) are two thin, movable folds placed in front of the eye, and protecting it from injury by their closure. The eyelids are composed of skin, superficial fascia, and areolar tissue, fibres of the Orbicularis palpebrarum muscle, palpebral and orbitotarsal ligaments, tarsal plates, and conjunctiva. The upper lid also contains the Levator palpebrae superioris muscle. In the lids are bloodvessels, lymph vessels, nerves, and Meibomian glands. There are two lids, the **upper** (*palpebra superior*) and the **lower** (*palpebra inferior*); the groundwork of both lids is made up of a fascial membrane called the **orbital septum** (*septum orbitale*). The upper lid is the larger and the more movable of the two, and is furnished with a separate elevator muscle, the **Levator palpebrae superioris**. The orbital septum, in each lid, consists of two portions. The part near the orbital margin is called the **orbital portion** (*pars orbitalis*). The part in which the tarsus lies is called the **tarsal portion** (*pars tarsalis*). Between the two portions in each lid is a sulcus, called, in the upper lid, the **superior orbitopalpebral sulcus** (*sulcus orbitopalpebralis superior*), and, in the lower lid, the **inferior orbitopalpebral sulcus** (*sulcus orbitopalpebralis inferior*). When the eyelids are opened an elliptical space, the **interpallpebral slit** (*rima palpebrarum*), is left between

their margins, the angles of which correspond to the junction of the upper and lower lids, and are called **canthi**.

The **outer canthus** (*commissura palpebrarum lateralis*) is more acute than the inner, and the lids here lie in close contact with the globe; but the **inner canthus** (*commissura palpebrarum medialis*) is prolonged for a short distance inward toward the nose, and the two lids are separated at the inner canthus by a triangular space, the **lacus lacrimalis**. At the commencement of the lacus lacrimalis, on the margin of each eyelid, is a small conical elevation, the **lacrimal papilla**, the apex of which is pierced by a small orifice, the **punctum lacrimale** (Fig. 828), the commencement of the lacrimal canal (Fig. 826). When the lids are closed a space remains between them and the globe to permit of the flow of tears inward (*rivus lacrimalis*).

The **Eyelashes** (*cilia*) (Fig. 824) are attached to the free edges of the eyelids; they are short, thick, curved hairs, arranged in a double or triple row at the margin of the lids; those of the upper lid, more numerous and longer than the lower, curve upward; those of the lower lid curve downward. Because of this arrangement the two sets do not interlace in closing the lids. Near the attachment of the eyelashes are the openings of **sebaceous glands** (*glandulae sebaceae*) (Fig. 824) and of a number of glands, **glands of Moll** (*glandulae ciliares [Molli]*) (Fig. 824), arranged in several rows close to the free margin of the lid. They are regarded as enlarged and modified sweat glands.

FIG. 823.—The tarsi and their ligaments. Right eye, front view. (Testut.)

Structure of the Eyelids (Fig. 784).—The eyelids are composed of the following structures, taken in their order from without inward: Integument, areolar tissue, fibres of the Orbicularis muscle, tarsal plate, and its ligament, Meibomian glands, and conjunctiva. The upper lid has, in addition, the aponeurosis of the Levator palpebrae, while both lids contain a certain amount of nonstriated muscle, called, respectively, the **Superior** and **Inferior tarsal muscles** (see p. 369) (Fig. 794). The **integument** is extremely thin, and continuous at the margin of the lids with the conjunctiva. The **subcutaneous areolar tissue** is very lax and delicate, seldom contains any fat, and is extremely liable to serous infiltration. The **Palpebral fibres of the Orbicularis muscle** (*m. ciliaris [Riolani]*) are thin, pale in color, and possess an involuntary action.

The **tarsal plates** (Fig. 823) are two thin elongated wedge-shaped plates of dense connective tissue about 2.5 cm. (an inch) in length. They are placed one in each lid, beneath the conjunctival surface, contributing to their form and support. The **superior tarsal plate**, **superior tarsus**, or **superior tarsal body** (*tarsus superior*) (Fig. 823), the larger, is of a semilunar form, about 8 mm. (one-third of an inch) in breadth at the centre, and becoming gradually narrowed at each extremity. To the anterior surface of this plate the aponeurosis of the Levator palpebrae is attached. The **inferior tarsal plate**, **inferior tarsus**, or **inferior tarsal body** (*tarsus inferior*)

(Fig. 823), the smaller of the two, is thinner and of an elliptical form. The **free or ciliary margin** of these plates is thick, and presents a perfectly straight edge. The **attached or orbital margin** is connected to the circumference of the orbit by the fibrous membrane of the lids, with which it is continuous. The outer angle of each plate is attached to the malar bone by the **external tarsal ligament** (*ligamentum palpebralis lateralis*) (Fig. 823). The inner angles of the two plates terminate at the commencement of the lacus lacrimalis; they are attached to the nasal process of the superior maxilla by the **internal tarsal ligament** or the **tendo oculi** (*ligamentum palpebrale mediale*) (Fig. 823). In reality these so-called ligaments are fascial expansions situated one in each lid, and are attached marginally to the edge of the orbit, where they are continuous with the periosteum. The superior ligament blends with the tendon of the Levator palpebrae, the inferior with the inferior tarsal plate. Externally, the superior and inferior ligaments fuse to form the external tarsal ligament just referred to; internally they are much thinner, and, becoming separated from the internal tarsal ligament, are fixed to the lacrimal bone immediately behind the lacrimal sac. The whole fascial sheet spanning the orbit, and reinforced by these ligaments, constitutes the **orbital septum** (*septum orbitale*), which is perforated by the vessels and nerves which pass from the orbital cavity to the face and scalp.

FIG. 824.—Vertical section through the upper eyelid. *a*. Skin. *b*. Orbicularis palpebrarum. *c*. Marginal fasciculus of Orbicularis (ciliary bundle). *d*. Levator palpebrae. *e*. Conjunctiva. *f*. Tarsal plate. *g*. Meibomian gland. *h*. Sebaceous gland. *i*. Eyelashes. *j*. Small hairs of skin. *k*. Sweat-glands. *l*. Posterior tarsal glands. (After Waldeyer.)

The **Meibomian or Tarsal Glands** (*glandulae tarsales* [*Meibomi*]) (Figs. 824 and 826) are situated in the tarsal plates, and may be distinctly seen through the conjunctiva on everting the eyelids, presenting the appearance of parallel strings of pearls. They are about thirty in number in the upper eyelid, and somewhat fewer in the lower. They correspond in length with the breadth of each plate, and are, consequently, longer in the upper than in the lower eyelid. Their ducts open on the free margin of the lids by minute foramina, which correspond in number to the follicles. The use of their secretion is to prevent adhesions of the lids.

Structure.—These glands are a variety of the cutaneous sebaceous glands, each consisting of a single straight tube or duct, having a cecal termination, and with numerous small alveoli opening into it. The tubes consist of basement membrane, lined at the mouths of the tubes by

stratified epithelium; the deeper parts of the tubes and the alveoli are filled with polyhedral cells. They are thus identical in structure with the sebaceous glands.

The **Conjunctiva** (Figs. 825 and 826) is the mucous membrane of the eye. It lines the inner surface of the eyelids, is reflected over the fore part of the sclera and cornea, and joins the lids to the eyeball. In each of these situations its structure presents some peculiarities.

The **palpebral portion** (*tunica conjunctiva palpebrarum*) (Fig. 826) of the conjunctiva lines the posterior surface of the lids. It is thick, opaque, highly vascular, and covered with numerous papillae, its deeper parts presenting a considerable amount of lymphoid tissue. At the margins of the lids it becomes continuous

with the lining membrane of the ducts of the Meibomian glands, and, through the lacrimal canals, with the lining membrane of the lacrimal sac and nasal duct. At the outer angle of the upper lid the lacrimal ducts open on its free surface; and at the inner angle of the eye it forms a semilunar fold, the *plica semilunaris* (*plica semilunaris conjunctivae*) (Fig. 828). The folds formed by the reflection of the conjunctiva from the lids on to the eye are called the **superior and inferior palpebral folds**, the former being the deeper of the two. These folds form the **superior and inferior conjunctival fornix** (Fig. 825).

The Bulbar Portion (*tunica conjunctiva bulbi*).—Upon the sclera the conjunctiva is loosely connected to the globe; it becomes thinner, loses its papillary structure, is transparent, and only slightly vascular in health. Upon the *cornea* the conjunctiva consists only of epithelium, constituting the anterior layer of the cornea (conjunctival epithelium) already described (p. 1093). Lymphatics arise in the conjunctiva in a delicate zone around the cornea, from which the vessels run to the ocular conjunctiva.

Fornices of Conjunctiva.—At the line of reflection of each fold of the conjunctiva from each lid on to the globe of the eye a pocket or arch is formed. These arches are termed the **fornices conjunctivae**, **superior and inferior** (Fig. 825).

Glands of Conjunctiva.—In the conjunctiva there are a number of mucous glands which are much convoluted. They are chiefly found in the upper lid. Other glands, analogous to lymphoid follicles, and called by Henle **trachoma glands**, are found in the conjunctiva, and, according to Stromeyer, are chiefly situated near the inner canthus of the eye. They were first described by Brush, who, in his description of Peyer's patches of the small intestines, called them "identical with structures existing in the under eyelid of the ox."

The **caruncula lacrimalis** is a small, reddish, conical-shaped body, situated at the inner canthus of the eye, and filling up the small triangular space in this situation, the **lacus lacrimalis**. It consists of an island of skin containing sebaceous and sweat glands, and is the source of the whitish secretion which constantly collects at the inner angle of the eye. A few slender hairs are attached to its surface. On the outer side of the caruncula is a slight semilunar fold of conjunctiva, the concavity of which is directed toward the cornea; it is called the **plica semilunaris** (Fig. 828). Müller found smooth muscle fibres in this fold, and in some of the domesticated animals a thin plate of dense white fibrous tissue has been discovered. This structure is considered to be the rudiment of the third eyelid in birds, the **membrana nictitans**.

The **nerves** in the conjunctiva are numerous and form rich plexuses. According to Krause they terminate in a peculiar form of tactile corpuscle, the "terminal bulb."

The **Lacrimal Apparatus** (*apparatus lacrimalis*) (Figs. 826 and 828) consists of the lacrimal gland, which secretes the tears, and its excretory ducts, which convey the fluid to the surface of the eye. This fluid is carried away by the lacrimal canals into the lacrimal sac, and along the nasal duct into the cavity of the nose.

The **Lacrimal Gland** (*glandula lacrimalis*) is lodged in a depression at the outer angle of the orbit, on the inner side of the external angular process of the frontal bone. It is of an oval form, about the size and shape of an almond. Its upper convex surface is in contact with the periosteum of the orbit, to which it is connected by a few fibrous bands. Its under concave surface rests upon the convexity of the eyeball and upon the Superior and External recti muscles. Its vessels and nerves enter its posterior border, while its anterior margin is closely adherent

FIG. 825.—Sagittal section of eye, showing superior and inferior fornices of the conjunctiva. (Testut.)

to the back part of the upper eyelid, where it is covered to a slight extent by the reflection of the conjunctiva. The fore part of the gland is separated from the rest by a fibrous septum; hence it is sometimes described as a separate lobe, called the **inferior lacrimal gland** (*glandula lacrimalis inferior*), the back part of the gland then being called the **superior lacrimal gland** (*glandula lacrimalis superior*). The ducts of the lacrimal gland, from six to twelve in number, run obliquely beneath the mucous membrane for a short distance, and, separating from each other, open by a series of minute orifices on the upper and outer half of the conjunctiva near its reflection on to the globe. These orifices are arranged in a row, so as to disperse the secretion over the surface of the membrane.

FIG. 826.—The Meibomian glands, etc., seen from the inner surface of the eyelids.

Structure.—In structure and general appearance the lacrimal resembles the serous salivary glands. In the recent state the cells are so crowded with granules that their limits can hardly be defined. Each cell contains an oval nucleus, and the cell protoplasm is finely fibrillated.

The **Lacrimal Canals** (Fig. 828) commence at the minute orifices, **puncta lacrimalia**, on the summit of small conical elevations, the **lacrimal papillæ** (*papillæ lacrimalis*), seen on the margin of the lids at the outer extremity of the lacus lacrimalis. The **superior canal** (*ductus lacrimalis superior*), the smaller and shorter of the two, at first ascends, and then bends at an acute angle, and passes inward and downward to the ampulla of the lacrimal sac. The **inferior canal** (*ductus lacrimalis inferior*) at first descends, and then passes almost horizontally inward to the ampulla. These canals are dense and elastic in structure and somewhat dilated at their angles.

FIG. 827.—Alveoli of lacrimal gland.

The mucous membrane is covered with stratified epithelium upon a basement membrane. Outside the latter is a layer of striped muscle continuous with the Tensor tarsi. The two canals join in a dilatation, the **ampulla** (*ampulla ductus lacrimalis*), which empties into the lacrimal sac.

The **Lacrimal Sac** (*saccus lacrimalis*) (Fig. 828) is the upper dilated extremity of the nasal duct, and is lodged in a deep groove formed by the lacrimal bone and the nasal process of the maxilla bone. It is oval in form, its upper extremity being closed in and rounded, while below it is continued into the nasal duct. It is covered by a fibrous expansion derived from the tendo oculi, and on its deep

surface it is crossed by the Tensor tarsi muscle (Horner's muscle, p. 367), which is attached to the ridge on the lacrimal bone.

Structure.—The lacrimal sac consists of a fibrous elastic coat, lined internally by mucous membrane, the latter being continuous, through the ampulla and lacrimal canals, with the mucous lining of the conjunctiva, and, through the nasal duct, with the mucous membrane of the nose.

The **Nasal Duct** (*ductus nasolacrimalis*) (Fig. 828) is a membranous canal, about 2 cm. (three-quarters of an inch) in length, which extends from the lower part of the lacrimal sac to the inferior meatus of the nose, where it terminates by a somewhat expanded orifice, provided with an imperfect valve, the **valve of Hasner** (*plica lacrimalis* [Hasneri]), formed by a fold of mucous membrane. It is contained in an osseous canal formed by the maxilla, the lacrimal, and the turbinated bones, is narrower in the middle than at each extremity, and takes a direction downward, backward, and a little outward. It is lined by mucous membrane, which is continuous below with that of the nose. The membrane in the lacrimal sac and nasal duct is covered with columnar epithelium, as in the nose; this epithelium is in places ciliated.

FIG. 828.—The lacrimal apparatus. Right side.

Surface Form.—The *palpebral fissure*, or opening between the eyelids, is elliptic in shape, and differs in size in different individuals and in different races of mankind. In the Mongolian races, for instance, the opening is very small, merely a narrow fissure, and this makes the eyeball appear small in these races, whereas the size of the eye is relatively very constant. The normal direction of the fissure is slightly oblique, in a direction upward and outward, so that the outer angle is on a slightly higher level than the inner. This is especially noticeable in the Mongolian races, in whom, owing to the upward projection of the malar bone and the shortness of the external angular process of the frontal bone, the tarsal plate of the upper lid is raised at its outer part and gives an oblique direction to the palpebral fissure. When the eyes are directed forward, as in ordinary vision, the upper part of the cornea is covered by the upper lid, and the lower margin of the cornea corresponds to the level of the lower lid, so that about the lower three-fourths of the cornea is exposed under ordinary circumstances.

On the margin of the lids, about 1 cm. from the inner canthus, are two small openings, the *puncta lacrimalia*, the commencement of the lacrimal canals. They are best seen by everting the eyelids. In the natural condition they are in contact with the conjunctiva of the eyeball, and are maintained in this position by the *Tensor tarsi muscle*, so that the tears running over the surface of the globe easily find their way into the lacrimal canals. The position of the *lacrimal sac* into which the canals open is indicated by a little tubercle, which is plainly to be felt on the lower margin of the orbit. The lacrimal sac lies immediately above and to the inner side of this tubercle, and a knife passed through the skin in this situation would open the cavity. The position of the lacrimal sac may also be indicated by the *tendo oculi* or *internal tarsal ligament*. If both lids be drawn outward, so as to tighten the skin at the inner angle, a prominent cord will be seen beneath the tightened skin. This is the *tendo oculi*, which lies immediately over the lacrimal sac, bisecting it, and thus forming a useful guide to its situation. A knife entered immediately beneath the tense cord would open the lower part of the sac. A probe introduced through this opening can be readily passed downward through the duct into the inferior meatus of the nose. The direction of the duct is downward, outward, and backward, and this course should be borne in mind in passing the probe, otherwise the point may be driven through the thin bony walls of the canal. A convenient plan is to direct the probe in such a manner that if it were pushed onward it would strike the first molar tooth of the lower jaw on the same side of the body. In other words, the surgeon standing in front of his patient should carry in his mind the position of

the first molar tooth, and should push his probe onward in such a way as if he desired to reach this structure.

Beneath the internal angular process of the frontal bone the pulley of the *Superior oblique muscle* of the eye can be plainly felt by pushing the finger backward between the upper and inner angle of the eye and the roof of the orbit; passing backward and outward from this pulley, the tendon can be felt for a short distance.

Applied Anatomy.—The eyelids are composed of various tissues, and consequently are liable to a variety of diseases. The skin which covers them is exceedingly thin and delicate, and is supported on a quantity of loose and lax subcutaneous tissue which contains no fat. In consequence of this it is very freely movable, and is liable to be drawn down by the contraction of neighboring cicatrices. Such contractions may produce an eversion of the lid known as *ectropion*. Inversion of the lids (*entropion*) from spasm of the *Orbicularis palpebrarum* or from chronic inflammation of the palpebral conjunctiva may also occur. In some individuals there is an extra row of eyelashes on the inner margin of the lid, directed toward the cornea (*distichiasis*). *Trichiasis* is a condition in which the lashes are directed toward the eye, but there is not inversion of the lid. The eyelids are richly supplied with blood, and are often the seat of vascular growths, such as *naevi*. *Rodent ulcer* also frequently commences in this situation. The loose cellular tissue beneath the skin is liable to become extensively infiltrated either with blood or inflammatory products, producing very great swelling. Even from very slight injuries to this tissue the extravasation of blood may be so great as to produce considerable swelling of the lids and complete closure of the eye, and the same is the case when the inflammatory products are poured out. The follicles are liable to become inflamed, constituting the disease known as *marginal blepharitis*, *blepharitis ciliaris*, or "*blear-eye*." Irregular or disorderly growth of the eyelashes not infrequently occurs, some of them being turned toward the eyeball and producing inflammation and follicles of the eyelashes, or the sebaceous glands associated with these follicles may be the seat of inflammation, constituting the ordinary *hordeolum* or "*sty*." The Meibomian glands are affected in the so-called "*tarsal tumor*," the tumor, according to some, being caused by the retained secretion of these glands; by others it is believed to be a neoplasm connected with the gland. The *Orbicularis palpebrarum* may be the seat of *spasm* (*blepharospasm*), either in the form of slight quivering of the lids or repeated twitchings, most commonly due to errors of refraction in children, or more continuous spasm, due to some irritation of the trigeminal or facial nerves. The *Orbicularis* may be *paralyzed*, generally associated with paralysis of the other facial muscles. Under these circumstances the patient is unable to close the lids, and if he attempts to do so, rolls the eyeball upward under the upper lid. The tears overflow from displacement of the lower lid, and the conjunctiva and cornea, being constantly exposed and the patient being unable to wink, become irritated from dust and foreign bodies. As a result there may be ulceration of the cornea, and possibly eventually complete destruction of the eye. In *paralysis of the Levator palpebrae superioris* there is drooping of the upper eyelid (*ptosis*), and other symptoms of implication of the oculomotor nerve. The eyelids may be the seat of *bruises*, *wounds*, or *burns*. After wounds or burns adhesions of the margins of the lids to each other or adhesion of the lids to the globe may take place. The eyelids are sometimes the seat of *emphysema* after fracture of some of the thin bones forming the inner wall of the orbit. If shortly after such an injury the patient blows his nose, air is forced from the nostrils through the lacerated structure into the connective tissue of the eyelids, which suddenly swell up and present the peculiar crackling on pressure which is characteristic of this affection.

Foreign bodies frequently get into the *conjunctival sac* and cause great pain, especially if they come in contact with the corneal surface, during the movements of the lid and the eye on each other. The conjunctiva is frequently involved in severe injuries of the eyeball, but is seldom ruptured alone; the most common form of injury to the conjunctiva alone is from a *burn*, either from fire, strong acids, or lime. In these cases the union is apt to take place between the eyelid and the eyeball. The conjunctiva is often the seat of *inflammation* arising from many different causes, and the arrangement of the conjunctival vessels should be remembered as affording a means of diagnosis between this condition and injection of the sclera, which is present in inflammation of the deeper structures of the globe. The inflamed conjunctiva is bright red; the vessels are large and tortuous, and greatest at the circumference, shading off toward the corneal margin; they anastomose freely and form a dense network, and they can be emptied by gentle pressure.

The *lacrimal gland* is occasionally, though rarely, the seat of *inflammation* (*dacryoadenitis*), either acute or chronic; it is also sometimes the seat of *tumors*, benign or malignant, and for these may require removal. This may be done by an incision through the skin just below the eyebrow; and the gland, being invested with a special capsule of its own, may be isolated and removed without opening the general cavity of the orbit. The *canals* may be *obstructed*, either as a congenital defect or by some foreign body, as an eyelash or a dacryolith, causing the tears to run over the cheek. The canals may also become occluded as the result of *burns* or *injury*; overflow of tears may, in addition, result from *deviation of the puncta* or from chronic inflammation of the lacrimal sac. When there is failure of the lacrimal tubes to drain off the tears and the

fluid gathers beneath and flows over the lids, the condition is known as *epiphora* or *stillicidium*. This latter condition is set up by some *obstruction to the nasal duct* frequently occurring in tuberculous subjects. In consequence of this the tears and mucus accumulate in the lacrimal sac, distending it. *Suppuration in the lacrimal sac (dacryocystitis)* is sometimes met with; this may be the sequel of a chronic inflammation; or may occur after some of the eruptive fevers in cases where the lacrimal passages were previously quite healthy. It may lead to *lacrimal fistula*.

THE EAR (ORGANON AUDITUS).

The organ of hearing is divisible into three parts—the **external ear**, the **middle ear** or **tympanum**, and the **internal ear** or **labyrinth**.

THE EXTERNAL EAR (AURIS EXTERNA).

The external ear consists of an expanded portion named **pinna** or **auricula**, and the **auditory canal** or **meatus**. The former serves to collect the vibrations of the air by which sound is produced; the latter conducts those vibrations to the tympanum.

FIG. 829.—The right pinna, viewed from without. (Spalteholz.)

The **Pinna**, or **Auricula** (Fig. 829), is attached to the side of the head midway between the forehead and occiput. It is of an ovoid form, with its larger end directed upward. Its *outer surface* is irregularly concave, directed slightly forward, and presents numerous eminences and depressions which result from the foldings of its fibrocartilaginous element. To each of these, names have been assigned. Thus, the external prominent rim of the auricle is called the **helix**. Another curved prominence, parallel with and in front of the helix, is called the

antihelix; this bifurcates above and forms the **crura** (*crura antheliceis*), which enclose a triangular depression, the **fossa of the antihelix** (*fossa triangularis [auriculæ]*). The narrow curved depression between the helix and antihelix is called the **fossa of the helix** or the **scaphoid fossa** (*scapha*); the antihelix describes a curve

FIG. 830.—The cartilage of the right pinna, isolated, with the muscles, viewed from the inside. (Spalteholz.)

around a deep, capacious cavity, the **concha auriculæ**, which is partially divided into two parts by the **crus of the helix** (*crus heliceis*), or the commencement of the helix; the upper part is termed the **cymba conchæ**, the lower part the **cavum conchæ**. In front of the concha, and projecting backward over the meatus, is a small pointed eminence, the **tragus**, so called from its being generally covered on its under surface with a tuft of hair resembling a goat's beard. Opposite the tragus, and separated from it by a deep notch (*incisura intertragica*), is a small tubercle, the **antitragus**. Below this is the **lobule** (*lobulus auricu-*

lae), composed of tough areolar and adipose tissue, wanting the firmness and elasticity of the rest of the pinna. Sometimes the lobule does not hang freely, but is adherent.

Where the helix turns downward a small tubercle, **tubercle of Darwin** (*tuberculum auriculæ [Darwini]*), is frequently seen. This tubercle is very evident about the sixth month of fetal life; at this stage the human pinna has a close resemblance to that of some of the adult monkeys.

The **cranial surface** of the pinna presents elevations which correspond to the depressions on its outer surface and after which they are named, *e. g.*, **eminentia conchæ**, **eminentia fossæ triangularis**, etc.

Structure.—The pinna is composed of a thin plate of yellow fibrocartilage, covered with integument and connected to the surrounding parts by the extrinsic ligaments and muscles, and to the commencement of the external auditory canal by fibrous tissue.

The **integument** is thin, closely adherent to the cartilage, and covered with hairs furnished with sebaceous glands which are most numerous in the concha and scaphoid fossa. The hairs are most numerous and largest on the tragus and antitragus.

The **cartilage of the pinna** (*cartilago auriculæ*) (Fig. 831) consists of one single piece; it gives form to this part of the ear, and upon its surface are found all the eminences and depressions above described. It does not enter into the construction of all parts of the pinna; thus, it does not form a constituent part of the lobule; it is deficient also between the lamina of the tragus and beginning of the crus helix, the notch between them (*incisura terminalis auris*) being filled up by dense fibrous tissue. At the front part of the pinna, where the helix bends upward, is a small projection of cartilage, called the **spine of the helix** (*spina heliceis*), while the lower part of the helix is prolonged downward as a tail-like process, the **cauda heliceis**; this is separated from the antihelix by a fissure, the **fissura antitragohelicina**. The cranial aspect of the cartilage

FIG. 831.—The right ear cartilage, isolated, viewed from without. (Spalteholz.)

exhibits a transverse furrow, the *sulcus antihelicis transversus*, which separates the prominence produced by the concha from that caused by the fossa triangularis. A vertical ridge (*pon-ticulus*) upon the eminentia conchae gives attachment to the Retrahens aurem muscle. The fissure of the helix is a short vertical slit, situated at the fore part of the pinna. Another fissure, the *fissure of the tragus*, is seen upon the anterior surface of the tragus. Anteriorly and inferiorly the cartilage of the pinna is continuous with the cartilage of the external auditory meatus by a *cartilaginous isthmus* (*isthmus cartilaginis auris*). Some authors regard the tragus as part of the cartilage of the meatus. The cartilage of the pinna is very pliable, elastic, of a yellowish color, and belongs to that form of cartilage which is known under the name of yellow fibrocartilage.

The *ligaments* of the pinna (*ligamenti auricularia* [Valsalva]) consist of two sets: 1. The *extrinsic* set, or those connecting it to the side of the head. 2. The *intrinsic* set, or those connecting the various parts of its cartilage together. The *extrinsic ligaments*, the most important, are three in number—*superior*, *anterior*, and *posterior*. The *superior ligament* (*ligamentum auriculare superius*) extends from the suprameatal spine to the spine of the helix. The *anterior ligament* (*ligamentum auriculare anterius*) extends from the spina helicis and tragus to the root of the zygoma. The *posterior ligament* (*ligamentum auriculare posterius*) passes from the posterior surface of the concha to the outer surface of the mastoid process of the temporal bone. The chief *intrinsic ligaments* are: (1) A strong fibrous band stretching across from the tragus to the commencement of the helix, completing the meatus in front, and partly encircling the boundary of the concha; and (2) a band which extends between the antihelix and the cauda helicis. Other less important bands are found on the cranial surface of the pinna.

The *muscles* of the pinna (Figs. 830 and 832) consist of two sets: (1) The *extrinsic*, which connect it with the side of the head, moving the pinna as a whole—viz., the Attollens, Attrahens, and Retrahens aurem (p. 366). (2) The *intrinsic*, which extend from one part of the auricle to another—viz.:

Helicis major.
Helicis minor.
Tragicus.

Antitragicus.
Transversus auriculae.
Obliquus auriculae.

The *Helicis major* (*m. helicis major*) is a narrow vertical band of muscle fibres, situated upon the anterior margin of the helix. It arises, below, from the spina helicis, and is inserted into the anterior border of the helix, just where it is about to curve backward.

The *Helicis minor* (*m. helicis minor*) is an oblique fasciculus which covers the crus helicis.

The *Tragicus* (*m. tragicus*) is a short, flattened band of muscle fibres situated upon the outer surface of the tragus, the direction of its fibres being vertical.

The *Antitragicus* (*m. antitragicus*) arises from the outer part of the antitragus; its fibres are inserted into the cauda helicis and antihelix. This muscle is usually very distinct.

The *Transversus auriculae* (*m. transversus auriculae*) is placed on the cranial surface of the pinna. It consists of scattered fibres, partly tendon and partly muscle, extending from the convexity of the concha to the prominence corresponding with the groove of the helix.

The *Obliquus auriculae* (Tod) (*m. obliquus auriculae*) consists of a few fibres extending from the upper and back part of the concha to the convexity immediately above it.

The *arteries of the pinna* are the posterior auricular from the external carotid, the anterior auricular from the temporal, and an auricular branch from the occipital artery. The *veins* of the pinna accompany the corresponding arteries. The

FIG. 832—The muscles of the pinna.

lymphatics enter into the preauricular nodes and the nodes upon the Sternomastoid muscle at its insertion. The **nerves** of the pinna are the great auricular, from the cervical plexus; the auricular branch of the vagus; the auriculotemporal branch of the inferior maxillary nerve; the small occipital from the cervical plexus, and the great occipital or internal branch of the dorsal division of the second cervical nerve. The muscles of the pinna are supplied by the facial nerve.

The **Auditory Canal**, or **Meatus** (*meatus acusticus externus*), extends from the bottom of the concha to the membrana tympani (Figs. 833 and 834). It is about 3.7 cm. (an inch and an half) in length if measured from the tragus; from the bottom of the concha its length is about 2.5 cm. (an inch). It forms a sort of S-shaped curve, and is directed at first inward, forward, and slightly upward (*pars externa*); it then passes inward and backward (*pars media*), and lastly is carried inward, forward, and slightly downward (*pars interna*). It forms an oval cylindrical canal, the greatest diameter being in the vertical direction at the external orifice,

FIG. 833.—Transverse section of external auditory meatus and tympanum. Left side. (Gegenbaur.)

but in the transverse direction at the tympanic end. It presents two constrictions, one near the inner end of the cartilaginous portion, and another, the **isthmus**, in the osseous portion, about 2 cm. (three-quarters of an inch) from the bottom of the concha. The **membrana tympani** (Figs. 833 and 834), which closes the inner end of the meatus, is directed obliquely, in consequence of which the floor of the canal is longer than the roof, and the anterior wall longer than the posterior. The auditory canal is formed

partly by cartilage and membrane, partly by bone, and is lined by perichondrium and periosteum, which is covered with skin.

The **cartilaginous portion** (*meatus acusticus externus cartilagineus*) is about 8 mm. (one-third of an inch) in length; it is formed by the cartilage of the pinna, prolonged inward, and firmly attached to a greater portion of the circumference of the auditory process of the temporal bone. The cartilage is deficient at its upper and back part, its place being supplied by a fibrous membrane. This part of the canal is rendered extremely movable by two or three deep fissures, the **fissures of Santorini** (*incisurae cartilaginis meatus acustici externi* [Santorini]), which extend through the cartilage in a vertical direction.

The **osseous portion** (*meatus acusticus externus osseus*) is about 16 mm. (two-thirds of an inch) in length, and narrower than the cartilaginous portion. It is directed inward and a little forward, forming a slight curve in its course, the convexity of which is upward and backward. Its inner end, which communicates, in the dry bone, with the cavity of the tympanum, is smaller than the outer and sloped, the anterior wall projecting beyond the posterior about 4 mm. (one-sixth of an inch); it is marked, except at its upper part, by a narrow groove, the **tympanic sulcus** (*sulcus tympanicus*), in which the circumferential margin of the membrana tympani is attached. Its outer edge is dilated and rough in the greater part of its circumference, for the attachment of the cartilage of the pinna. Its transverse section is oval, the greatest diameter being from above downward and backward. The front and lower parts of this canal are formed by a curved plate of bone,

the tympanic plate, which, in the fetus, exists as a separate ring (*annulus tympanicus*), incomplete at its upper part. (See Section on Osteology, p. 87.)

The skin lining the meatus is very thin, adheres closely to the cartilaginous and osseous portions of the tube, and covers the surface of the membrana tympani, forming a very thin outer layer. After maceration the thin pouch of epidermis, when withdrawn, preserves the form of the meatus. In the thick subcutaneous tissue of the cartilaginous part of the meatus are numerous **ceruminous glands** (*glandulae ceruminosae*) which secrete the *ear wax* or *cerumen*. They resemble in structure sweat glands, and their ducts open on the surface of the skin.

FIG. 834.—Vertical section through the external auditory meatus and tympanum, passing in front of the fenestra ovalis. (Testut.)

Relations of the Meatus.—In front of the osseous part is the *glenoid fossa*, which receives the condyle of the mandible (Fig. 825), which, however, is separated from the cartilaginous part by the retromandibular part of the *parotid gland*. The movements of the mandible influence to some extent the lumen of the cartilaginous portion. Behind the osseous part are the *mastoid air cells* (*cellulae mastoideae*), separated from it by a thin layer of bone (Fig. 836).

The **arteries** supplying the external meatus are branches from the posterior auricular, internal maxillary, and superficial temporal.

The **veins** of the external meatus accompany the corresponding arteries and pass to the internal maxillary, temporal, and posterior auricular veins. The **lymphatics** accompany the veins and enter the parotid and posterior auricular lymph nodes. The **nerves** are chiefly derived from the auriculotemporal branch of the inferior maxillary nerve, the *auricularis magnus*, and the auricular branch of the *vagus*.

The point of junction of the osseous and cartilaginous portions of the tube is an obtuse angle, which projects into the canal at its antero-inferior wall. This produces a sort of constriction in this situation, and renders it the narrowest portion of the canal—an important point to be borne in mind in connection with the presence of foreign bodies in the ear. The cartilaginous is connected to the bony part by fibrous tissue, which renders the outer part of the tube very movable, and therefore by drawing the pinna upward and backward the canal is rendered almost straight. At the external orifice are a few short crisp hairs which serve to prevent the entrance of small particles of dust, flies, or other insects. In the external auditory meatus the secretion of the ceruminous glands serves to catch any small particles which may find their way into the canal, and prevent their reaching the membrana tympani, where their presence might excite irritation. In young children the meatus is short, the osseous part being very deficient, and consisting merely of a bony ring (*annulus tympanicus*), which supports the membrana tympani. In the fetus the osseous part is entirely absent. The shortness of the canal in children

should be borne in mind in introducing the aural speculum, so that it shall not be pushed in too far, at the risk of injuring the membrana tympani; indeed, even in the adult the speculum should never be introduced beyond the constriction which marks the junction of the osseous and cartilaginous portions. In using this instrument it is advisable that the pinna should be drawn upward, backward, and a little outward, so as to render the canal as straight as possible, and thus assist the operator in obtaining, by the aid of reflected light, a good view of the membrana tympani. Just in front of the membrane is a well-marked depression, situated on the floor of the canal and bounded by a somewhat prominent ridge; in this foreign bodies may become lodged. By aid of the speculum, combined with traction of the auricle upward and backward, the whole of the membrana tympani is rendered visible. It is a pearly-gray membrane, slightly glistening in the adult, placed obliquely, so as to form with the floor of the meatus a very acute angle (about 55 degrees), while with the roof it forms an obtuse angle. At birth it is more horizontal—being situated in almost the same plane as the base of the skull. About midway between the anterior and posterior margins of the membrane, and extending from the centre obliquely upward, is a reddish-yellow streak; this is the handle of the malleus, which is inserted into the membrane (Fig. 837). At the upper part of this streak, close to the roof of the meatus, a little white rounded prominence is plainly to be seen; this is the processus brevis of the malleus, projecting against the membrane. The membrana tympani does not present a plane surface; on the contrary, its centre is drawn inward, on account of its connection with the handle of the malleus, and thus the external surface is rendered concave.

The connections of the nerves of the auditory canal explain the fact of the occurrence, in cases of any irritation of the meatus, of constant coughing and sneezing from implication of the vagus, or of yawning from implication of the auriculotemporal, of vomiting which may follow syringing the ears of children, and the occasional heart failure similarly induced in elderly persons. No doubt also the association of *earache with toothache* in cancer of the tongue is due to implication of the inferior maxillary, which supplies also the teeth and the tongue. The upper half of the membrana tympani is much more richly supplied with blood than the lower half. For this reason, and also to avoid the chorda tympani nerve and ossicles, *incisions through the membrane* should be made at the lower and posterior part.

Applied Anatomy.—*Malformations*, such as imperfect development of the external parts, absence of the meatus, or supernumerary auricles, are occasionally met with. Or the pinna may present a *congenital fistula*, which is due to defective closure of the first visceral cleft, or rather of that portion of it which is not concerned in the formation of the Eustachian tube, tympanum, and meatus. In some cases the cephaloauricular angle is almost absent; in others, it is nearly a right angle. *Projecting ears and long ears* are said by some observers to be more common among degenerates, criminals, and the insane than among the normal, the non-criminal, and the sane. The skin of the auricle is thin and richly supplied with blood, but in spite of this it is frequently the seat of *frost-bite*, due to the fact that it is much exposed to cold, and lacks the usual underlying subcutaneous fat found in most other parts of the body. A collection of blood is sometimes found between the cartilage and perichondrium (*hematoma auris*), usually the result of traumatism, but not necessarily due to this cause. It is said to occur most frequently in the ears of the insane. *Keloid* sometimes grows in the auricle around the puncture made for ear-rings, and *epithelioma* occasionally affects this part. Deposits of *urate of soda* are often met with in the pinna in gouty subjects.

The external auditory meatus can be most satisfactorily examined by light reflected down a funnel-shaped speculum; by gently moving the latter in different directions and by gently drawing the pinna upward, backward, and a little outward, so as to render the canal as straight as possible, the whole of the canal and membrana tympani can be brought into view. The points to be noted are the presence of wax or foreign bodies, the size of the canal, and the condition of the membrana tympani. The *accumulation of wax* (impacted cerumen) is often the cause of deafness, and may give rise to very serious consequences, causing ulceration of the membrane and even absorption of the bony wall of the canal. *Foreign bodies* are not infrequently introduced into the ear by children, and, when situated in the first portion of the canal, may be removed with tolerable facility by means of a minute hook or loop of fine wire, the parts being illuminated with reflected light; but when they have slipped beyond the narrow middle part of the meatus, their removal is in nowise easy, and attempts to effect it, in inexperienced hands, may be followed by destruction of the membrana tympani and possibly injury of the contents of the tympanum. The caliber of the external auditory canal may be narrowed by *inflammation* of its lining membrane, running on to *suppuration*; by *periostitis*; by *polypi*, *sebaceous tumors*, and *exostoses*.

THE MIDDLE EAR, DRUM, OR TYMPANUM (AURIS MEDIA)

(Figs. 835, 839).

The middle ear or tympanum is an irregular cavity, compressed laterally, and situated within the petrous portion of the temporal bone. It is placed above

the jugular fossa; the carotid canal lying in front, the mastoid cells behind, the external auditory meatus externally, and the labyrinth internally. It is lined with mucous membrane, is filled with air, and communicates with the mastoid cells, through the mastoid antrum, and with the nasopharynx by the Eustachian tube. The tympanum is traversed by a chain of movable bones, which connect the membrana tympani with the labyrinth, and serve to convey the vibrations communicated to the membrana tympani across the cavity of the tympanum to the internal ear. In shape it is roughly biconcave, the concave surfaces being placed vertically and forming the external and internal walls. The cavity forms an angle of 45 degrees with the median plane.

The **Tympanic Cavity** (*cavum tympani*) (Figs. 839 and 840) consists of two parts—the **atrium** or **tympanic cavity proper** (Fig. 840), opposite the tympanic membrane, and the **attic** or **epitympanic recess** (*recessus epitympanicus*) (Figs. 838 and 839), above the level of the upper part of the membrane; the latter contains the upper half of the malleus and the greater part of the incus. The diameter of the tympanic cavity, including the attic, measures about 15 mm. (three-fifths of an inch) vertically and transversely. From without inward it measures about 6 mm. (one-quarter of an inch) above and 4 mm. (one-sixth of an inch) below; opposite the centre of the tympanic membrane it is only about 2 mm. (one-twelfth of an inch). It is bounded externally by the membrana tympani and meatus; internally, by the outer surface of the internal ear; it communicates behind with the mastoid antrum and through it with the mastoid cells, and in front with the Eustachian tube.

FIG. 835.—View of the inner wall of the tympanum (enlarged).

The **roof of the tympanum** (*paries tegmentalis*) is broad, flattened, and formed of a thin plate of bone (*tegmen tympani*) (Fig. 839), which separates the cranial and tympanic cavities. It is situated on the anterior surface of the petrous portion of the temporal bone, close to its angle of junction with the squamous portion of the same bone, and is prolonged backward so as to roof in the mastoid antrum; it is also carried forward to cover in the canal for the Tensor tympani muscle. Its outer edge corresponds with the remains of the petrosquamous suture.

The **floor** (*paries jugularis*) (Fig. 839) is narrow, and is separated by a thin plate of bone (*fundus tympani*) from the jugular fossa. It presents, near the inner wall, a small aperture, the opening of the **canaliculus tympanicus**, for the transmission of Jacobson's nerve (*n. tympanicus*). On the floor near the posterior wall there is often to be found a slight bony projection (*prominentia styloideae*).

The **outer wall** (Fig. 834) is formed mainly by the membrana tympani, partly by the ring of bone into which this membrane is inserted. This ring of bone is incomplete at its upper part, forming a notch (*incisura tympanica* [Rivini])

(Fig. 835), close to which are three small apertures—the *iter chordæ posterius*, the *Glaserian fissure*, and the *iter chordæ anterior*.

The *iter chordæ posterius* (*canaliculus chordæ tympani*) (Fig. 796) is in the angle of junction between the posterior and external walls of the tympanum, immediately behind the *membrana tympani* and on a level with the upper end of the handle of the malleus; it leads into a minute canal, which descends in front of the facial canal and terminates in the aqueduct near the stylomastoid foramen. Through it the *chorda tympani* nerve enters the tympanum.

The *Glaserian* or *petrotympanic fissure* (*fissura petrotympanica*) [*Glaseri*] (Fig. 838) opens just above and in front of the ring of bone into which the *membrana tympani* is inserted; in this situation it is a mere slit about 2 mm. in length. It lodges the long process and anterior ligament of the malleus, and gives passage to the tympanic branch of the internal maxillary artery.

The *iter chordæ anterior* or canal of *Huguier* (Fig. 838) is seen at the inner end of the preceding fissure; through it the *chorda tympani* nerve leaves the tympanum.

The inner wall of the tympanum (*paries labyrinthica*) (Figs. 835 and 839) is adjacent to the labyrinth; it is vertical in direction, and looks directly outward. It presents for examination the following parts:

Fenestra ovalis.

Fenestra rotunda.

Promontory.

Ridge of the facial canal.

Prominence of the lateral semicircular canal.

The *fenestra ovalis* (*fenestra vestibuli*) (Fig. 835) is a reniform opening leading from the tympanum into the vestibule of the internal ear. Its long diameter is directed horizontally, and its convex border is upward. In the recent state it is occupied by the base of the stapes (Figs. 834 and 840), the circumference of which is connected to the margin of the foramen by an annular ligament.

The *fenestra rotunda* (*fenestra cochleæ*) (Fig. 835) is situated below and a little behind the fenestra ovalis, from which it is separated by a rounded elevation, the *promontory*; at its border is a narrow ridge of bone (*crista fenestrae cochleæ*). The fenestra rotunda is closed in the recent state by a membrane (*membrana tympani secundaria*); this membrane is concave toward the tympanum, convex toward the cochlea. It consists of three layers—the external or mucous, derived from the mucous lining of the tympanum; the internal, from the lining membrane of the cochlea; and an intermediate or fibrous layer.

The *promontory* (*promontorium*) (Fig. 839) is a rounded hollow prominence, formed by the projection outward of the first turn of the cochlea; it is placed between the fenestræ, and is furrowed on its surface (*sulcus promontorii*) for the lodgement of the *tympanic plexus*. A minute spicule of bone frequently connects the promontory to the pyramid.

The *prominentia canalis facialis* (Fig. 839) indicates the position of the bony canal in which the facial nerve is contained; this canal traverses the inner wall of the tympanum above the fenestra ovalis, and behind that opening curves nearly vertically downward along the posterior wall.

The *posterior wall of the tympanum* (*paries mastoidea*) (Fig. 839) is wider above than below, and presents for examination the—

Opening of the antrum.

Pyramid.

Fossa incudis.

The *opening of the antrum* is a large irregular aperture, which extends backward from the epitympanic recess and leads into a considerable air space, the *mastoid antrum* (*antrum tympanicum*) (see p. 83). The antrum communicates

with large irregular cavities contained in the interior of the mastoid process, the **mastoid air cells**. These cavities vary considerably in number, size, and form; they are lined by mucous membrane continuous with that lining the cavity of the tympanum.

The **fossa incudis** (Fig. 839) is placed in the posterior and inferior part of the epitympanic recess. It lodges the short process of the incus.

The **pyramid** (*eminentia pyramidalis*) (Fig. 835) is a conical eminence situated immediately behind the fenestra ovalis, and in front of the vertical portion of the facial canal; it is hollow in the interior, and contains the Stapedius muscle; its summit projects forward toward the fenestra ovalis and presents a small aperture which transmits the tendon of the muscle. The cavity in the pyramid is prolonged into a minute canal, which communicates with the facial canal and transmits the twig from the facial nerve which supplies the Stapedius.

The **anterior wall of the tympanum** (*paries carotica*) is wider above than below; it corresponds with the carotid canal, from which it is separated by a thin plate of bone (Fig. 839), perforated by the **caroticotympanic canaliculus**, which transmits the tympanic branch of the internal carotid artery and the caroticotympanic nerves. It presents for examination the—

Canal for the Tensor tympani.

Orifice of the Eustachian tube.

The processus cochleariformis.

The orifice of the canal for the Tensor tympani and the orifice of the Eustachian tube are situated at the upper part of the anterior wall, being incompletely separated from each other by a thin, delicate, horizontal plate of bone, the **processus cochleariformis** (*septum canalis musculotubarii*) (Figs. 835 and 839). The canalis musculotubarius is divided by this long process into the canal for the Tensor tympani and the canal for the Eustachian tube. These canals run from the tympanum forward, inward, and a little downward, to the angle between the squamous and petrous portions of the temporal bone.

The **canal for the Tensor tympani** (*semicanalis m. tensoris tympani*) (Figs. 835 and 839) is the superior and the smaller of the two; it is rounded and lies beneath the forward prolongation of the tegmen tympani. It extends on to the inner wall of the tympanum and ends immediately above the fenestra ovalis. The processus cochleariformis passes backward below this part of the canal, forming its outer wall and floor; it expands above the anterior extremity of the fenestra ovalis and terminates by curving outward so as to form a pulley over which the tendon passes. The bony wall of this canal is incomplete, and the osseous vacancy is filled by tough connective tissue.

The **Eustachian tube** (*tuba auditiva* [*Eustachii*]) (Figs. 835 and 836) is the channel through which the tympanum communicates with the pharynx. Its length is 36 mm. (an inch and a half), and its direction downward, inward, and forward, forming an angle of about 45 degrees with the sagittal plane and one of from 30 to 40 degrees with the horizontal plane. The **canal for the Eustachian tube** (*semicanalis tubae auditivae*) (Fig. 836) is formed partly of bone, partly of cartilage and fibrous tissue.

The **osseous portion** (*pars ossea tubae auditivae*) is about 12 mm. (half an inch) in length. It is the outer portion of the tube. It commences in the anterior wall of the tympanum, below the processus cochleariformis, and, gradually narrowing, terminates at the angle of junction of the petrous and squamous portions of the temporal bone, its extremity presenting a jagged margin which serves for the attachment of the cartilaginous portion.

The **cartilaginous portion** (*pars cartilaginea tubae auditivae*), about 2.5 cm. (an inch) in length, is formed of a triangular plate of elastic fibrocartilage (*cartilago*

tubae auditivae), the apex of which is attached to the margin of the inner extremity of the osseous canal, while its base lies directly under the mucous membrane of the nasopharynx, where it forms an elevation or cushion above and behind the pharyngeal orifice of the tube. The upper edge of the cartilage is curled upon itself, being bent outward so as to present on transverse section the appearance of a hook (*lamina lateralis*); a groove or furrow is thus produced, which opens below and externally, and this part of the canal is completed by fibrous membrane. On transverse section the cartilage exhibits the laminae which above are continuous with each other—the hard, thick lamina medialis and the thin and hooked lamina lateralis. The cartilage of the Eustachian tube, with a hood plate of cartilage, forms the posterior portion of the inner wall (the *lamina medialis*). The cartilage is fixed to the base of the skull, and lies in a groove (*sulcus tubae auditivae*) between

FIG. 836.—Eustachian tube, laid open by a cut in its long axis. (Testut.)

the petrous portion of the temporal and the greater wing of the sphenoid; this groove ends opposite the middle of the internal pterygoid plate, in a projection, the **processus tubarius**. The cartilaginous and bony portions of the tube are not in the same plane, the former inclining downward a little more than the latter. They join each other at a large obtuse angle, open below. The diameter of the canal is not uniform throughout, being greatest at the pharyngeal orifice and least at the junction of the bony and cartilaginous portions, where it is named the **isthmus** (*isthmus tubae auditivae*); it again expands somewhat as it approaches the tympanic cavity. The position and relations of the pharyngeal orifice are described with the anatomy of the nasopharynx. The mucous membrane of the tube is continuous in front with that of the nasopharynx, and behind with that which lines the tympanum; it is covered with ciliated epithelium and is thin in the osseous portion, while in the cartilaginous portion it contains many mucous glands and near the pharyngeal orifice a considerable amount of lymphoid tissue, which has been named by Gerlach the **tubal tonsil**. The tube is opened during deglutition by the Salpingopharyngeus and Dilator tubae muscles.

The **Membrana Tympani** (Figs. 837 and 838) separates the cavity of the tympanum from the bottom of the external meatus. It is a thin, semitransparent

FIG. 837.—The right membrana tympani, viewed from the outside, from in front, and from below. (Spalteholz.)

FIG. 838.—The right membrana tympani with the hammer and the chorda tympani, viewed from within, from behind, and from above. (Spalteholz.)

membrane, nearly oval in form, somewhat broader above than below, and directed very obliquely downward and inward, so as to form an angle of about 55 degrees with the floor of the meatus (Fig. 834). The antero-inferior portion is, therefore, placed at the greatest distance from the external orifice of the meatus. In a newborn child the membrana tympani is almost horizontal. The greatest diameter of the membrane tympani is from 9 to 10 mm.; its least diameter is from 8 to 9 mm. The greater part of its circumference (*limbus membranae tympanae*) is thickened to form an **annular ring** (*annulus fibrocartilagineus*), which is fixed in a groove, the **sulcus tympanicus**, at the inner extremity of the external meatus. This sulcus is deficient superiorly at the incisure or **notch of Rivinus** (*incisura tympanica* [Rivini]) (Fig. 837). From the extremities of the notch (*spinae tympanicae*) two folds, the **anterior** and **posterior tympanomalleolar folds**, are prolonged

FIG. 839.—The medial wall and part of the posterior and anterior walls of the right tympanic cavity, lateral view. (Spalteholz.)

to the short process of the malleus (Fig. 837). The small, somewhat triangular part of the membrane situated above these folds is lax and thin, and is named the **membrana flaccida of Shrapnell** (Figs. 837 and 838); in it a small orifice is sometimes seen. The larger lower portion of the tympanic membrane is stretched tightly, and is called the **tense portion** or **pars tensa** (Figs. 837 and 838).

The handle of the malleus is firmly attached to the inner aspect of the membrana tympani as far as its centre (Fig. 838), which it draws inward toward the tympanic cavity. The most depressed part of the concavity is called the **umbo** (*umbo membranae tympanae*) (Fig. 837). On the outer surface of the drum membrane a light stripe (*stria malleolaris*) is seen. It runs from in front and above downward and backward, and is produced by the handle of the malleus, showing through the membrane (Fig. 837).

Structure.—The **tympanic membrane** is composed of three layers—an **external** (*cuticular*), a **middle** (*fibrous*), and an **internal** (*mucous*). The **cuticular layer** (*stratum cutaneum*) is derived from the integument lining the meatus. The **fibrous** or **middle layer** (*membrana propria*)

consists of two strata—an external, of **radiating fibres** (*stratum radiatum*), which diverge from the handle of the malleus, and an internal, of **circular fibres** (*stratum circulare*), which are plentiful around the circumference, but sparse and scattered near the centre of the membrane. **Branched or dendritic fibres**, as pointed out by Grüber, are also present, especially in the posterior half of the membrane.

The **arteries** are derived from the deep auricular branch of the internal maxillary, which ramifies beneath the cuticular layer and from the stylomastoid branch of the posterior auricular and tympanic branch of the internal maxillary, which are distributed on the mucous surface. The arteries of the cutaneous set anastomose with the arteries of the mucous set by minute branches which penetrate the drum membrane near its margin. The **superficial veins** open into the external jugular; those on the mucous surface drain partly into the lateral sinus and veins of the dura and partly into a plexus on the Eustachian tube. The outer surface of the drum membrane receives its **nerve supply** from the auriculotemporal branch of the inferior maxillary and the auricular branch of the vagus. The inner surface is supplied by the tympanic branch of the glossopharyngeal.

There are two sets of **lymphatics**, the cutaneous and mucous, which freely communicate. The spaces between the dendritic fibres of Grüber are lymph spaces (Kessel).

The Ossicles of the Tympanum (*ossicula auditus*) (Fig. 840).—The tympanum contains in its upper part a chain of movable bones, three in number, the **malleus**, **incus**, and **stapes**. The first is attached to the membrana tympani, the last to the fenestra ovalis, the incus being placed between the two, and connected to both by delicate articulations.

The **Malleus** (Fig. 841), so named from its fancied resemblance to a hammer, is placed farthest in front and outward. It consists of a **head**, **neck**, and three processes—the **handle**, or **manubrium**, the **processus gracilis**, and the **processus brevis**.

The **head** (*capitulum mallei*) is the large upper extremity of the bone, and is situated in the epitympanic recess (Fig. 838). It is oval in shape, and articulates posteriorly with the incus, being free in the rest of its extent. The facet for articulation with the incus is covered by cartilage; it is constricted near the middle, and is divided by a ridge into an upper, greater, and a lower, lesser part; which form nearly a right angle with each other. Opposite the constriction the lower margin of the facet projects in the form of a process, the **cog tooth**, or **spur of the malleus**. On the back of the head below the spur is a crest (*crista mallei*), to which the posterior ligament of the malleus is attached.

The **neck** (*collum mallei*) is the narrow contracted part just beneath the head; below this is a prominence, to which the various processes are attached. The chorda tympani nerve crosses the inner surface (Fig. 838).

The **handle** (*manubrium mallei*) is a vertical process of bone, which is connected by its outer margin with the fibrous layer of the membrana tympani, its entire length being fastened to the fibrous layer of the drum membrane by its own periosteum and by a layer of cartilage (Figs. 838 and 840). It is directed downward, inward, and backward; it decreases in size toward its extremity, where it is curved slightly forward, and is flattened from within outward. The handle forms a variable angle with the head of the hammer. It averages about 130 degrees, but is always greater in the right ear than in the left. It forms an angle with the

FIG. 840.—Chain of ossicles and their ligaments, seen from the front in a vertical, transverse section of the tympanum. (Testut.)

horizontal, averaging on the right side 50 degrees and on the left side 45 degrees (Spalteholz). Internally the handle is covered by the mucous membrane of the tympanum. On the inner side, near its upper end, is a slight projection, into which the tendon of the Tensor tympani is inserted (Fig. 838).

The **processus gracilis** (*processus anterior* [*Folii*]) is a long and delicate process, which springs from the eminence below the neck and is directed forward and outward to the Glaserian fissure, to which it is connected by ligamentous fibres. In the fetus this is the longest process of the malleolus, and is in direct continuity with the cartilage of Meckel.

FIG. 841.—Viewed from in front.

FIG. 842.—Viewed from behind. (Spalteholz.)

FIGS. 841 and 842.—The right malleus (enlarged).

The **processus brevis** (*processus lateralis*) is a slight conical projection, which springs from the root of the manubrium; it is directed outward and is attached to the upper part of the tympanic membrane by cartilage and to the margins of the notch of Rivinus by the two tympanomalleolar folds.

The **Incus** (Figs. 843 and 844) has received its name from its supposed resemblance to an anvil, but it is more like a bicuspid tooth with two roots,

FIG. 843.—Lateral view.

FIG. 844.—Medial and front view. (Spalteholz.)

FIGS. 843 and 844.—The right incus (enlarged).

which differ in length, and are widely separated from each other. It consists of a **body** and **two processes**. The body and the short process are placed in the epitympanic recess (Fig. 840).

The **body** (*corpus incudis*) is somewhat quadrilateral, but compressed laterally. On its anterior surface is a deeply concavo-convex facet, which articulates with the head of the malleus, and the lower part is hollowed for the spur of the malleus.

The **two processes** diverge from each other at an angle of 90 to 100 degrees.

The **short process** (*crus breve*), somewhat conical in shape, projects almost horizontally backward, and articulates with a depression, the *fossa incudis*, in the lower and back part of the epitympanic recess.

The **long process** (*crus longum*), longer and more slender than the preceding, descends nearly vertically behind and parallel to the handle of the malleus, and, bending inward, terminates in a rounded globular projection, the **os orbiculare** or **lenticular process** (*processus lenticularis*), which is tipped with cartilage, and articulates with the head of the stapes. In the fetus the os orbiculare exists as a separate bone.

The **Stapes** (Fig. 845), so called from its close resemblance to a stirrup, consists of a head, neck, two *crura*, and a base.

The **head** (*capitulum stapedis*) presents a depression, tipped with cartilage, which articulates with the os orbiculare.

The **neck**, the constricted part of the bone succeeding the head, receives the insertion of the Stapedius muscle.

The two *crura* (*crus anterior* and *crus posterior*) diverge from the neck and are connected at their extremities by a flattened, oval-shaped plate, the **base** (*basis stapedis*), which forms the foot-plate of the stapes and is fixed to the margin of the fenestra ovalis by ligamentous fibres. The foot-plate almost fills the oval window (Fig. 834). Of the two *crura*, the anterior is shorter and less curved than the posterior. In a recent specimen a membrane will be observed filling the space between the *crura* and the foot-plate. This membrane is connective tissue and is called the *membrana obturatoria stapedis*. The stapes lies practically horizontal.

FIG. 845.—The right stapes (enlarged). A. Viewed from above. B. Medial view. (Spalteholz.)

Articulations of the Ossicles of the Tympanum (*articulationes ossiculorum auditus*) (Fig. 840).—These small bones are connected with each other and with the walls of the tympanum by ligaments, and are moved by small muscles. The articular surfaces of the malleus and incus and the orbicular process of the incus and head of the stapes are covered by cartilage, connected by delicate capsular ligaments and lined by synovial membrane.

Ligaments Connecting the Ossicula with the Walls of the Tympanum (*lig. ossiculorum auditus*).—The malleus is fastened to the wall of the tympanum by three ligaments—the **anterior**, **superior**, and **external ligaments**.

The **anterior ligament of the malleus** (*lig. mallei anterior*) is attached by one extremity to the neck of the malleus just above the processus gracilis, and by the other to the anterior wall of the tympanum, close to the Glaserian fissure, some of its fibres being prolonged through the fissure to reach the spine of the sphenoid.

The **superior ligament of the malleus** (*lig. mallei superior*) is a delicate round bundle of fibres which descends perpendicularly from the roof of the epitympanic recess to the head of the malleus. It is sometimes called the **suspensory ligament**.

The **external ligament of the malleus** (*lig. mallei laterale*) is a triangular plane of fibres passing from the posterior part of the notch in the tympanic ring to the head of the malleus. The malleus rotates around an axis composed of the external and anterior ligaments, hence these two ligaments constitute what Helmholtz called the **axis ligament of the malleus**.

The incus is fastened to the wall of the tympanum by two ligaments, the **posterior** and the **superior**.

The **posterior ligament of the incus** (*lig. incudis posterior*) is a short, thick, ligamentous band which connects the extremity of the short process of the incus to the posterior and lower part of the epitympanic recess, near the margin of the opening of the mastoid cells.

A **superior ligament of the incus** (*lig. incudis superior*) has been described, but it is little more than a fold of mucous membrane.

The vestibular surface and the circumference of the base of the stapes are covered by hyaline cartilage, and the **annular ligament of the stapes** (*lig. annulare baseos stapedis*) connects the circumference of the base to the margin of the fenestra ovalis.

The muscles of the tympanum (*m. ossiculorum auditus*) are two:¹

Tensor tympani.

Stapedius.

The **Tensor tympani** (*m. tensor tympani*) (Fig. 839), the larger, is contained in the bony canal above the osseous portion of the Eustachian tube, from which it is separated by the processus cochleariformis. It arises from the under surface of the petrous bone, from the cartilaginous portion of the Eustachian tube, and from the osseous canal in which it is contained. Passing backward through the canal, it terminates in a slender tendon which enters the tympanum and makes a sharp bend outward around the extremity of the processus cochleariformis, and is inserted into the handle of the malleus near its root. Its nerve supply is from the motor root of the trigeminal nerve by way of the otic ganglion.

The **Stapedius** (*m. stapedius*) (Fig. 839) arises from the side of a conical cavity hollowed out of the interior of the pyramid; its tendon emerges from the orifice at the apex of the pyramid, and, passing forward, is inserted into the neck of the stapes. Its surface is aponeurotic, its interior fleshy, and its tendon occasionally contains a slender bony spine, which is constant in some mammalia. It is supplied by the tympanic branch of the facial nerve.

Actions.—The *Tensor tympani* draws the handle of the malleus inward and thus increases the tension of the tympanic membrane. When the *Stapedius* contracts it draws the head of the stapes backward, and in consequence the anterior end of the foot-plate passes outward toward the tympanum, and the posterior end inward toward the vestibule, and the annular ligament is made tense. It probably compresses the contents of the vestibule.

Movements of the Ossicles of the Tympanum.—The chain of bones is a lever-like arrangement, by means of which the vibrations of the membrana tympani are transferred to the membrane covering the oval window, and from this to the perilymph in the labyrinth. When the tympanic membrane moves inward, the handle of the malleus moves with it. The movement of the malleus moves the incus, and the movement of the incus drives the foot of the stapes toward the labyrinth. When the handle of the malleus moves inward, the spur on the head becomes locked with the body of the incus. During outward movement it is unlocked. The ordinary outward movement of the drum membrane causes the above-described movements to be reversed. When there is overforceful outward movement the incus does not go outward quite as far as the malleus, but slides at the joint between the malleus and incus. This reluctance of the incus saves the foot of the stapes from being pulled away from the oval window.

The **mucous membrane of the tympanum** (*tunica mucosa tympanica*) is continuous with that of the nasopharynx through the Eustachian tube. It invests the ossicles, and the muscles and nerves contained in the tympanic cavity, forms the internal layer of the membrana tympani, and is reflected into the mastoid antrum and air cells, which it lines throughout. It forms several vascular folds (*plicæ*), which extend from the walls of the tympanum to the ossicles, enveloping these as well as the chorda tympani nerve and the Tensor tympani muscle.

The **anterior malleolar fold** (*plica malleolaris anterior*) comes off from the membrana tympani between the anterior edge of the notch of Rivinus and the handle of the malleus, envelops the processus gracilis of the malleus, the anterior ligament of the malleus, and the anterior portion of the chorda tympani nerve, and terminates in a free concave edge (Spalteholz). The **posterior malleolar fold** (*plica malleolaris posterior*) is the larger of the two. It comes off from the margin of the notch of Rivinus, envelops the external ligament of the malleus, the posterior part of the chorda tympani nerve, is attached to the handle of the malleus, and ends in a free concave margin (Spalteholz). The **fold of the incus** (*plica incudis*) takes origin from the roof of the epitympanic recess and passes to the body and short process of the incus; and a similar fold passes from the head of the malleus to the anterior wall of the epitympanic recess. The entire stapes, with its obturator membrane, is enwrapped by the **fold of the stapes** (*plica stapedis*). This fold also ensheaths the tendon of the Stapedius muscle and often reaches to the posterior wall of the cavity of the tympanum. These folds separate off pouch-like cavities, and give the interior of the tympanum a somewhat honeycombed appearance.

The **inferior external pouch of the tympanum** or the **pouch of Prussak** (*recessus membranae tympani superior*) is between the flaccid portion of the membrana tympani, the external ligament of the malleus, and the neck of the malleus. The anterior and posterior malleolar folds with the tympanic membrane form two pouches. These are the **anterior and posterior pouches** or **recesses of Troeltsch** (*recessus membranae tympani, anterior and posterior*). The anterior pouch is blind above and has a slit-like opening below. The posterior pouch is continued into the blind superior pouch of the tympanic membrane. In the tympanum this membrane is pale, thin, slightly vascular, and covered for the most part with columnar ciliated epithelium, but that

¹ Two additional muscles have been described as the *Mm. laxator tympani major et minor*; they correspond to the anterior and lateral ligaments of the malleus.

covering the pyramid, ossicula, and membrana tympani possesses a flattened, nonciliated epithelium. In the antrum and mastoid cells its epithelium is also nonciliated. In the osseous portion of the Eustachian tube the membrane is thin, but in the cartilaginous portion it is very thick, highly vascular, covered with ciliated epithelium, and provided with numerous mucous glands.

Vessels and Nerves.—The arteries supplying the tympanum are six in number. Two of them are larger than the rest—viz., the tympanic branch of the internal maxillary, which enters by way of the petrotympanic or Glaserian fissure and supplies the membrana tympani; and the stylomastoid branch of the posterior auricular, which passes through the stylomastoid foramen and the facial canal, and supplies the inner wall and floor of the tympanum, the mastoid cells and antrum, and the Stapedius muscle. This vessel anastomoses around the tympanic membrane with the tympanic. The middle meningeal sends a small branch to the Tensor tympani muscle near its origin. The petrosal branch of the middle meningeal enters the tympanum by way of the hiatus canalis facialis. Minute branches from the posterior branch of the middle meningeal pass through the petrosquamous fissure and are distributed to the antrum and epitympanic recess. Two tympanic branches come off from the internal carotid artery in its course through the carotid canal. A branch from the ascending pharyngeal and another from the Vidian accompany the Eustachian tube. The two tympanic branches from the internal carotid are given off in the carotid canal and perforate the thin anterior wall of the tympanum. The veins of the tympanum terminate in the pterygoid plexus, the middle meningeal vein, and the superior petrosal sinus.

The nerves of the tympanum constitute the **tympanic plexus** (*plexus tympanicus* [Jacobsoni]), which ramifies upon the surface of the promontory (Fig. 839). The plexus is formed by (1) the tympanic branch of the glossopharyngeal; (2) the small deep petrosal nerve; (3) the small superficial petrosal nerve; and (4) a branch which joins the great superficial petrosal.

The **tympanic branch of the glossopharyngeal** or **Jacobson's nerve** (*n. tympanicus*) enters the tympanum by an aperture in its floor close to the inner wall and divides into branches, which ramify on the promontory and enter into the formation of the plexus. The **small deep petrosal nerve** (*n. petrosus profundus*), from the carotid plexus of the sympathetic, passes through the wall of the carotid canal, and joins the branches of Jacobson's nerve. The branch to the great superficial petrosal passes through an opening on the inner wall of the tympanum in front of the fenestra ovalis. The **small superficial petrosal nerve** (*n. petrosus superficialis minor*), derived from the otic ganglion, passes through a foramen (*canaliculus innominatus*) in the middle fossa of the base of the skull (sometimes through the foramen ovale), passes backward and enters the petrous bone through a small aperture, situated external to the hiatus canalis facialis on the anterior surface of this bone; it then courses downward through the bone, and, passing by the geniculate ganglion, receives a connecting filament from it (Fig. 845) and enters the tympanic cavity, where it communicates with Jacobson's nerve, and assists in forming the tympanic plexus.

The **branches of distribution** of the tympanic plexus are supplied to the mucous membrane of the tympanum; one special branch passing to the fenestra ovalis, another to the fenestra rotunda, and a third to the Eustachian tube. The small superficial petrosal may be looked upon as the continuation of the tympanic nerve (Jacobson's) through the plexus to the otic ganglion.

In addition to the tympanic plexus there are the nerves supplying the muscles. The Tensor tympani is supplied by a branch from the third division of the trigeminal through the otic ganglion, and the Stapedius by the tympanic branch of the facial.

The **chorda tympani** (Figs. 835 and 838) crosses the tympanic cavity. It is apparently given off from the facial as it passes vertically downward at the back of the tympanum, about 6 mm. (a quarter of an inch) before its exit from the stylomastoid foramen. It passes from below upward and forward in a distinct canal, and enters the cavity of the tympanum through an aperture, **iter chordae posterius**, already described (p. 1128), and becomes invested with mucous membrane. It passes forward, through the cavity of the tympanum, crossing internal to the membrana tympani and over the handle of the malleus to the anterior inferior angle of the tympanum, and emerges from that cavity through the **iter chordae anterior** or **canal of Huguier** (p. 1128).

Applied Anatomy.—The principal point in connection with the *surgical anatomy* of the tympanum is its relations to other parts. Its roof is formed by a thin plate of bone, which, with the dura, is all that separates it from the temporal lobe of the brain. Its floor is immediately above the *jugular fossa* and the *carotid canal*, the fossa being behind and the canal in front. Its posterior wall presents the opening of the *mastoid cells*. On its anterior wall is the opening of the *Eustachian tube*. Thus, it follows that in disease of the middle ear we may get *subdural abscess*, *septic meningitis*, or *abscess of the cerebrum* or *cerebellum* from extension of the inflammation through the bony roof; *thrombosis of the lateral sinus*, with or without pyemia, by extension through the floor; or *mastoid abscess* by extension backward. In addition to this, we may get fatal hemorrhage from the internal carotid in destructive changes of the middle ear; and in throat disease we may get the inflammation extending up the Eustachian tube to the

middle ear. The Eustachian tube is accessible from the nose. If the nose and mouth be closed and an attempt made to expire air, a sense of pressure with dulness of hearing is produced in both ears, from the air finding its way up the Eustachian tube and bulging out the membrana tympani. During the act of swallowing, the pharyngeal orifice of the tube, which is normally closed, is opened, probably by the action of the Dilator tubæ muscle. This fact was employed by Politzer in devising an easy method of inflating the tube. The nozzle of a rubber syringe is inserted into the nostril; the patient takes a mouthful of water and holds it in his mouth, both nostrils are closed with the finger and thumb to prevent the escape of air, and the patient is then requested to swallow; as he does so the surgeon squeezes the bulb and the air is forced out of the syringe into the nose, and is driven into the Eustachian tube, which is now open. The impact of the air against the membrana tympani can be heard by the surgeon, if the membrane is intact, sound being conveyed by means of a piece of rubber tubing, one end of which is inserted into the meatus of the patient's ear, the other into that of the surgeon. The direct examination of the Eustachian tube is made by the Eustachian catheter. This is passed along the floor of the nostril, close to the septum, with the point touching the floor, to the posterior wall of the pharynx. When this is felt, the catheter is to be withdrawn about half an inch, and the point rotated outward through a quarter of a circle, and pushed again slightly backward, when it will enter the orifice of the tube, and will be found to be caught, and air forced into the catheter will be heard impinging on the tympanic membrane if the ears of the patient and surgeon are connected by a rubber tube.

THE INTERNAL EAR, OR LABYRINTH (AURIS INTERNA).

The internal ear is the essential part of the organ of hearing, receiving the ultimate distribution of the auditory nerve. It is called the **labyrinth**, from the complexity of its shape, and consists of two parts, the **osseous labyrinth**, a series of cavities channelled out of the substance of the petrous bone, and the **membranous labyrinth**, the latter being contained within the former.

FIG. 846.—The osseous labyrinth laid open (enlarged).

The **Osseous Labyrinth** (*labyrinthus osseus*) (Fig. 846) consists of three parts—the **vestibule**, **semicircular canals**, and **cochlea**. These are cavities hollowed out of the substance of the bone, and lined by periosteum. A clear fluid is contained in the space between the osseous labyrinth and the membranous labyrinth. The space is called the **perilymph space**, and the fluid is called **perilymph**.

The **Vestibule** (*vestibulum*) (Figs. 840 and 846) is the common central cavity of communication between the parts of the internal ear. It is situated on the inner side of the tympanum, behind the cochlea, and in front of the semicircular canals.

It is somewhat ovoid in shape, flattened from within outward, and measures about 5 mm. (one-fifth of an inch) from before backward, as well as from above downward, and about 3 mm. (one-eighth of an inch) from without inward. On its *outer or tympanic wall* is the *fenestra ovalis* (*fenestra vestibuli*), closed, in the recent state, by the base of the stapes, and its annular ligament. On its *inner wall*, at the fore part, is a small circular depression, the *spherical recess* (*recessus sphaericus*), in which the saccule is placed. This recess is perforated, at its anterior and inferior part, by about a dozen minute holes (*macula cribrosa media*), for the passage of filaments of the auditory nerve to the saccule. Above and behind this depression is an oblique ridge, the *crista vestibuli*, the anterior extremity of which is called the *pyramid* (*pyramis vestibuli*). This ridge bifurcates posteriorly to enclose a small depression, the *recessus cochlearis*, which is perforated by eight small holes for the passage of filaments of the auditory nerve which supply the posterior end of the ductus cochlearis. An oval depression is placed in the roof and inner wall of the vestibule above and behind the crista vestibuli. It is called the *fovea hemielliptica*, *elliptical recess*, or *spherical recess* (*recessus ellipticus*), and receives the utricle. The pyramid and the adjacent elliptical recess are perforated by numerous minute foramina (*macula cribrosa superior*). The openings in the pyramid transmit filaments from the vestibular nerve to the utricle; the openings in the elliptical recess transmit filaments from the vestibular nerve to the ampullæ of the superior and lateral semicircular canals. Below and behind the elliptical recess is a groove which deepens into a canal and is called the *aqueductus vestibuli*. This canal passes to the posterior surface of the petrous portion of the temporal bone and opens as a mere crack between the internal auditory meatus and the groove for the lateral sinus. It transmits a small vein, and contains a tubular prolongation of the lining membrane of the vestibule, the *ductus endolymphaticus*, which ends in a *cul-de-sac* between the layers of the dura mater within the cranial cavity. *Behind*, the semicircular canals open into the vestibule by five orifices. In *front* is an elliptical opening, which communicates with the scala vestibuli of the cochlea by an orifice, *apertura scalæ vestibuli cochleæ*. This opening is bounded below by a thin plate of bone (*lamina spiralis ossea*), which takes origin from the vestibular floor external to the spherical recess and in the cochlea forms the bony portion of the partition between the scala tympani and the scala vestibuli. In the anterior portion of the vestibular floor is a fissure (*fissura vestibuli*), which passes into the bony part of the canal of the cochlea. The external boundary of this fissure is a small, thin plate of bone (*lamina spiralis secundaria*).

The **Bony Semicircular Canals** (*canales semicirculares ossei*) (Fig. 846) are three bony canals situated above and behind the vestibule. They are of unequal length, compressed from side to side, and each describes the greater part of a circle. They measure about 0.8 mm. (one-thirtieth of an inch) in diameter, and each presents a dilatation at one end, called the *ampulla ossea*, which measures more than twice the diameter of the tube. These canals open into the vestibule by five orifices, one of the apertures being common to two of the canals.

The **superior semicircular canal** (*canalis semicircularis superior*), 15 to 20 mm. in length, is vertical in direction, and is placed transversely to the long axis of the petrous portion of the temporal bone, on the anterior surface of which its arch forms a round projection. It describes about two-thirds of a circle. Its outer extremity, which is ampullated, communicates by a distinct orifice with the upper part of the vestibule; the opposite end of the canal, which is not dilated, joins with the corresponding part of the posterior canal to form the *crus commune*, which opens into the upper and inner part of the vestibule.

The **posterior semicircular canal** (*canalis semicircularis posterior*), also vertical in direction, is directed backward, nearly parallel to the posterior surface of the

petrous bone; it is the longest of the three, measuring from 18 to 22 mm.; its ampullated end commences at the lower and back part of the vestibule, its opposite end joining to form the common canal already mentioned. In the wall of the ampulla of the posterior canal are a number of small openings (*macula cribrosa inferior*) for the passage of nerves to the ampulla.

The **lateral** or **horizontal canal** (*canalis semicircularis lateralis*) is the shortest of the three. It measures from 12 to 15 mm., and its arch is directed outward and backward; thus each semicircular canal stands at right angles to the other two. Its ampullated end corresponds to the upper and outer angle of the vestibule, just above the fenestra ovalis, where it opens close to the ampullary end of the superior canal; its opposite end opens by a distinct orifice at the upper and back part of the vestibule.

The **cochlea** (Figs. 846 and 847) bears some resemblance to a common snail-shell; it forms the anterior part of the labyrinth, is conical in form, and placed almost horizontally in front of the vestibule; its apex (*cupula*) is directed forward and outward, with a slight inclination downward, toward the upper and front part

FIG. 847.—Osseous cochlea in vertical section. The broken, white lines indicate the position of the basilar membrane of the canal of the cochlea. Semidiagrammatic. (Testut.)

of the inner wall of the tympanum; its base (*basis cochleae*) corresponds with the anterior depression at the bottom of the internal auditory meatus, and is perforated by numerous apertures for the passage of the cochlear divisions of the auditory nerve. It measures nearly a quarter of an inch (5 mm.) from base to apex, and its breadth across the base is somewhat greater (about 9 mm.). It consists of a conical-shaped central axis, the **modiolus**; of a canal, the **bony canal of the cochlea**, the inner wall of which is formed by the central axis, wound spirally around it for two turns and three-quarters, from the base to the apex, and of a delicate lamina, the **lamina spiralis ossea**, which projects from the modiolus, and, following the windings of the canal, partially subdivides it into two. In the recent state a membrane, the **membrana basilaris**, stretches from the free border of this lamina, to the outer wall of the cochlea, and completely separates this canal into two passages, which, however, communicate with each other at the apex of the modiolus by a small opening, named the **helicotrema**.

The **Modiolus** (Figs. 848 and 849) is the central axis or pillar of the cochlea. It is conical in form, and extends from the base to the apex of the cochlea. Its **base** (*basis modioli*) is broad, and appears at the bottom of the internal auditory

meatus, where it corresponds with the area cochleae. It is perforated by numerous orifices, which transmit filaments of the cochlear division of the auditory nerve, the nerves for the first turn and a half being transmitted through the foramina of the *tractus spiralis foraminosus*; those for the apical turn through the

FIG. 848.—Vertical section through the right cochlea, medial portion, viewed from the lateral side. (Spalteholz).

foramen centrale. The foramina of the *tractus spiralis foraminosus* pass up through the modiolus and successively bend outward to reach the attached margin of the lamina spiralis ossea. Here they become enlarged, and by their apposition form a *spiral canal* (*canalis spiralis modioli*), which follows the course of the attached

FIG. 849.—The cochlea laid open (enlarged).

margin of the lamina spiralis ossea and lodges the *ganglion spirale* (of Corti) (*ganglion spirale cochleae*). The *foramen centrale* is continued as a canal up the middle of the modiolus to its apex, and from this canal numerous minute foramina pass outward to the unattached edge of the lamina spiralis. In the foramina are vessels and nerves. The modiolus diminishes rapidly in size in the second and succeeding coil.

The **bony canal** or the **spiral canal of the cochlea** (*canalis spiralis cochleæ*) (Fig. 849) takes two turns and three-quarters around the modiolus. The first turn of the canal is called the **basal coil**, the second is called the **central coil**, the third turn is called the **apical coil**. The promontory on the inner wall of the tympanic cavity is caused by the basal coil. The bony canal of the cochlea is a little over an inch (about 30 mm.) in length, and diminishes gradually in size from the base to the summit, where it terminates in the **cupola** (*cupula*), which forms the apex of the cochlea. The commencement of this canal is about a tenth of an inch (2.5 mm.) in diameter; it diverges from the modiolus toward the tympanum and vestibule, and presents three openings. One, the **fenestra rotunda**, communicates with the tympanum; in the recent state this aperture is closed by a membrane, the **membrana tympani secundaria**. Another aperture, of an elliptical form, opens into the vestibule. The third is the aperture of the **aquæductus cochleæ**, leading to a minute funnel-shaped canal, which opens on the basilar surface of the petrous bone internal to the jugular fossa, and transmits a small vein, and also forms a communication between the subarachnoidean space of the skull and the perilymph space in the scala tympani.

The **lamina spiralis ossea** is a bony shelf or ledge which projects outward from the modiolus into the interior of the spiral canal, and, like the canal, takes nearly two and three-quarter turns around the modiolus. It reaches about half-way toward the outer wall of the spiral canal, and partially divides its cavity into two passages or **scalæ**, of which the upper is named the **scala vestibuli**, while the lower is termed the **scala tympani**. Near the summit of the cochlea the lamina terminates in a hook-shaped process, the **hamulus** (*hamulus laminae spiralis*), which assists in forming the boundary of a small opening, the **helicotrema**, by which the two scalæ communicate with each other. From the *canalis spiralis modioli* numerous foramina pass outward through the osseous spiral lamina as far as its outer or free edge. In the lower part of the first turn a second bony lamina (*lamina spiralis secundaria*) projects inward from the outer wall of the bony tube; it does not, however, reach the primary osseous spiral lamina, so that if viewed from the vestibule a narrow fissure, the **fissura vestibuli**, is seen between them.

The fundus of the internal auditory meatus is described on page 85.

The **Membranous Labyrinth** (*labyrinthus membranaceus*) (Figs. 850 and 851) is contained within the bony cavities just described, having the same general form as the cavities in which it is contained, though considerably smaller, being separated from the bony walls by a quantity of fluid, the **perilymph** (*perilympa*). It does not, however, float loosely in this fluid, but in places is fixed to the walls of the cavity. The membranous sac contains fluid, the **endolymph** (*endolympha*), and on the sac the ramifications of the auditory nerve are distributed.

Within the osseous vestibule the membranous labyrinth does not quite preserve the form of the bony cavity, but presents two membranous sacs, the **utricle** and the **sacculæ**.

The **Utricle** (*utrículus*) is the larger of the two, of an oblong form, compressed laterally, and occupies the upper and back part of the vestibule, lying in contact with the fovea semielliptica and the part below it. The highest portion of the utricle is called the **recess** (*recessus utriculi*); it is placed in the elliptical recess, and opening into it are the ampullæ of the superior and lateral semicircular canals. The central portion of the recess of the utricle receives upon the side the lateral semicircular canal. This opening has no ampulla. The **superior sinus** is a prolongation upward and backward from the central portion of the utricle and in the superior sinus the crus commune and the superior and posterior semicircular canals open. The lower and inner portion of the utricle is the **inferior sinus**, and into it the ampulla of the posterior semicircular canal opens. The floor and anterior wall of the recess of the utricle are much thicker than else-

where, and form the **macula acustica utriculi**, which receives the utricular filaments of the auditory nerve and has attached to its internal surface a layer of calcareous particles which are called **otoliths**. The cavity of the utricle communicates behind

FIG. 850.—The membranous labyrinth (enlarged).

with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal (*ductus utriculosaccularis*), which joins with a canal from the saccule, the **ductus endolymphaticus**.

The **Saccule** (*sacculus*) is the smaller of the two vesicular sacs; it is globular in form, lies in the recessus sphaericus near the opening of the **scala vestibuli**

FIG. 851.—The right membranous labyrinth or an adult, isolated, medial and posterior view. (Spalteholz.)

of the cochlea. Its anterior part exhibits an oval thickening, the **macula acustica sacculi**, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the pos-

The **bony canal** or the **spiral canal of the cochlea** (*canalis spiralis cochleae*) (Fig. 849) takes two turns and three-quarters around the modiolus. with the membranous semicircular canals by five orifices. From its anterior wall is given off a small canal (*ductus utriculosaccularis*), which joins with a canal from the saccule, the **ductus endolymphaticus**.

The **Saccule** (*sacculus*) is the smaller of the two vesicular sacs; it is globular in form, lies in the recessus sphaericus near the opening of the **scala vestibuli**

FIG. 851.—The right membranous labyrinth or an adult, isolated, medial and posterior view. (Spalteholz.)

of the cochlea. Its anterior part exhibits an oval thickening, the **macula acustica sacculi**, to which are distributed the saccular filaments of the auditory nerve. Its cavity does not directly communicate with that of the utricle. From the pos-

terior wall is given off a canal, the *ductus endolymphaticus*. This duct is joined by the *ductus utriculosaccularis*, and then passes along the aqueductus vestibuli and ends in a blind pouch on the posterior surface of the petrous portion of the temporal bone, where it is in contact with the dura. From the lower part of the sacculle a short tube, the *canalis reuniens* of *Hensen* (*ductus reuniens* [*Hensei*]), passes downward and outward to open into the *ductus cochlearis* near its vestibular extremity.

The **Membranous Semicircular Canals** (*ductus semicirculares*) are about one-third the diameter of the osseous canals, but in number, shape, and general form they are precisely similar, and each presents at one end an ampulla (*ampullae membranaceae*). The canals open by five orifices into the utricle, one opening being common to the inner end of the superior and the upper end of the posterior canal. In the ampullae the wall is thickened, and projects into the cavity as a fiddle-shaped, transversely placed elevation, the *septum transversum*, in which the nerves end.

The utricle, sacculle, and membranous canals are attached here and there to the bone by numerous fibrous bands, the so-called ligaments (*ligamenta labyrinthi canaliculorum*).

FIG. 852.—Floor of scala media, showing the organ of Corti, etc.

Structure.—The walls of the utricle, sacculle, and membranous semicircular canals consist of three layers. The *outer layer* is a loose and flocculent structure, apparently composed of ordinary fibrous tissue, containing bloodvessels and pigment cells. The *middle layer*, thicker and more transparent, bears some resemblance to the hyaloid membrane, but it presents on its internal surface, especially in the semicircular canals, numerous papilliform projections, and, on the addition of acetic acid, presents an appearance of longitudinal fibrillation and elongated nuclei. The *inner layer* is formed of polygonal nucleated epithelial cells. In the maculae of the utricle and sacculle, and in the transverse septa of the ampullae of the canals, the middle coat is thickened: the epithelium is columnar, is increased in height, and passes into the neuroepithelium. The **neuroepithelium** consists of supporting cells and hair cells.

1. The **supporting cells** are long and fusiform, and contain an oval nucleus. Their deep ends are attached to the *membrana propria*, while their free extremities are united to form a thin cuticle. The protoplasm contains yellowish pigment granules.

2. The **hair cells** are columnar, with bulged lower ends and free upper ends. The bulged lower ends, each of which contains a spherical nucleus, do not reach higher than the middle of the epithelial layer. Each free upper end is surmounted by a long, tapering filament. These filaments constitute **auditory hair**, and they project into the cavity. Each filament is found to consist of many fine hairs. The filaments of the auditory nerve enter these parts, and, having pierced the outer and thickened middle layer, they lose their myelin sheaths, and their axones divide into three or four branches at the larger and deeper ends of the hair cells. These branches form a horizontal plexus (*stratum plexiforme*).

Numerous small prismatic bodies termed **statoliths**, **otoconia**, or **otoliths**, and consisting of a mass of minute crystalline grains of carbonate of lime, held together in a gelatinous substance, are contained in the walls of the utricle and sacculle opposite the distribution of the nerves. The membrane is called the **otolith membrane**. A calcareous material is also, according to Bowman, sparingly scattered in the cells lining the ampullae of the semicircular canals. The conical thickening in the ampulla corresponds to the otolith membrane.

The membranous cochlea, ductus cochlearis, or *scala media* consists of a spirally arranged tube enclosed in the bony canal of the cochlea and lying along its outer wall.

FIG. 853.—Cochlea in transverse section. Observe especially the canal of the cochlea, which is a part of the membranous labyrinth. (Testut.)

FIG. 854.—Trans-section of the margin of the macula sacculi of a guinea-pig. $\times 325$. (After K  lliker.)

The osseous spiral lamina, as already stated, extends only part of the distance between the modiolus and the outer bony wall of the cochlea. A membrane, the **basilar membrane** (*membrana basilaris*) (Fig. 852), stretches from its free edge

to the outer wall of the cochlea, and completes the roof of the scala tympani. A second and more delicate membrane, the **membrane of Reissner** (*membrana vestibularis* [*Reissneri*]) (Fig. 852), extends from the thickened periosteum covering the lamina spiralis ossea, at an angle of about 45 degrees, to the outer wall of the cochlea, to which it is attached at some little distance above the membrana basilaris. A canal is thus shut off between the scala tympani below and the scala vestibuli above; this is the **membranous canal of the cochlea** (*ductus cochlearis* or *scala media*) (Fig. 853). It is triangular on transverse section, its roof being formed by the membrane of Reissner, its outer wall by the periosteum which lines the bony canal, and its floor by the membrana basilaris, and the outer part of the lamina spiralis ossea, on the former of which is placed the organ of Corti. Reissner's membrane is thin and homogeneous, and is covered on its upper and under surfaces by a layer of epithelium. The periosteum, which forms the outer

FIG. 855.—Part of the cochlear nerve, highly magnified. (Henle.)

wall of the ductus cochlearis, is greatly thickened and altered in character; forming what is called the **spiral ligament of the cochlea** (*ligamentum spirale cochleae*) (Fig. 852). It projects inward below as a triangular prominence, the **crista basilaris**, which gives attachment to the outer edge of the membrana basilaris, and immediately above which is a concavity, the **sulcus spiralis externus** (Fig. 852). The upper portion of the ligamentum spirale contains numerous capillary loops and small bloodvessels within

the epithelium, and forms what is termed the **stria vascularis**. The stria is limited below by a prominence (*prominentia spiralis*), in which a bloodvessel (*vas prominens*) is distinctly visible.

The **lamina spiralis ossea** (Fig. 853) consists of two plates of bone extending outward; between these are the canals for the transmission of the filaments of the auditory nerve. On the upper plate of that part of the osseous spiral lamina which is outside Reissner's membrane the periosteum is thickened to form the **limbus laminae spiralis**, and this terminates externally in a concavity, the **sulcus spiralis internus**, which presents, on section, the form of the letter C; the upper part of the letter, formed by the overhanging extremity of the limbus, is named the **labium vestibulare**; the lower part, prolonged and tapering, is called the **labium tympanicum**, and is perforated by numerous foramina (*foramina nervosa*) for the passage of the component parts of the cochlear nerve. Externally, the labium tympanicum is continuous with the membrana basilaris. The upper surface of the labium vestibulare is intersected at right angles by a number of furrows, between which are numerous elevations; these present the appearance of teeth along the free margin of the labium, and have been named by Huschke the **auditory teeth**. The basilar membrane may be divided into two areas, inner and outer. The inner is thin, and is named the **zona arcuata** or **zona tecta** (Fig. 852); it supports the organ of Corti. The outer is thicker and striated, and is termed the **zona pectinata**. The under surface of the membrane is covered by a layer of vascular connective tissue. One of these vessels is somewhat larger than the rest, and is named the **vas spirale** (Fig. 856); it lies below Corti's tunnel.

The **organ of Corti**¹ (*organon spirale* [*Cortii*]) (Figs. 856 and 857) is situated upon the inner part of the membrana basilaris—that is, the part directed toward

¹ Corti's original paper is in the Zeitschrift f. Wissen. Zool., iii., 109.

the canal of the ductus cochlearis—and appears as a ridge (*crista spiralis*), winding spirally throughout the whole length of the ductus cochlearis. It is seen to be composed of a remarkable arrangement of cells, which may be likened to the keyboard of a piano. Of these cells, the central ones are rod-like bodies and are called the **inner and outer rods of Corti**. Their bases are expanded and placed on the basilar

FIG. 856.—Section through the organ of Corti. Magnified. (G. Retzius.)

membrane, at some little distance from each other, while their intermediate portions are inclined toward each other, so as to meet at their opposite extremities, and form a series of arches roofing over a minute tunnel, the **canal or tunnel of Corti**, between them and the basilar membrane which ascends spirally through the whole length of the cochlea.

FIG. 857.—Organ of Corti. Diagrammatic view of a small portion. (Testut.)

The **inner rods** (Fig. 856), some 6000 in number, are more numerous than the outer ones, and rest on the basilar membrane, close to the labium tympanicum; they project obliquely upward and outward, and terminate above in expanded extremities which resemble in shape the upper end of the ulna, with its sigmoid cavity, coronoid and olecranon processes. On the outer side of the rod, in the

angle formed between it and the basilar membrane, is a nucleated mass of protoplasm; while on the inner side is a row of epithelial cells, the **inner hair cells** (Fig. 856), surmounted by a brush of fine, stiff, hair-like processes. On the inner side of these cells are two or three rows of columnar supporting cells, which are continuous with the cubical cells lining the sulcus spiralis internus.

The **outer rods** (Fig. 856), numbering about 4000, also rest by broad foot-plates on the basilar membrane; they incline upward and inward, and their upper extremity resembles the head and bill of a swan; the back of the head fitting into the concavity—the analogue of the sigmoid cavity—of one or more of the internal rods, and the bill projecting outward as a phalangeal process of the membrana reticularis, presently to be described.

In the head of these outer rods is an oval portion, where the fibres of which the rod appears to be composed are deficient, and which stains more deeply with carmine than the rest of the rod. At the base of the rod, on its internal side—that is to say, in the angle formed by the rod with the basilar membrane—is a similar protoplasmic mass to that found on the outer side of the base of the inner

FIG. 858.—Longitudinal section of the cochlea, showing the relations of the scala, the ganglion spirale, etc. S.V. Scala vestibuli. S.T. Scala tympani. S.M. Scala media. L.S. Ligamentum spirale. G.S. Ganglion spirale.

rod; these masses of protoplasm are probably the undifferentiated portions of the cells from which the rods are developed. External to the outer rod are three or four successive rows of epithelial cells, more elongated than those found on the internal side of the inner rod, but, like them, furnished with minute hairs or cilia. These are termed the **outer hair cells**, in contradistinction to the inner hair cells above referred to. There are about 12,000 outer hair cells, and about 3500 inner hair cells.

The hair cells are somewhat oval in shape; their free extremities are on a level with the heads of Corti's rods, and from each some twenty fine hairlets project and are arranged in the form of a crescent, the concavity of which opens inward. The deep ends of the cells are rounded and contain large nuclei; they reach only as far as the middle of Corti's rods, and are in contact with the ramifications of the nerve filaments. Between the rows of the outer hair cells are rows of supporting cells, called the **cells of Deiters**; their expanded bases are planted on the basilar membrane, while their opposite ends present a clubbed extremity or **phalangeal process**. Immediately to the outer side of Deiters' cells are some

five or six rows of columnar cells, the **supporting cells of Hensen**. Their bases are narrow, while their upper parts are expanded and form a rounded elevation on the floor of the ductus cochlearis. The columnar cells lying outside Hensen's cells are termed the **cells of Claudius**. A space is seen between the outer rods of Corti and the adjacent hair cells; this is called the **space of Nuel**.

The **lamina reticularis**, or **membrane of Kölliker**, is a delicate framework perforated by rounded holes. It extends from the inner rods of Corti to the external row of the outer hair cells, and is formed by several rows of "minute fiddle-shaped cuticular structures" called **phalanges**, between which are circular apertures containing the free ends of the hair cells. The innermost row of phalanges consists of the phalangeal processes of the outer rods of Corti; the outer rows are formed by the modified free ends of Deiters' cells.

Covering over these structures, but not touching them, is the **membrana tectoria** or **membrane of Corti** (Figs. 852 and 856), which is attached to the vestibular surface of the lamina spiralis close to the attachment of the membrane of Reissner. It is thin near its inner margin, and overlies the auditory teeth of Huschke. Its outer half is thick, and along its lower edge, opposite the inner hair cells, is a clear band, named **Hensen's stripe**. Externally, the membrane becomes much thinner, and is attached to the outer row of Deiters' cells (Retzius). It is made up of multitudes of delicate fibres embedded in a transparent matrix of a soft, transparent collagenous character with marked adhesiveness (Hardesty).

The **osseous labyrinth** is lined by an exceedingly thin fibroserous membrane, analogous to a periosteum, from its close adhesion to the inner surfaces of these cavities, and performing the office of a serous membrane by its free surface. It lines the vestibule, and from this cavity is continued into the semicircular canals and the scala vestibuli of the cochlea, and through the helicotrema into the scala tympani. A delicate tubular process is prolonged along the aqueduct of the vestibule to the inner surface of the dura. This membrane is continued across the fenestra ovalis and fenestra rotunda, and consequently has no communication with the lining membrane of the tympanum. Its attached surface is rough and fibrous, and closely adherent to the bone; its free surface is smooth and pale, covered with a layer of epithelium, and secretes a thin, limpid fluid, the **perilymph**.

The **scala media** (*ductus cochlearis*) is closed above and below. The upper blind extremity is termed the **lagena**, and is attached to the cupola at the upper part of the helicotrema; the lower end is lodged in the recessus cochlearis of the vestibule. Near this blind extremity, the scala media receives the **canalis reuniens of Hensen** (Fig. 850), a very delicate canal, by which the ductus cochlearis is brought into continuity with the saccule.

The **auditory nerve** (*n. acusticus*), the special nerve of the senses of hearing and of equilibrium, divides, at the bottom of the internal auditory meatus, into two branches, the **cochlear** and **vestibular**.

The **vestibular nerve** (*n. vestibularis*), the posterior of the two, presents, as it lies in the internal auditory meatus, a ganglion, the **vestibular ganglion** or the **ganglion of Scarpa** (*ganglion vestibulare*); the nerve divides into three branches which pass through minute openings at the upper and back part of the bottom of the meatus (*area vestibularis posterior*), and, entering the vestibule, are distributed to the utricle and to the ampulla of the external and superior semicircular canals. The nerve filaments enter the ampullary enlargements opposite the septum transversum, and arborize around the hair cells. In the utricle and saccule the nerve fibres pierce the **membrana propria** of the maculæ, and end in arborizations around the hair cells.

The **cochlear nerve** (*n. cochlearis*) gives off the branch to the saccule, the filaments of which are transmitted from the internal auditory meatus through the foramina of the *area vestibularis inferior*, which lies at the lower and back part

of the floor of the meatus. It also gives off the branch for the ampulla of the posterior semicircular canal, which leaves the meatus through the **foramen singulare**.

The rest of the cochlear nerve divides into numerous filaments at the base of the modiolus; those for the basal and middle coils pass through the foramina in the tractus foraminosus, those for the apical coil through the canalis centralis, and the nerves bend outward to pass between the lamellæ of the osseous spiral lamina. Occupying the spiral canal of the modiolus is the **spiral ganglion**, or **ganglion of Corti** (*ganglion spirale*), consisting of bipolar nerve cells, which really constitute the true cells of origin of this nerve, one pole being prolonged centrally to the brain and the other peripherally to the hair cells of Corti's organ. Reaching the outer edge of the osseous spiral lamina, the nerve fibres pass through the foramina in the labium tympanicum. Some of these fibres end by arborizing around the bases of the inner hair cells, while others pass between Corti's rods and across the tunnel, to terminate in a similar manner in relation to the outer hair cells.

The **arteries** of the labyrinth are the **internal auditory**, from the basilar, and the **stylomastoid**, from the posterior auricular. The internal auditory divides at the bottom of the internal auditory meatus into two branches, cochlear and vestibular. The **cochlear artery** divides into numerous minute branches, which enter foramina in the tractus spiralis foraminosa and course in the lamina spiralis ossea to reach the membranous structures. The largest of the cochlear branches is in the canalis centralis. The **vestibular branches** accompany the nerves, and supply the membranous structures in the vestibule and semicircular canals. Two arteries go to each canal. The two vessels enter opposite extremities of the canal, and anastomose at the summit of the canal. The vestibular vessels form a minute capillary network in the substance of each membranous labyrinth.

The **veins** of the vestibule and semicircular canals, the **auditory veins**, accompany the arteries, and receive those of the cochlea at the base of the modiolus, to form the **internal auditory vein** (*vv. auditivæ internæ*), which opens into the posterior part of the inferior petrosal sinus or into the lateral sinus.

THE ORGANS OF TASTE (ORGANON GUSTUS).

The peripheral organs of the sense of taste consist of certain flask-shaped groups of modified epithelial cells, termed **taste buds** (*calyculi gustatorii*), situated on the tongue and adjacent parts. They occupy nests in the stratified epithelium

FIG. 859.—Section of part of the papilla foliata of a rabbit. (Magnified.)

and are present in large numbers on the sides of the circumvallate papillæ (Fig. 859), and to a less extent on their opposed walls. They are also found on the fungiform papillæ over the back part and sides of the tongue, and in the general

epithelial covering of the same areas. They are very plentiful over the fimbriae linguae, and are also present on the under aspect of the soft palate, uvula, and on the lingual surface of the epiglottis.

Each **taste bud** is flask-like in shape, its broad base resting on the corium, and the neck opening by an orifice, the gustatory pore, between the cells of the epithelium. The bud is formed by two kinds of cells, supporting cells and gustatory cells. The **supporting cells** are mostly arranged like the staves of a cask, and form an outer envelope for the bud. Some, however, are found in the interior of the bud between the gustatory cells. The **gustatory cells** occupy the central portion of the bud; they are spindle-shaped, and each possesses a large spherical nucleus near the middle of the cell. The peripheral end of the cell terminates at the gustatory pore in a fine, hair-like filament, the **gustatory hair**. The central process passes toward the deep extremity of the bud, and there ends in a single or bifurcated varicose filament, which was formerly supposed to be continuous with the terminal fibril of a nerve; the investigations of Lenhossék and others would seem to prove, however, that this is not so, but that the nerve fibrils after losing their myelin sheaths enter the taste bud, and terminate in fine extremities between

FIG. 860.—Taste buds from the papilla foliata of a rabbit. $\times 850$. (Szymonowicz.)

the gustatory cells. Other nerve fibrils may be seen ramifying between the supporting cells and terminating in fine extremities; these, however, are believed to be nerves of ordinary sensation, and not gustatory. "The latest researches have shown that dendrites of sensor neurones (sensor nerves) enter the taste buds and end free in telodendria. The latter surround the neuroepithelial, and, to some extent, the sustentacular cells, their relations depending on contact."¹

Nerves of Taste.—The chorda tympani nerve is generally regarded as the nerve of taste for the anterior two-thirds of the tongue; the nerve for the posterior third is the glossopharyngeal.

THE SKIN (INTEGUMENTUM COMMUNE).

The skin covers the body surface and is continuous with the mucous membrane at the origin and termination of the alimentary canal and at the openings of other canals. The skin is a protective coat, a regulator of body temperature, contains multitudes of the terminations of sensor nerves, and is the seat of the **organ of**

¹ Journal of Anatomy and Physiology, 1891.

touch (*organon tactus*). These nerve terminations are connected with nerve fibres of temperature, pressure, and pain. Connected with the skin are sweat glands which have important excretory functions and sebaceous glands. From its superficial part come appendages, the hairs, and nails. The skin is elastic and varies in thickness from 0.5 mm. to 4 mm. ($\frac{1}{30}$ to $\frac{1}{8}$ inch). It is thinnest in the eyelids and prepuce, and thickest over the back of the neck, back of the shoulders, palms of the hands, and soles of the feet. Its color depends in part on the blood within it, and in part upon pigment. The deepest hue is about the anus, in the genital region, in the axillæ, over the mammary glands, and in the parts exposed to air, light, and varied temperatures. The color varies with age, being pinkish in extreme youth and becoming yellow in old age. It varies with

exposure and with climate, being deepest in those who brave all weathers and temperatures and in those who dwell beneath a tropical sun. It also varies with race, and this is so well recognized that races are classified by the color of the skin into the Black, White, Yellow, and Brown races. The color of the skin is also affected in certain diseases; being extremely pale in anemia, brown in Addison's disease, yellow in jaundice, etc.

In most situations the skin is movable, but in some it is attached closely to underlying structures, and is consequently immovable on the scalp, the palms of the hands, the soles of the feet, and the outer portion of the pinna of the ear. The skin is fairly smooth, but close examination dis-

FIG. 861.—The furrows and ridges of the surface of the skin from the palm or surface of the middle finger. (Toldt.)

closes multitudes of openings, creases, furrows, depressions, folds, and hairs. Hair follicles open upon the surface, and the ducts of sebaceous glands and of sweat glands perforate the skin.

About the joints are **folds of skin** (*retinacula cutis*), and temporary folds or wrinkles are created by the contraction of superficial muscles. The *facial wrinkles* of advancing years are due to habitual expression and loss of skin elasticity. A *dimple* is a permanent pit or depression due to adhesion of the surface to parts beneath. The ridges and furrows on the palms, soles, and flexor aspects of the digits are permanent, and over the palmar surface of the digits they are arranged in definite forms which endure through life and are so distinctive that they have been utilized by police officials in determining the identity of individuals. These folds are due to the papillæ of the skin being arranged in rows; some of the papillæ proliferate, and linear depressions occur in the horny layer (Phillipson).

Fig. 861 shows **skin ridges** (*cristae cutis*), **skin furrows** (*sulci cutis*), furrows opposite joints due to acts of flexion, and called **flexure furrows**, and **longitudinal furrows**.

When the skin is punctured by a round awl it tends to split in a definite direction, which direction varies with the region stabbed. These clefts are known as the **cleavage lines of Langer** (Figs. 862 and 863), and depend upon the arrangement of the connective-tissue bundles of the corium. These connective-tissue bundles certainly influence the formation of folds and furrows. In many portions of the body the cutaneous surface is divided by linear furrows into irregularly

shaped areas (Fig. 864). The skin consists of two layers: a superficial layer, the **epidermis**, and a deep layer, the **corium** or **dermis**.

The **Cuticle**, **Scarf Skin**, or **Epidermis** (Figs. 865 and 866) is composed of layers of epithelium and is derived from the ectoderm. The epithelium is strati-

FIG. 862.—Anterior surface.

FIG. 863.—Posterior surface.

The general course of the connective-tissue bundles of the corium, determined by the direction assumed by the linear clefts made in the skin when it is punctured by a round awl. (Langer.)

fied, and is devoid of bloodvessels. Two layers can be readily made out, the **superficial** or **horny layer** and the **deeper** or **Malpighian layer**.

The **horny layer** (*stratum corneum*) is formed by several layers of non-nucleated scaly cells. The cells consist of keratin. The surface cells of the horny layers

are being constantly rubbed off, and are being replaced by cells from the Malpighian layer, which are converted into keratin as they approach the surface.

The **Malpighian layer** (*stratum Malpighii*) of the epidermis is divided into four layers, named, from without inward, the **stratum lucidum**, the **stratum granulosum**, the **stratum mucosum**, and the **stratum germinativum**.

FIG. 864.—The furrows of the skin and the areas which these furrows delimit, reproduced from an impression of the dorsal surface of the wrist. (Toldt.)

The **stratum lucidum** is the most superficial part of the Malpighian layer. It consists of several layers of flat cells, the nuclei of which are beginning to disappear. The cells contain eleidin granules. In regions where the epidermis is thin the stratum lucidum is absent.

The **stratum granulosum** consists of several layers of nucleated flat cells, containing keratohyaline granules. These granules are probably formed from the disintegrating nucleus, and in the stratum lucidum are converted into eleidin, an intermediate substance in the formation of keratin.

FIG. 865.—Vertical section through the skin of the finger-tip. The layers of the epidermis and of the corium. The subcutaneous areolar tissue. The sudoriferous or sweat-gland. (Toldt.)

The **mucous layer** or the **stratum mucosum** consists of numerous layers of nucleated, polygonal, spine-shaped cells known as **prickle cells** or **finger cells**. Between the cells of the stratum mucosum are spaces containing pigment granules and leukocytes. Processes from the prickle cells join adjacent cells. This layer contains numerous connective-tissue fibres arranged in a network, and known as **epidermic fibrils**.

The **stratum cylindricum** or **stratum germinativum** is composed of cylindrical or prickle cells, the points of which are directed downward. Fine fibrils pass up

from the corium between the cells, and there is cement substance as well between them.

The **Corium, Cutis Vera, Dermis, or True Skin** (Figs. 866 and 870) is a connective-tissue structure which arises from the mesoderm. It consists especially of connective tissue and elastic fibres; it contributes elasticity to the skin, and is the seat of the sense organs. The corium is composed of two layers, the **papillary** and the **reticular**.

FIG. 866.—Diagrammatic sectional view of the skin. (Magnified.)

The **superficial or papillary layer or corpus papillare of the corium** (*stratum papillare*) lies just beneath the epidermis, contains the papillæ, and is composed of a network of fine bundles of fibrous tissue. The papillæ are composed of fine strands of connective tissue and elastic tissue. They project from the corium beneath the epidermis and enter into depressions of the epidermis. They vary greatly in size, averaging $\frac{1}{100}$ of an inch in height and $\frac{1}{200}$ of an inch in width at the base. In the face, especially in the eyelids, they are insignificant. On the glans penis, the palms of the hands, and the soles of the feet, and in the nipples, they are large. In the palmar surfaces of the hands and fingers and the plantar surfaces of the feet and toes they produce permanent ridges (Fig. 869). A ridge is composed of two or more rows of papillæ, and the ducts of sweat glands emerge

between rows of papillæ, and open on the curved surface ridges (Fig. 865). Most of the papillæ contain loops of capillaries, and are called **vascular papillæ**. Some contain nerve terminations, and are called **nerve papillæ**. Between the papillary

FIG. 867.—Section of epidermis. (Ranvier.)

layer of the corium and the epidermis is a very thin and structureless membrane called the **basal membrane**.

The **deep or reticular layer** (*stratum reticulare*) rests upon the subcutaneous tissue. It passes superficially into the papillary layer, and at most places into the subcutaneous tissue without a sharp line of differentiation. At some places, for instance in the nipple, the deep layer of the corium rests upon a layer of muscle tissue. In the face this muscle tissue is striated and sends prolongations to the papillary layer; in the nipple and scrotum it is nonstriated. The reticular layer is composed of bundles of white fibrous tissue, arranged in a network. In the meshes of the network are fat, bloodvessels, lymphatics, sebaceous glands, sweat glands, and hair follicles.

FIG. 868.—Vertical section through the skin of the trunk in the region of the arch of the ribs. One of the small hairs is seen in longitudinal section. (Toldt.)

spaces. In almost all regions the spaces contain fat, but in the scrotum, external ear, penis, and eyelid they do not contain fat. When the connective-tissue fibres of the panniculus adiposus are long and nearly parallel to the skin surface,

The **subcutaneous areolar tissue**, or **tela subcutanea** (*panniculus adiposus*), connects the skin to the parts beneath; it is composed of bundles of connective tissue which cross repeatedly and form

the skin becomes wrinkled; when they are short and nearly at right angles to the surface, the skin cannot wrinkle.

Pigmentation of the Skin.—As previously stated, in certain regions the skin of the white race is brown because of pigmentation (areolæ, nipples, around the anus,

FIG. 869.—The furrows and ridges of true skin on the palmar surface of one of the fingers, the epidermis having been removed. (Toldt.)

axillæ, scrotum, labia majora). This is due to pigment within the epithelial and connective-tissue cells of the papillary layer of the corium, and in the basal cells of the epidermis. There are few or none of these pigmented cells in the stratum corneum of one of the Caucasian race.

“In negroes and other colored races the deep pigmentation is due to a similar distribution of the pigment granules in the entire epidermis; but even here the

FIG. 870.—The distribution of the bloodvessels in the skin of the sole of the foot. (Spalteholz.)

pigmentation decreases toward the surface, although the uppermost cells of the stratum corneum always contain some pigment. The nuclei of the cells are always free from coloring matter. The question as to the origin of the pigment is as yet unsolved.”¹

¹ A Text-book of Histology. By A. A. Böhm and M. von Davidoff. Translated and edited by G. Carl Huber.

The **arteries** supplying the skin vary in number, and vary much in size, being largest in regions exposed to pressure, as the skin of the palms, soles, and buttocks. The arteries enter the skin from a network in the subcutaneous tissue, and by an anastomosis in the deepest part of the corium form a network (*rete arteriosum cutaneum*). The vessels send branches to the fat and to the sweat glands. Branches from the network just described ascend and form a second network in the corium beneath the papillæ. This is called the **subpapillary network** (*rete arteriosum subpapillare*). From this network fine capillary vessels pass into the papillæ, forming, in the smaller papillæ, a single capillary loop, but in the larger a more or less convoluted vessel. From this network branches go to the hair follicles and sebaceous glands. The blood from the papillæ passes into a plexus (*rete venosum*) beneath the papillæ. This communicates with another plexus between the corium and subcutaneous tissue. In some regions one or more retia are interposed between these two. The **veins** from the sweat glands, sebaceous glands, superficial fat, and hair follicles are received by the *retia venosa*. From the deepest rete veins pass to the subcutaneous tissue, and these veins enter the large subcutaneous veins.

There are numerous **lymphatics** supplied to the skin which form two networks, superficial and deep, communicating with each other and with the lymphatics of the subcutaneous tissue by oblique branches. They originate in the cell spaces of the tissue.

The **nerves** of the skin terminate partly in the epidermis (Fig. 867) and partly in the cutis vera (Fig. 866). The former are prolonged into the epidermis from a dense plexus in the superficial layer of the corium and terminate between the cells in bulbous extremities; or, according to some observers, in the deep epithelial cells themselves. The latter terminate in end bulbs, touch corpuscles, or Pacinian bodies (Figs. 590 and 866), in the manner already described (p. 819), and, in addition to these, a considerable number of fibrils are distributed to the hair follicles, which are said to entwine about the follicle in a circular manner. Other nerve fibres are supplied to the smooth muscle fibres (*m.m. arrectores pilorum*) of the hair follicles and to the muscle coat of the bloodvessels. These are probably amyelinic fibres.

THE APPENDAGES OF THE SKIN.

The appendages of the skin are the **nails**, the **hairs**, the **sudoriferous** and **sebaceous glands**, and their ducts.

The nails and hairs are peculiar modifications of the epidermis, consisting essentially of the same cellular structure as that tissue.

FIG. 871.—Longitudinal section through human nail and its nail groove (sulcus). (From Böhm and Davidoff's Histology.)

The **Nails** (*ungues*) (Figs. 871 and 874) are flattened, elastic structures of a horny texture, placed upon the dorsal surface of the terminal phalanges of the fingers and toes. Each nail is convex on its outer surface, concave within. Its chief mass, called the **body** (*corpus unguis*), lies upon the nail bed. The **free edge** is called the *margo liber*. Each **lateral margin** (*margo lateralis*), like the proximal **short edge of the nail** (*margo occultus*), lies in a groove of the cutis, the **ungual sulcus** (*sulcus matricis unguis*). The **ungual wall** (*valium unguis*) overlies the lateral and posterior edges. The nail is implanted by means of a portion, called the **root** (*radix unguis*), into a groove in the skin. The root is beneath the ungual wall and is composed of cells which have not yet become horny. It is white in color. The nail has a very firm adhesion to the cutis vera, being accurately moulded

upon the surface of the true skin, as the epidermis is in other parts. The part of the cutis beneath the body and root of the nail is called the **matrix** (*matrix unguis*), because it is the part from which the nail is produced. Corresponding to the body of the nail, the matrix is thick, and raised into a series of **longitudinal ridges** (*cristae matrixis unguis*), which are very vascular, and the color is seen through the transparent tissue. Behind this, near the root of the nail, the papillæ are small, less vascular, and have no regular arrangement, and here the tissue

FIG. 872.—Transverse section through human nail and its sulcus. (From Böhm and Davidoff's Histology.)

of the nail is somewhat more opaque; hence this portion is of a whiter color, and is called the **lunula** on account of its crescentic shape.

The cuticle, as it passes forward on the dorsal surface of the finger or toe, is attached to the surface of the nail, a little in advance of the nail root; at the extremity of the finger it is connected with the under surface of the nail a little behind its free edge. The cuticle and the horny substance of the nail (both epidermic structures) are thus directly continuous with each other. The nails consist of a greatly thickened stratum lucidum, the stratum corneum forming merely

FIG. 873.—Transverse section through the nail and the terminal portion of the ring finger. (Toldt.)

the thin cuticular fold (*eponychium*) which overlaps the lunula. The cells have a laminated arrangement, and are essentially similar to those composing the epidermis. The deepest layer of cells, which lie in contact with the papillæ of the matrix, are columnar in form and arranged perpendicularly to the surface; those which succeed them are of a rounded or polygonal form, the more superficial ones becoming broad, thin, and flattened, and so closely compacted as to make the limits of each cell very indistinct. It is by the successive growth of new cells at the root and under surface of the body of the nail that it advances forward and

maintains a due thickness, while, at the same time, the growth of the nail in the proper direction is secured. As these cells in their turn become displaced by the growth of new ones, they assume a flattened form and finally become closely

FIG. 874.—The finger-nail completely isolated, seen from the convex side. (Toldt.)

compacted together into a firm dense, horny texture. In *chemical composition* the nails resemble the upper layers of the epidermis, containing, however, a somewhat larger proportion of carbon and sulphur (Mulder).

The **Hairs** (*pili*) (Figs. 878 and 879) are peculiar modifications of the epidermis, and consist essentially of the same structure as that membrane. They are found on nearly every part of the surface of the body, excepting the palms of the hands, soles of the feet, the nipples, the inner surface of the prepuce, and the glans penis. Hairs include **hairs of the head** (*capilli*); of the **eyebrows** (*supercilia*); of the **beard** (*barba*); of the **ears** (*tragi*); of the **nostrils** (*vibrissæ*); the **eyelashes** (*cilia*); hairs of the **axilla** (*hirci*); of the **pubes** (*pubes*); and the small hairs of the **skin** or **woolly hairs** (*lanugo*). They vary much in length, thickness, and color in different parts of the body and in different races of mankind. In some parts, as in the skin of the eyelids, they are so short as not to project beyond the follicles containing them; in others, as upon the scalp, they are of considerable length; again, in other parts, as the eyelashes, the hairs of the pubic region, and the whiskers and beard, they are remarkable for their thickness. Straight hairs are stronger

FIG. 878.—Vertical section through the skin of the head. The hairs of the head in longitudinal section. (Toldt.)

than curly hairs, and present on transverse section a cylindrical or oval outline; curly hairs, on the other hand, are flattened. The hairs are usually oblique to the surface from which they arise (Fig. 878). Their direction depends upon the region from which they spring, being fairly regular in certain regions. Thus are formed **hair streams** (*flumina pilorum*) and **hair whirlpools** (*vortices pilorum*).

A hair consists of the **root**, the part implanted in the skin; the **shaft**, the portion projecting from its surface; and the **point**.

The **root of the hair** (*radix pili*) presents at its extremity a bulbous enlargement, the **hair bulb** (*bulbus pili*) (Fig. 877), which is whiter in color and softer in texture than the shaft, and is lodged in a follicular involution of the epidermis called the **hair follicle** (*folliculus pili*) (Fig. 868). When the hair is of considerable length the follicle extends into the subcutaneous cellular tissue. The hair follicle commences on the surface of the skin with a funnel-shaped opening, and passes inward in an oblique or curved direction—the latter in curly hair—to become dilated at its deep extremity or **fundus** (*fundus folliculi pili*), where it corresponds with the bulbous condition of the hair which it contains. It has opening into it, near its free extremity, the orifices of the ducts of one or more sebaceous glands (Figs. 877 and 878). At the bottom of each hair follicle is a small, conical, vascular eminence or papilla, the **hair papilla** (*papilla pili*) (Figs. 877 and 878), similar in every respect to the papillæ found upon the surface of the skin; it is continuous with the dermic layer of the follicle, is highly vascular, and is probably supplied

with nerve fibrils. In structure the hair follicle consists of two coats—an **outer** or **dermic**, and an **inner** or **epidermic** (Figs. 877 and 879).

The **outer** or **dermic coat** is formed mainly of fibrous tissue; it is continuous with the corium, is highly vascular, and is supplied by numerous minute nerve filaments. It consists of three layers. The most internal, the **cuticular lining of the follicle**, consists of a hyaline basement membrane, the **hyaline layer**, having a glassy, transparent appearance, which is well marked in the larger hair follicles, but is not very distinct in the follicles of minute hairs. It is continuous with the basement membrane of the surface of the corium. External to this is the **inner fibrous layer**, a compact layer of fibres and spindle-shaped cells arranged circularly around the follicle. This layer extends from the bottom of the follicle as high as the entrance of the ducts of the sebaceous glands. Externally is the **outer fibrous layer**, a thick layer of connective tissue, arranged in longitudinal bundles, forming a more open texture and corresponding to the reticular part of the corium. In this are contained the bloodvessels and nerves.

FIG. 879.—A moustache hair with its hair follicle in transverse section. (Toldt.)

The **inner** or **epidermic layer** is closely adherent to the root of the hair, so that when the hair is plucked from its follicle this layer most commonly adheres to it and forms what is called the **root sheath**. It consists of two strata, named respectively the **outer** and **inner root sheaths**; the former of these corresponds with the Malpighian layer of the epidermis, and resembles it in the rounded form and soft character of its cells; at the bottom of the hair follicles these cells become continuous with those of the root of the hair. The inner root sheath consists of a delicate cuticle next the hair, composed of a thin layer of imbricated scales having a downward direction, so that they fit accurately over the upwardly directed imbricated scales of the hair itself; then of one or two layers of horny, flattened nucleated cells, known as **Huxley's layer**; and finally of a single layer of horny oblong cells without visible nuclei, called **Henle's layer**.

The hair follicle contains the **root of the hair**, which terminates in a bulbous extremity, and is excavated so as to exactly fit the papilla from which it grows. The bulb is composed of polyhedral epithelial cells, which as they pass upward into the root of the hair become elongated and spindle-shaped, except some in the centre, which remain polyhedral. Some of these latter cells contain pigment granules, which give rise to the color of the hair. It occasionally happens that these pigment granules completely fill the cells of the medullary substance in the centre of the bulb, which gives rise to the dark tract of pigment often found, of greater or less length, in the axis of the hair.

The **shaft of the hair** (*scapus pili*) (Fig. 877) consists of a central pith or **medulla**, the fibrous part of the hair, and the true cuticle externally. The **medulla** (*substantia medullaris pili*) occupies the centre of the shaft and ceases toward the point of the hair. It is usually wanting in the fine hairs covering the surface of the body, and commonly in those of the head. It is found in the shafts of all thick hairs and in the deeper parts of the root of most hairs. It is more opaque and deeper colored when viewed by transmitted light than the fibrous part; but when viewed by reflected light it is white. It is composed of rows of polyhedral cells, which contain granules of eleidin and frequently air spaces. The **fibrous portion** or **cortical substance of the hair** (*substantia corticalis pili*) constitutes the chief part of the shaft; its cells are elongated and unite to form flattened fusiform fibres. Between the fibres are found minute spaces which contain either pigment granules in dark hair or minute air spaces in white hair. In addition to this there is also a diffused pigment contained in the fibres. The cells which form the **outer hair membrane** or **true cuticle** (*cuticula pili*) consist of a single layer which surrounds those of the fibrous part; they are converted into thin, flat scales, having an imbricated arrangement.

Connected with the hair follicles are minute bundles of involuntary muscle fibres, termed **Arrectores pilorum** (*mm. arrectores pilorum*) (Figs. 868 and 877). They arise from the superficial layer of the corium, and are inserted into the outer surface of the hair follicle, below the entrance of the duct of the sebaceous gland. They are placed on the side toward which the hair slopes, and by their action elevate the hair.¹ When the hair is elevated a depression forms over the seat of origin of the muscle, and the parts about the hair are elevated. This condition is known as **goose skin**. It is probable that the contraction of these muscles aids in emptying sebaceous glands.

Bloodvessels and Nerves (Fig. 868).—A hair follicle possesses a rich network of capillaries about the hyaline membrane, and capillary loops pass to the papilla. We have little knowledge as to nerve terminations of the human hair. "In other mammals the nerves end below the sebaceous glands. Myelinic fibres lose their myelin sheaths, divide, and penetrate to the hyaline membrane. Here some of the branches encircle the hair, while others end freely on the hyaline membrane as naked axis cylinders. These branch regularly and run parallel to the long axis of the hair."²

The **Sebaceous Glands** (*glandulae sebaceae*) are small, sacculated, glandular organs, lodged in the substance of the corium. They are found in most parts of the skin, but are especially abundant in the scalp and face; they are also very numerous around the apertures of the anus, nose, mouth, and external ear, but are wanting in the palms of the hands and soles of the feet. Each gland consists of a single duct, more or less capacious, which terminates in a cluster of small secreting pouches or saccules. The sacculi connected with each duct vary in number, as a rule, from two to five, but in some instances may be as many as twenty. They are composed of a transparent, colorless membrane, enclosing a number of epithelial cells. Those of the outer or marginal layer are small and polyhedral, and are continuous with the lining cells of the duct. The remainder of the sac is filled with larger cells, containing fat, except in the centre, where the cells have become broken up, leaving a cavity containing their debris and a mass of fatty matter, which constitutes the sebaceous secretion. The orifices of the ducts open most frequently into the hair follicles, but occasionally upon the general surface, as in the labia minora and the free margins of the lips. On the nose and face the glands are of large size, distinctly lobulated, and often become much

¹ Arthur Thomson suggests that the contraction of these muscles on follicles which contain weak, flat hairs will tend to produce a permanent curve in the follicle, and this curve will be impressed on the hair which is moulded within it, so that the hair, on emerging through the skin, will be curled. Curved hair follicles are characteristic of the scalp of the Bushman.

² Histology and Microscopic Anatomy. By Ladislaus Szymonowicz. Translated and edited by John Bruce MacCallum, M.D.

enlarged from the accumulation of pent-up secretion. The largest sebaceous glands are those found in the eyelids—the Meibomian glands.

The **Sudoriferous** or **Sweat Glands** (*glandulae sudoriferae*) (Figs. 868 and 878) are the organs by which a large portion of the aqueous and gaseous materials is excreted by the skin. They are found in almost every part of this structure, being absent on the red border of the lips, the glans penis, and inner surface of the prepuce. On the eyelids they are somewhat modified, and are called **ciliary glands** (*glandulae ciliares* [Molli]); about the anus they are extremely large, and are called **circumanal glands** (*glandulae circumanales*). The sweat glands are situated in small pits below the under surface of the corium, or, more frequently, in the subcutaneous areolar tissue, surrounded by a quantity of adipose tissue. They are small, lobular, reddish bodies, consisting of a single convoluted tube, from which the efferent duct (*ductus sudoriferus*) proceeds outward through the corium and cuticle, becomes somewhat dilated at its extremity, and opens on the surface of the cuticle by an oblique valve-like aperture (*porus sudoriferus*). The duct, as it passes through the epidermis, presents a spiral arrangement, being twisted like a corkscrew, in those parts where the epidermis is thick; where, however, the epidermis is thin, the spiral arrangement does not exist. In the superficial layers of the corium the duct is straight, but in the deeper layers it is convoluted or even twisted. The spiral course of these ducts is especially distinct in the thick cuticle of the palm of the hand and sole of the foot. The size of the glands varies. They are especially large in those regions where the flow of perspiration is copious, as in the axillæ, where they form a thin, mamillated layer of a reddish color, which corresponds exactly to the situation of the hair in this region; they are large also in the groin. Their number varies. They are most numerous on the palm of the hand, presenting, according to Krause, 2800 orifices on a square inch of the integument, and are rather less numerous on the sole of the foot. In both of these situations the orifices of the ducts are exceedingly regular, and open on the curved surface ridges. In other situations they are more irregularly scattered, but the number in a given extent of surface presents a fairly uniform average. In the neck and back they are least numerous, their number amounting to 417 on the square inch (Krause). Their total number is estimated by the same writer at 2,381,248, and supposing the aperture of each gland to represent a surface of $\frac{1}{16}$ of an inch in diameter, he calculates that the whole of these glands would present an evaporating surface of about eight square inches. Each gland consists of a single tube intricately convoluted, terminating at one end by a blind extremity, and opening at the other end upon the surface of the skin. The wall of the duct is thick, the lumen seldom exceeding one-third of the diameter of the tubes. The tube, both in the gland and where it forms the excretory duct, consists of two layers (except in the epidermis, where the epithelium of this layer forms the wall)—an outer, formed by fine areolar tissue, and an inner layer of epithelium. The external coat is thin, continuous with the superficial layer of the corium, and extends only as high as the surface of the corium. The epithelial lining in the distal part of the coiled tube consists of a single layer of cubical cells, supported on a basement membrane. Between the epithelium and the fibrocellular coat lies a layer of longitudinally or obliquely arranged involuntary muscle fibres, the contraction of which aid in the expulsion of the sweat. In the proximal part there are two or more layers of polyhedral cells lined on the internal surface (next the lumen of the tube) by a delicate membrane devoid of muscle fibres. The contents of the smaller sweat glands is quite fluid; but in the larger glands the contents are semifluid and opaque, and contain a number of colored granules and cells which appear analogous to epithelial cells.

The **bloodvessels** are branches from the subcutaneous vessels and the arterial plexus of the deep part of the corium. Numerous amyelinic **nerve fibres** lie upon the *membrana propria* of a sweat gland. From them fibrils pass inward and terminate by end bulbs upon the cells of the gland.

THE ORGANS OF VOICE AND RESPIRATION.

THE respiratory organs (*apparatus respiratorius*) consist of the **larynx**, or organ of voice, the **trachea**, **bronchi**, **lungs**, and **pleuræ**.

THE LARYNX.

The **larynx**, or organ of voice, is placed at the upper part of the air passage. It is situated between the trachea and base of the tongue, at the upper and fore part of the neck, where it forms a considerable projection in the middle line. On *either side* of it lie the great vessels of the neck; *behind*, it forms part of the boundary of the pharynx, and is covered by the mucous membrane lining that cavity. Its vertical extent corresponds to the fourth, fifth, and sixth cervical vertebræ, but it is placed somewhat higher in the female and also during childhood. In infants between six and twelve months of age Symington found that the tip of the epiglottis was a little above the level of the cartilage between the odontoid process and body of the axis, and that between infancy and adult life the larynx descends for a distance equal to two vertebral bodies and two intervertebral disks.

According to Sappey, the average measurements of the adult larynx are as follows:

	In males.	In females.
Vertical diameter	44 mm.	36 mm.
Transverse diameter	43 "	41 "
Antero-posterior diameter	36 "	26 "
Circumference	136 "	112 "

Until puberty there is no marked difference between the larynx of the male and that of the female. In the latter its further increase in size is only slight, whereas in the former the increase is great; all the cartilages are enlarged, and the thyroid becomes prominent as the pomum Adami in the middle line of the neck, while the length of the glottis is nearly doubled.

The larynx is broad above, where it presents the form of a triangular box, flattened behind and at the sides, and bounded in front by a prominent vertical ridge. Below, it is narrow and cylindrical. It is composed of cartilages, which are connected by ligaments and moved by numerous muscles. It is lined by mucous membrane, which is continuous above with that lining the pharynx and below with that of the trachea. On each side internal to the thyroid cartilage a small recess, the **recessus pyriformis**, extends forward from the cavity of the pharynx (p. 950).

The **Cartilages of the Larynx** (*cartilagine laryngis*) are nine in number, three single and three pairs:

Thyroid.	Two Arytenoid.
Cricoid.	Two Cornicula Laryngis.
Epiglottis.	Two Cuneiform.

The **Thyroid Cartilage** (*cartilago thyroidea*) (Figs. 881 and 882) is the largest cartilage of the larynx. It consists of two lateral **lamellæ** or **alæ**, united at an acute
(1165)

angle in front, forming a vertical projection in the midline, which is prominent above and called the **pomum Adami** (*prominentia laryngea*). This prominence is subcutaneous, is more distinct in the male than in the female, and is often separated from the integument by a bursa, the **bursa subcutanea prominentiae laryngeae**. The anterior borders of the alæ of the thyroid cartilage which are continuous below are separated above by a V-shaped notch, the **thyroid notch** (*incisura thyroidea [superior]*). The posterior borders are free, rounded, and somewhat thickened, and are extended in the form of superior and inferior cornua.

The *outer surface* of each ala (Fig. 881) presents an **oblique ridge** (*linea obliqua*), which passes downward and forward from a tubercle situated near the root of the superior cornu, the **superior tubercle** (*tuberculum thyroideum superius*), to a small tubercle near the anterior part of the lower border, the **inferior tubercle** (*tuberculum thyroideum inferius*). This ridge gives attachment to the Sternothyroid and Thyrohyoid muscles, and the portion of cartilage included between it and the posterior border gives attachment to part of the Inferior constrictor muscle.

FIG. 880.—Sagittal section of a man twenty-one years of age. (After W. Braune.)

FIG. 881.—Side view of the thyroid and cricoid cartilages.

The *inner surface* (Fig. 882) of each ala is smooth, slightly concave, and covered by the mucous membrane of the outer wall of the sinus pyriformis above and behind; but in front, in the receding angle formed by the junction of the alæ, are attached the epiglottis, the true and false vocal cords, the Thyroarytenoid and Thyroepiglottidean muscles, and the thyroepiglottidean ligament.

The *upper border* (Fig. 881) is sinuously curved, being concave at its posterior part, then rising into a convex outline in front; it gives attachment throughout its whole extent to the **thyrohyoid membrane**.

The *lower border* (Fig. 882) is nearly straight in front, but behind, close to the cornu, it is concave, the two parts being separated by the inferior tubercle. A small part of it, in and near the median line, is connected to the cricoid cartilage by the

middle portion of the **cricothyroid membrane** (*membrana cricothyroidea*); and, on either side, by the Cricothyroid muscle.

The **posterior borders** (Fig. 882) are thick and rounded, and each terminates above, in a **superior cornu** (*cornu superius*), and below, in an **inferior cornu** (*cornu inferius*). The two superior cornua are long and narrow, directed upward, backward, and inward, and terminate in conical extremities, which give attachment to the lateral thyrohyoid ligaments. The two inferior cornua are short and thick; they pass downward, with a slight inclination forward and inward, and each presents on its inner surface a small oval articular facet for articulation with the side of the cricoid cartilage (Fig. 881). The posterior border receives the insertion of the Stylopharyngeus and Palatopharyngeus muscles on each side.

During infancy the *alæ* of the thyroid cartilage are joined to each other by a narrow, lozenge-shaped strip, named the **intrathyroid cartilage**. This strip extends from the upper to the lower border of the thyroid cartilage in the middle line, and is distinguished from the *alæ* by being more transparent and more flexible.

The **Cricoid Cartilage** (*cartilago cricoidea*) (Figs. 881 and 882) is so called from its resemblance to a signet ring (*χιρικός*, a ring). It is smaller, but thicker and stronger than the thyroid cartilage, and forms the lower and back part of the cavity of the larynx. It is hyaline cartilage, and consists of two parts—a **quadrate portion**, situated behind, and a narrow ring, or **arch**, one-fourth or one-fifth the depth of the posterior part, situated in front. The posterior square portion rapidly narrows at the sides of the cartilage, at the expense of the upper border, into the anterior portion. It represents a modified tracheal ring.

Its **posterior portion**, or **lamina** (*lamina cartilaginis cricoideae*), is very deep and broad, and measures from above downward about an inch (2.5 cm.); it presents, on its posterior surface, in the middle line, a vertical ridge for the attachment of the longitudinal fibres of the *œsophagus*, and on either side a broad depression for the *Cricoarytenoideus posticus* muscle.

Its **anterior portion**, or **arcus** (*arcus cartilaginis cricoideae*), is narrow and convex, and measures vertically about one-fourth or one-fifth of an inch (5 to 6 mm.); it affords attachment externally in front and at the sides to the Cricothyroid muscles, and, behind, to part of the Inferior constrictor.

FIG. 882.—The cartilages of the larynx. Posterior view.

At the junction of the posterior quadrate portion with the rest of the cartilage is a small round articular eminence, for articulation with the inferior cornu of the thyroid cartilage.

The **lower border** of the cricoid cartilage is horizontal, and connected to the uppermost ring of the trachea by fibrous membrane (Figs. 881 and 882).

Its **upper border** is directed obliquely upward and backward, owing to the great depth of the posterior surface. It gives attachment, in front, to the middle portion of the cricothyroid membrane; at the sides, to the lateral portion of the same membrane and to the lateral Cricoarytenoid muscle; behind, it presents, in the middle, a shallow notch, and on each side of this is a smooth, oval surface, directed upward and outward, for articulation with the base of an arytenoid cartilage.

The **inner surface** of the cricoid cartilage is smooth, and lined with mucous membrane.

The **Arytenoid Cartilages** (*cartilagine arytenoideae*) (Fig. 882) are two in number, and situated at the upper border of the cricoid cartilage, at the back of the larynx in the interval between the posterior borders of the alæ of the thyroid cartilages. Each cartilage is in form a three-sided pyramid, and presents for examination **three surfaces**, a **base**, and an **apex**.

The **posterior surface** is triangular, smooth, concave, and gives attachment to the transverse portion of the Arytenoid muscle.

The **antero-external surface** is somewhat convex and rough. It presents, near its apex, a small elevation, the **colliculus**; from this a **ridge** (*crista arcuata*) passes backward and then forward and downward into a sharp-pointed process, the **vocal process**. This ridge separates a deep depression above, the **fovea triangularis**, from a broader and shallower depression below, the **fovea oblonga**. A short distance above the base a small tubercle on the anterior border gives origin to the ligament of the false vocal cord, the superior thyroarytenoid ligament. To the outer part of the ridge, as well as the surface above and below, is attached the Thyroarytenoid muscle.

The **internal surface** is narrow, smooth, and flattened, and forms the lateral boundary of the respiratory part of the glottis.

The **base** (*basis*) of each cartilage is broad, and presents a concave smooth surface, for articulation with the cricoid cartilage. Two of its angles require special mention: The **external angle**, which is short, rounded, and prominent, projects backward and outward, and is termed the **muscular process** (*processus muscularis*), from receiving the insertion of the Posterior and Lateral cricoarytenoid muscles. The **anterior angle**, also prominent, but more pointed, projects horizontally forward, and gives attachment to the inferior thyroarytenoid ligament, the supporting ligament of the true vocal cord. This angle is called the **vocal process** (*processus vocalis*).

The **apex** of each cartilage is pointed, curved backward and inward, and surmounted by a small conical, cartilaginous nodule, the **corniculum laryngis**, articulated with or united to the arytenoid cartilage.

The **Cornicula Laryngis** or **Cartilages of Santorini** (*cartilagine corniculatae*) (Figs. 882 and 888) are two small conical nodules, consisting of yellow elastic cartilage, which articulate with the summits of the arytenoid cartilages and serve to prolong them backward and inward. They are situated in the posterior parts of the arytenoepiglottic folds, and are sometimes united to the arytenoid cartilages.

The **Cuneiform Cartilages** or **Cartilages of Wrisberg** (*cartilagine cuneiformes*) (Figs. 882 and 887) are two small, elongated pieces of yellow elastic cartilage, placed one on each side, in the arytenoepiglottic fold (*plica aryepiglottica*) (Fig. 887), where they give rise to small whitish elevations on the inner surface of the mucous membrane, just in front of the arytenoid cartilages.

The **Epiglottis** (*cartilago epiglottica*) (Figs. 882 and 883) is a thin, flexible lamella of fibrocartilage, of a yellowish color, shaped like a leaf, and projecting behind the tongue in front of the superior opening of the larynx. The projecting extremity is broad and rounded; its attached part or apex (*petiolus epiglottidis*) is long, narrow, and connected to the receding angle between the two alæ of the thyroid cartilage, just below the median notch, by a ligamentous band, the **thyroepiglottic ligament** (Fig. 884). The lower part of its anterior surface is connected to the upper border of the body of the hyoid bone by an elastic ligamentous band, the **hyoepiglottic ligament**.

Its **anterior or lingual surface** is curved forward, toward the tongue, and covered at its upper, free part by mucous membrane, which is reflected on to the sides and base of the organ, forming a median and two lateral folds, the **glossoepiglottic folds** (Fig. 887); the lateral folds are partly attached to the wall of the pharynx. The depressions between the epiglottis and base of the tongue on each side of the median fold are named the **vallecule**. The lower part of the anterior surface of the epiglottis lies behind the hyoid bone, the thyrohyoid membrane, and upper part of the thyroid cartilage, but is separated from these structures by a mass of fatty tissue.

Its **posterior or laryngeal surface** is smooth, concave from side to side, concavo-convex from above downward; its lower part projects backward as an elevation, the **tubercle** or **cushion** (*tuberculum epiglotticum*) (Fig. 883). When the mucous membrane is removed, the surface of the cartilage is seen to be indented by a number of small pits, in which mucous glands are lodged. To its sides the **arytenoepiglottic folds** are attached (Fig. 887).

Structure.—The cornicula laryngis and cuneiform cartilages, the epiglottis, and the apices of the arytenoids at first consist of hyaline cartilage, but later elastic fibres grow in from the perichondrium, and eventually they are converted into yellow fibrocartilage; they show little tendency to calcification. The thyroid, cricoid, and the greater part of the arytenoids consist of hyaline cartilage, and become more or less ossified as age advances. Ossification commences about the twenty-fifth year in the thyroid cartilage, somewhat later in the cricoid and arytenoids; by the sixty-fifth year these cartilages may be completely converted into bone.

Ligaments.—The ligaments of the larynx are *extrinsic*—i. e., those connecting the thyroid cartilage and epiglottis with the hyoid bone, and the cricoid cartilage with the trachea; and *intrinsic*, those which connect the several cartilages of the larynx to each other.

Extrinsic Ligaments.—The ligaments connecting the thyroid cartilage with the hyoid bone are four in number—the thyrohyoid membrane, the two lateral thyrohyoid ligaments, and the hyoepiglottic ligament.

The **Thyrohyoid Membrane** (*membrana hyothyreoidea*) (Fig. 884) is a broad, fibroelastic, membranous layer, attached below to the upper border of the thyroid cartilage, and above to the upper margin of the posterior surface of the body and greater cornua of the hyoid bone, thus passing behind the posterior surface of the hyoid, and being separated from it by a synovial bursa (*bursa m. sternohyoidei*), which facilitates the upward movement of the larynx during deglutition. It is thicker in the middle line than at either side. This thickening is due to elastic fibres, and constitutes the **middle thyrohyoid ligament** (*ligamentum hyothyroideum medium*). On each side the posterior extremity of the membrane is thickened by elastic fibres, constituting the **lateral thyrohyoid ligament** (*ligamentum hyothyroideum laterale*). The thyrohyoid membrane is pierced on each side by the superior laryngeal vessels and the internal branch of the superior laryngeal nerve. The anterior surface of the thyrohyoid membrane is in relation with the Thyrohyoid, Sternohyoid, and Omohyoid muscles and with the body of the hyoid bone. The two lateral ligaments are rounded, elastic cords, which pass between the superior

cornua of the thyroid cartilage and the extremities of the greater cornua of the hyoid bone. A small cartilaginous nodule (*cartilago triticea*), sometimes bony, is frequently found in each.

The ligament connecting the epiglottis with the hyoid bone is the *hyoepiglottic*. In addition to this extrinsic ligament, the epiglottis is connected to the tongue by the three glossoepiglottic folds of mucous membrane, which may also be considered as extrinsic ligaments of the epiglottis. The **hyoepiglottic ligament** (*ligamentum hyoepiglotticum*) is an elastic band, which extends from the anterior surface of the epiglottis, near its apex, to the upper border of the body of the hyoid bone.

The **cricotracheal ligament** (*ligamentum cricotracheale*) connects the cricoid cartilage with the first ring of the trachea. It resembles the fibrous membrane which connects the cartilaginous rings of the trachea.

Intrinsic Ligaments.—The ligaments connecting the thyroid cartilage to the cricoid are three in number—the **cricothyroid membrane** and the two **capsular ligaments**.

The **Cricothyroid Membrane** (*conus elasticus*) (Figs. 881 and 891) is composed mainly of yellow elastic tissue. It consists of three parts, a central triangular portion and two lateral portions. The *central part* (*ligamentum cricothyroideum medium*) is thick and strong,

FIG. 883.—Coronal section of larynx, rear view of front half. (Testut.)

narrow above and broadening out below. It connects the contiguous margins of the thyroid and cricoid cartilages. It is convex, concealed on each side by the Cricothyroid muscle, but subcutaneous in the middle line; it is crossed horizontally by a small anastomotic arterial arch, formed by the junction of the two cricothyroid arteries. The *lateral portions* are thinner and lie close under the mucous membrane of the larynx. They extend from the superior border of the cricoid cartilage to the inferior margin of the true vocal cords with which they are continuous. These cords may therefore be regarded as the free borders of the lateral portions of the cricothyroid membrane; they

extend from the vocal processes of the arytenoid cartilages to the receding angle of the thyroid cartilage near its centre. The lateral portions are lined internally by mucous membrane, and are separated from the thyroid cartilage by the Cricothyroid lateralis and Thyroarytenoid muscles.

A **capsular ligament**, strengthened posteriorly by a well-marked fibrous band, encloses the articulation of the inferior cornu of the thyroid with the cricoid cartilage on each side. The articulation is lined by synovial membrane.

Each arytenoid cartilage is connected to the cricoid by a **capsular ligament** (*capsula articularis cricoarytaenoidea*) and a **posterior cricoarytenoid ligament** (*ligamentum cricoarytenoideum posterius*). The capsular ligament is thin and loose, and is attached to the margin of the articular surfaces, and lined by synovial

laterally, by a fold of mucous membrane, enclosing ligamentous and muscular fibres, stretched between the side of the epiglottis and the apex of the arytenoid cartilage; this is the **arytenoepiglottic fold** (Figs. 884 and 887), on the margin of which the cuneiform cartilage forms a more or less distinct whitish prominence.

The **superior or false vocal cords** (*plicae ventriculares*) (Figs. 883 and 884), so called because they are not directly concerned in the production of the voice, are two thick folds of mucous membrane, each enclosing a very narrow band of connective tissue, the so-called **superior thyroarytenoid ligament**. This is attached in front to the angle of the thyroid cartilage immediately below the attachment of the epiglottis, and behind to the antero-external surface of the arytenoid cartilage. The lower border of this ligament, enclosed in mucous membrane, forms a free crescentic margin, which constitutes the upper boundary of the ventricle of the larynx.

FIG. 885.—Muscles of larynx, front view. The Sternothyroids and right Thyrohyoid have been removed. (Testut.)

FIG. 886.—Muscles of larynx, from behind. (Testut.)

The **inferior or true vocal cords** (*plicae vocales*) (Figs. 883 and 884), so called from their being concerned in the production of sound, are two strong bands named the **inferior thyroarytenoid ligaments**. Each ligament consists of a band of yellow elastic tissue, attached in front to the depression between the alæ of the thyroid cartilage, and behind to the vocal process at the base of the arytenoid. Its lower border is continuous with the thin lateral part of the cricothyroid membrane. Its upper border forms the lower boundary of the ventricle of the larynx. Externally, the Thyroarytenoideus muscle lies parallel with it. It is covered internally by mucous membrane, which is extremely pale, thin, and closely adherent to its surface. The node-like attachment of the ligament to the thyroid cartilage appears as a yellow spot (*macula flava*); the vocal process also shines through the mucosa as a yellowish spot.

The **ventricle of the larynx or laryngeal sinus** (*ventriculus laryngis* [Morgagni]) (Figs. 883 and 884) is an oblong fossa, situated between the superior and inferior vocal cords on each side, and extending nearly their entire length. This fossa is bounded, above, by the free crescentic edge of the false vocal cord; below, by the

straight margin of the true vocal cord; externally, by the mucous membrane covering the corresponding Thyroarytenoideus muscle. The anterior part of the ventricle leads up by a narrow opening into a cecal pouch of mucous membrane of variable size, called the **laryngeal saccule**.

The **laryngeal saccule** (*appendix ventriculi*) (Fig. 883), or laryngeal pouch, is a membranous sac, placed between the superior vocal cord and the inner surface of the thyroid cartilage, occasionally extending as far as its upper border or even higher; it is conical in form, and curved slightly backward. On the surface of its mucous membrane are the openings of sixty or seventy mucous glands, which are lodged in the submucous areolar tissue. This sac is enclosed in a fibrous capsule, continuous below with the superior thyroarytenoid ligament; its laryngeal surface is covered by a few delicate muscle fasciculi which arise from the apex of the arytenoid cartilages and become lost in the fold of mucous membrane extending between the arytenoid cartilage and the side of the epiglottis (they were named by Hilton the *compressor sacculi laryngis*); while its exterior is covered by the Thyroarytenoideus and Thyroepiglottideus muscles. These muscles compress the laryngeal saccule, and express the secretion it contains upon the vocal cords to lubricate their surfaces.

FIG. 887.—Larynx, viewed from above. (Testut.)

The **Rima Glottidis** (Figs. 883 and 887) is the elongated fissure or chink between the true vocal cords in front, and between the bases and vocal processes of the arytenoid cartilages behind. It is therefore frequently subdivided into an anterior, interligamentous or **vocal portion**, the **glottis vocalis** (*pars intermembranacea*), and a posterior, intercartilaginous or **respiratory portion**, the **glottis respiratoria** (*pars intercartilaginea*). Posteriorly it is limited by the mucous membrane passing between the arytenoid cartilages. The vocal portion averages about three-fifths of the length of the entire aperture. It is the narrowest part of the cavity of the larynx, and its level corresponds to the bases of the arytenoid cartilages. Its length, in the male, measures rather less than an inch (23 mm.); in the female it is shorter (16 to 20 mm.). The width and shape of the rima glottidis vary with the movements of the vocal cords and arytenoid cartilages during respiration and phonation. In the condition of rest—*i. e.*, when those structures are uninfluenced by muscular action, as in quiet respiration, the glottis vocalis is triangular, with its apex in front and its base behind, the latter being represented by a line

about 8 mm. ($\frac{1}{8}$ inch) long, connecting the anterior extremities of the vocal processes, while the inner surfaces of the arytenoids are parallel to each other, and hence the glottis respiratoria is rectangular. During extreme adduction of the cords, as in the emission of a high note, the glottis vocalis is reduced to a linear slit by the apposition of the cords, while the glottis respiratoria is triangular, its apex corresponding to the anterior extremities of the vocal processes of the arytenoids, which are approximated by the inward rotation of the cartilages. Conversely in extreme abduction of the cords, as in forced inspiration, the arytenoids and their vocal processes are rotated outward, and the glottis respiratoria is triangular in shape, but with its apex directed backward. In this condition the entire glottis is somewhat lozenge-shaped, the sides of the glottis vocalis diverging from before backward, those of the glottis respiratoria diverging from behind forward, the widest part of the aperture corresponding with the attachment of the cords to the vocal processes.

Muscles of the Larynx.—The *extrinsic* muscles are those which pass between the larynx and parts around—these have been described on pages 387 to 389. The *intrinsic* muscles, confined entirely to the larynx, are:

Cricothyroideus.	Cricoarytenoideus lateralis.
Cricoarytenoideus posticus.	Arytenoideus.
Thyroarytenoideus.	

The Arytenoideus is a single muscle, the other four are paired.

Dissection.—In order to expose the Lateral cricothyroid and Thyroarytenoid muscles the thyroid cartilage of one side must be removed. Begin by taking away the Cricothyroid muscle, then dividing the lateral thyrohyoid ligament; disarticulate the inferior cornu of the thyroid cartilage from the cricoid cartilage, then carefully cut through the thyroid cartilage a short distance from its union with its twin.

The **Cricothyroid** (*m. cricothyroideus*) (Figs. 888 and 889) is triangular in form, and situated at the fore part and side of the cricoid cartilage. It *arises* from the front and lateral part of the cricoid cartilage; its fibres diverge, passing obliquely upward and outward to be *inserted* into the lower border of the thyroid cartilage and into the anterior border of the lower cornu. The inner borders of these two muscles are separated in the middle line by a triangular interval occupied by the central part of the cricothyroid membrane.

The **Posterior Cricoarytenoid** (*m. cricoarytaenoideus posterior*) (Figs. 888 and 889) *arises* from the broad depression occupying each lateral half of the posterior surface of the cricoid cartilage; its fibres pass upward and outward, converging to be *inserted* into the outer angle (muscular process) of the base of the arytenoid cartilage. The upper fibres are nearly horizontal, the middle oblique, and the lower almost vertical.

The **Lateral Cricoarytenoid** (*m. cricoarytaenoideus lateralis*) (Figs. 888 and 889) a paired muscle, is smaller than the preceding, and of an oblong form. It *arises* from the upper border of the side of the cricoid cartilage, and, passing obliquely upward and backward, is *inserted* into the muscular process of the arytenoid cartilage in front of the posterior Cricoarytenoid muscle. The deep surface is applied to the cricothyroid membrane, its external or superficial surface is subjacent to the thyroid cartilage.

The **Arytenoideus** (Figs. 888 and 889) is a single muscle filling up the posterior concave surface of the arytenoid cartilages. It *arises* from the posterior surface and outer border of one arytenoid cartilage, and is inserted into the corresponding parts of the opposite cartilage. It consists of three planes of fibres, two oblique and one transverse. The **oblique fibres** (*m. arytenoideus obliquus*),

the most superficial, form two fasciculi, which pass from the base of one cartilage to the apex of the opposite one, and which, therefore, cross each other like the limbs of the letter X. The **transverse fibres** (*m. arytaenoideus transversus*), the deepest and most numerous, pass transversely across between the two cartilages. A few of the oblique fibres are continued around the outer margin of the cartilage, and blend with the Thyroarytenoid in the arytenoepiglottic fold, and are called the **Aryepiglotticus** muscle.

The **Thyroarytenoid** (*m. thyroarytenoideus*) (Figs. 888 and 889), a paired muscle, is broad and flat. It lies parallel with the outer side of the true vocal cord. It arises in front from the lower half of the receding angle of the thyroid cartilage, and from the cricothyroid membrane. Its fibres pass backward and outward, to be inserted into the base and antero-external surface of the arytenoid cartilage. This muscle consists of two fasciculi.¹

The **inner portion** (*m. vocalis*) is a triangular band which is inserted into the vocal process of the arytenoid cartilage, and into the adjacent portion of its antero-external surface; it lies parallel with the true vocal cord, to which it is adherent. This fasciculus on its deeper surface

FIG. 888.—Muscles of larynx. Side view. Right ala of thyroid cartilage removed.

FIG. 889.—Interior of the larynx, seen from above. (Enlarged.)

gives off some fibres which are attached to the true vocal cord. These are called the **Aryvocalis** (Ludwig). The **outer portion** (*m. thyreoarytenoideus*), the thinner, is inserted into the antero-external surface and outer border of the arytenoid cartilage above the preceding fibres; it lies on the outer side of the laryngeal saccule, immediately beneath the mucous membrane.

A considerable number of the fibres of the Thyroarytenoideus are prolonged into the arytenoepiglottic fold, where some of them become lost, while others are continued forward to the margin of the epiglottis. They have received a distinctive name, **Thyroepiglotticus** (*m. thyreoepiglotticus*), and are sometimes described as a separate muscle.

¹ Henle describes these two portions as separate muscles, under the names of the External and Internal thyroarytenoids.

Actions.—In considering the action of the muscles of the larynx, they may be conveniently divided into two groups—viz.: (1) Those which open and close the glottis. (2) Those which regulate the degree of tension of the vocal cords.

1. The muscles which open the glottis are the two Posterior cricoarytenoids; and those which close it are the Arytenoideus and the two Lateral cricoarytenoids.

2. The muscles which regulate the tension of the vocal cords are the two Cricothyroids, which render tense and elongate them, and the two Thyroarytenoids, which relax and shorten them.

The *Posterior cricoarytenoids* separate the chordae vocales, and consequently open the glottis, by rotating the arytenoid cartilages outward around a vertical axis passing through the cricoarytenoid joints, so that their vocal processes and the vocal cords attached to them become widely separated.

The *Lateral cricoarytenoids* close the glottis by rotating the arytenoid cartilages inward so as to approximate their vocal processes.

The *Arytenoideus muscle* approximates the arytenoid cartilages, and thus closes the opening of the glottis, especially at its back part.

The *Cricothyroid muscles* produce tension and elongation of the vocal cords. This is effected as follows: the thyroid cartilage is fixed by its Extrinsic muscles; then the Cricothyroid muscles, when they act, draw upward the front of the cricoid cartilage, and so depress the posterior portion, which carries with it the arytenoid cartilages, and thus elongate the vocal cords.

The *Thyroarytenoid muscles*, consisting of two parts having different attachments and different directions, are rather complicated as regards their action. Their main use is to draw the arytenoid cartilages forward toward the thyroid, and thus shorten and relax the vocal cords. But, owing to the connection of the inner portion with the vocal cord, this part, if acting separately, is supposed to modify its elasticity and tension, and the outer portion, being inserted into the outer part of the anterior surface of the arytenoid cartilage, may rotate it inward, and thus narrow the rima glottidis by bringing the two cords together.

The manner in which the superior aperture of the larynx is closed during deglutition is referred to on page 400.

The **mucous membrane of the larynx** is continuous above with that lining the mouth and pharynx, and it is prolonged through the trachea and bronchi into the lungs. It lines the posterior surface and the anterior part of the upper surface of the epiglottis, to which it is closely adherent. In the rest of the larynx, above the true vocal cords, it is lax and rests upon a considerable submucous layer. The mucous membrane, with the submucous coat, ligamentous and muscular fibres, forms the arytenoepiglottic folds, which folds are the lateral boundaries of the superior aperture of the larynx. It lines the whole of the cavity of the larynx, forms by its reduplication the chief part of the superior or false vocal cord, and, from the ventricle, is continued into the laryngeal sacculæ. It is then reflected over the true vocal cords, where it is thin and very intimately adherent; covers the inner surface of the cricothyroid membrane and cricoid cartilage; and is ultimately continuous with the lining membrane of the trachea. The fore part of the anterior surface and the upper half of the posterior surface of the epiglottis, the upper part of the arytenoepiglottic folds, and the true vocal cords are covered by stratified squamous epithelium; the rest of the laryngeal mucous membrane is covered by stratified ciliated cells.

The mucous membrane above the rima glottidis is extremely sensitive, and during life the lightest touch of a foreign body produces cough.

Glands.—The mucous membrane of the larynx is furnished with numerous muciparous glands, the orifices of which are found in nearly every part; they are very numerous upon the epiglottis, being lodged in little pits in its substance; they are also found in large numbers along the posterior margin of the arytenoepiglottic fold, in front of the arytenoid cartilages, where they are termed the **arytenoid glands**. They exist also in large numbers upon the inner surface of the laryngeal sacculæ. None are found on the surface of the true vocal cords.

Vessels and Nerves.—The **arteries of the larynx** (Fig. 890) are the **laryngeal branches** derived from the superior and inferior thyroid. The **superior laryngeal artery** from the superior thyroid accompanies the internal branch of the superior laryngeal nerve; the **inferior laryngeal artery** from the inferior thyroid courses along with the recurrent laryngeal nerve. The **veins** accompany the arteries; those accompanying the superior laryngeal artery join the **superior thyroid vein**, which opens into the internal jugular vein; while those accompanying the inferior laryngeal artery join the **inferior thyroid vein**, which opens into the innominate vein. The **lymphatics** consist of two sets, superior and inferior. The superior accompany the superior laryngeal artery, pierce the thyrohyoid membrane, and terminate in the nodes situated at the bifurcation of the carotid artery. Of the inferior lymphatics, some pass through the cricothyroid membrane to terminate in a node lying in front of that membrane or in front of the upper part of the trachea, while others pass to the deep cervical nodes and to the nodes along the inferior thyroid artery.

The **nerves** are derived from the **internal and external laryngeal branches of the superior laryngeal nerve**, from the **inferior or recurrent laryngeal**, and from the **sympathetic**. The

internal laryngeal nerve is almost entirely sensor, but some motor filaments are said to be carried by it to the Arytenoideus muscle. It divides into a branch which is distributed to both surfaces of the epiglottis, a second to the arytenoepiglottic folds, and a third, the largest, which supplies the mucous membrane over the back of the larynx and communicates with the recurrent laryngeal. The external laryngeal branch supplies the Cricothyroid muscle. The recurrent laryngeal passes upward under the lower border of the Inferior constrictor, and enters the larynx between the cricoid and thyroid cartilages. It supplies all the muscles of the larynx except the Cricothyroid and part of the Arytenoideus. The sensor branches of the laryngeal nerves form subepithelial plexuses, from which fibres ascend to end between the cells covering the mucous membrane. Sympathetic filaments accompany all of the laryngeal nerves.

Over the posterior surface of the epiglottis, in the arytenoepiglottidean folds, and less regularly in some other parts, taste buds, similar to those in the tongue, are found.

FIG. 890.—The origin and distribution of the arteries of the larynx. (Luschka.)

THE TRACHEA AND BRONCHI (Fig. 891).

The **trachea**, or **windpipe**, is a cartilaginous, membranous, elastic, cylindrical tube, flattened posteriorly, which extends from the lower part of the larynx, on a level with the sixth cervical vertebra, to opposite the body or upper border of the fifth thoracic vertebra, where it divides (*bifurcatio tracheae*) into **two bronchi**, one for each lung. The trachea is nearly, but not quite, cylindrical, being flattened posteriorly (Fig. 893). The largest diameter of the tube is at the middle; from this point the diameter diminishes toward the bronchi and toward the laryngeal end. The trachea measures about four inches and a half (11 cm.) in length; its diameter, in the cadaver, from side to side is from three-quarters of an inch to an inch (19 to 25 mm.), being always greater in the male than in the female. Its calibre is not quite uniform throughout; the middle third is somewhat wider than the rest of the tube, while just below, before its bifurcation, the trachea is slightly diminished in diameter where it is in relation with the arch of the aorta. In the living subject, owing to the muscle tone of the wall, the transverse diameter is 12.5 mm. (0.5 inch); the antero-posterior, 11 mm. (0.44 inch).

Relations.—The anterior surface of the trachea is convex, and covered in the neck, from above downward, by the isthmus of the thyroid gland, the inferior thyroid veins, the arteria

thyroidea ima (when that vessel exists), the Sternohyoid and Sternothyroid muscles, the cervical fascia, and, more superficially, by the anastomosing branches between the anterior jugular veins; **in the thorax** it is covered from before backward by the first piece of the sternum, the remains of the thymus gland, the left innominate vein, the arch of the aorta, the innominate and left common carotid arteries, and the deep cardiac plexus. Posteriorly, it is in relation with the œsophagus; laterally, **in the neck**, it is in relation with the common carotid arteries, the lateral lobes of the thyroid gland, the inferior thyroid arteries, and recurrent laryngeal nerves; and, **in the thorax**, it lies in the upper part of the **interpleural space** (*superior mediastinum*), and is in relation on the right with the pleura and right vagus, and near the root of the neck with the innominate artery; on its left side are the recurrent laryngeal nerve, the aortic arch, the left common carotid and subclavian arteries.

FIG. 891.—Front view of cartilages of larynx, the trachea and bronchi.

The **Right Bronchus** (*bronchus dexter*) (Fig. 891), wider, shorter, and more vertical in direction than the left, is about an inch in length (2.5 cm.), and enters the hilum of the right lung opposite the fifth thoracic vertebra. It forms an angle

to the median plane of about 25 degrees. The vena azygos major arches over it from *behind*; and the right pulmonary artery lies *below* and then in *front* of it. About three-quarters of an inch from its commencement it gives off a branch to the upper lobe of the right lung. This is termed the **eparterial branch bronchus** (*ramus bronchialis eparterialis*), because it is given off above the right pulmonary artery. The bronchus now passes below the artery, is known as the **hyparterial branch bronchus** (*ramus bronchialis hyparterialis*), and divides into two branches for the middle and lower lobes.

FIG. 892.—Internal surface of the bronchi. (Poirier and Charpy.)

The **Left Bronchus** (*bronchus sinister*) (Fig. 891) is smaller and longer than the right, being nearly two inches in length. It forms an angle to the median plane of about 46 degrees. It is slightly curved and enters the root of the left lung, opposite the sixth thoracic vertebra, about an inch lower than the right bronchus. It passes beneath the arch of the aorta, crosses in front of the œsophagus, the thoracic duct, and the descending aorta, and has the left pul-

FIG. 893.—Transverse section of the trachea, just above its bifurcation, with a bird's-eye view of the interior.

monary artery lying at first above, and then behind it. The left bronchus has no branch corresponding to the eparterial branch of the right bronchus in the sense that it is given off above the pulmonary artery. The first hyparterial branch bronchus of the left side is the morphological equivalent of the right eparterial branch bronchus, as shown by Huntington.¹

The further subdivision of the bronchi will be considered with the anatomy of the lung.

If a transverse section of the trachea is made a short distance above its point of bifurcation, and a bird's-eye view taken of its interior (Fig. 893), the septum placed at the bottom of the trachea and separating the two bronchi will be seen to occupy the left of the median line, and the right bronchus appears to be a more direct continuation than the left, so that any solid body dropping into the trachea would naturally be directed toward the right bronchus. This tendency is aided by the larger size of the right tube as compared with its fellow. This fact serves to explain why a foreign body in the trachea more frequently falls into the right bronchus than into the left.²

Structure of the Trachea.—The trachea is composed of imperfect cartilaginous rings, fibrous membrane, muscular fibres, mucous membrane, and glands.

The **Cartilages** vary from sixteen to twenty in number; each forms an incomplete ring, which surrounds about two-thirds of the cylinder of the trachea, being imperfect behind, where the

¹ The Eparterial Bronchial System of the Mammalia, Annals N. Y. Acad. Sci., 1898.

² Reigel asserts that the entrance of a foreign body into the *left* bronchus is by no means so infrequent as is generally supposed. See also Med.-Chir. Transactions, vol. lxxi, p. 121.

tube is completed by fibrous membrane. The cartilages are placed horizontally above each other, separated by narrow intervals bridged by fibroelastic tissue. They measure about $\frac{1}{4}$ of an inch in depth, and $\frac{1}{3}$ of an inch in thickness, tapering at their posterior ends. Their outer surfaces are flattened, but internally they are convex, from being thicker in the middle than at the margins. Two or more of the cartilages often unite, partially or completely, and are sometimes bifurcated at their extremities. They are highly elastic, but sometimes become calcified in advanced life. In the right bronchus the cartilages vary in number from six to eight; in the left, from nine to twelve. They are shorter and narrower than those of the trachea. The peculiar cartilages are the first and the last.

The **first cartilage** is broader than the rest, and sometimes divided at one end; it is connected by fibrous membrane with the lower border of the cricoid cartilage, with which or with the succeeding cartilage it is sometimes blended.

The **last cartilage** is thick and broad in the middle, in consequence of its lower border being prolonged into a triangular hook-shaped process which curves downward and backward between the two bronchi. It terminates on each side in an imperfect ring which encloses the commencement of the bronchi. The cartilage above the last is often somewhat broader than the rest at its centre.

Dorsal view.

Ventral view.

FIGS. 894 AND 895.—Radiographs of trachea and bronchi filled with fusible metal. (After J. A. Blake.)

The Fibrous Membrane.—The cartilages are enclosed in a fibroelastic membrane which forms a double layer, one layer, the thicker of the two, passing over the outer surface of the ring, the other over the inner surface; at the upper and lower margins of the cartilages these two layers blend together to form a single membrane, which intervenes between the rings. They are thus, as it were, embedded in the membrane. In the space behind, between the extremities of the rings, the membrane forms a single distinct layer.

The **muscular fibres** are disposed in two layers, **longitudinal** and **transverse**.

The **longitudinal fibres** are external, and consist merely of a few scattered longitudinal bundles of fibres.

The **transverse fibres**, the **Trachealis muscle of Todd and Bowman**, form a thin internal layer which extends transversely between the ends of the cartilages and the intervals between them, thus extending the entire length of the posterior part of the trachea. The muscular fibres are of the unstriated variety.

The **mucous membrane** is continuous above with that of the larynx, and below with that of the bronchi. Microscopically, it consists of stratified ciliated epithelial cells, among which a number of goblet cells are seen; the basal cells are often branched and rest upon the basement membrane, beneath which is a layer of fibroelastic tissue containing diffuse lymphoid tissue. The tunica propria blends with the next coat, the submucosa, and here are found the cartilage rings and a number of mucous glands, the tracheal glands.

The **tracheal glands** (*glandulae tracheales*) are found in great abundance at the posterior part of the trachea. They are racemose glands, and consist of a basement membrane lined by columnar mucus-secreting cells. They are situated at the back of the trachea, outside the layer of muscular tissue, between it and the outer fibrous layer. Their excretory ducts pierce the

muscular and inner fibrous layers, and pass through the submucous and mucous layers to open on the surface of the mucous membrane. Some glands of smaller size are also found at the sides of the trachea, between the layers of fibrous tissue connecting the rings, and others immediately beneath the mucous coat. The secretion from these glands serves to lubricate the inner surface of the trachea.

Vessels and Nerves.—The trachea is supplied with blood by the inferior thyroid arteries. The veins terminate in the thyroid venous plexus. The nerves are derived from the vagus and its recurrent branches and from the sympathetic.

Lymph Nodes.—The trachea is surrounded by lax connective tissue which contains numerous lymph nodes, known as the **peritracheobronchial nodes**. They are divided into four groups (Baréty). A group to the **right side**, in the angle between the trachea and right bronchus and ascending to the region of the subclavian vessels. A group to the **left side**, in the angle formed by the trachea and left bronchus, and ascending to about the arch of the aorta and the recurrent laryngeal nerve. The two groups just described are usually called **tracheal nodes** (*lymphoglandulae tracheales*). A third group is in the angle formed by the bifurcation of the trachea. These constitute the **bronchial nodes** (*lymphoglandulae bronchiales*), ten or twelve in

FIG. 896.—The tracheobronchial and bronchopulmonary lymph nodes, seen from in front. The dotted lymph nodes and lymph vessels are not visible from in front: d^1, d^2 . First and second dorsal branch bronchi, v^1, v^2 . First and second ventral branch bronchi. (Sukiennikow.)

number. A fourth group, the **interbronchial nodes**, are found in angles of bifurcation of the larger bronchi in the lung parenchyma. Very early in life the peritracheobronchial nodes become dark or even black from the deposition of carbonaceous substance brought by the leukocytes from the bronchial tubes. This condition is called **anthracosis**.

Surface Form.—In the middle line of the neck some of the cartilages of the larynx can readily be distinguished. In the angle below the chin the hyoid bone can easily be distinguished, and a finger's breadth below it is the pomum Adami, the prominence between the upper borders of the two alae of the thyroid cartilage. About an inch below this, in the middle line, is a depression corresponding to the cricothyroid space, in which the operation of laryngotomy is performed. This depression is bounded below by a prominent arch, the anterior ring of the cricoid cartilage, below which the trachea can be felt, though it is only in the emaciated adult that the separate rings can be distinguished. The lower part of the trachea is not easily observed, for as it descends in the neck, following the curvature of the vertebral column, it takes a deeper position, and is farther removed from the surface. The level of the vocal cords corresponds to the middle of the anterior margin of the thyroid cartilage.

With the *laryngoscope*, the following structures can be seen. The base of the tongue and the upper surface of the epiglottis, with the glossoepiglottic ligaments; the superior aperture of

the larynx, bounded on either side by the arytenoepiglottidean folds, in which may be seen two rounded eminences corresponding to the cornicular and cuneiform cartilages. Beneath these, the true and false vocal cords, with the ventricle between them. Still deeper, the cricoid cartilage and some of the anterior parts of the rings of the trachea, and sometimes, in deep inspiration, the bifurcation of the trachea.

Applied Anatomy.—*Foreign bodies* often find their way into the air passages. These may be large, soft substances, as a piece of meat, which may become lodged in the upper aperture of the larynx or in the rima glottidis, and cause speedy suffocation unless rapidly got rid of, or unless an opening is made into the air passages below, so as to enable the patient to breathe. Smaller bodies, frequently of a hard nature, such as cherry- or plum-stones, small pieces of bone, buttons, etc., may find their way through the rima glottidis into the trachea or bronchus, or may become lodged in the ventricle of the larynx. The dangers then depend not so much upon the mechanical obstruction as upon the spasm of the glottis which they excite from reflex irritation. When lodged in the ventricle of the larynx, they may produce very few symptoms beyond sudden loss of voice or alteration in the voice sounds, immediately following the inhalation of the foreign body. When, however, they are situated in the trachea, they are constantly striking against the vocal cords during expiratory efforts, and produce attacks of dyspnea from spasm of the glottis. When lodged in the bronchus, they usually become fixed there, and, occluding the lumen of the tube, cause a loss of the respiratory murmur on the affected side, which is, as stated above, more often the right.

Beneath the mucous membrane of the upper part of the air passages there is a considerable amount of submucous tissue which is liable to become much swollen from effusion in inflammatory affections, constituting the disease known as "*edema of the glottis*." This effusion does not extend below the level of the true vocal cords, on account of the fact that the mucous membrane is closely adherent to these structures, without the intervention of any submucous tissue. So that, in cases of this disease in which it is necessary to open the air passages to prevent suffocation, the operation of laryngotomy is sufficient.

Chronic laryngitis is an inflammation of the mucous membrane of the larynx, which occurs in those who speak much in public, and is known as "*clergyman's sore throat*." It is due to the dryness induced by the large amount of cold air drawn into the air passages during prolonged speaking, which incites increased activity in the mucous glands to keep the parts moist, and this eventually terminates in inflammation of these structures.

Ulceration of the larynx may occur from syphilis, either as a superficial ulceration, or from the softening of a gumma; from tuberculous disease (laryngeal phthisis), or from malignant disease (epithelioma).

The air passages may be opened surgically in two different situations—through the cricothyroid membrane (*laryngotomy*), or in some part of the trachea (*tracheotomy*); and to these some surgeons have added a third method—opening the cricothyroid membrane and dividing the cartilage with the upper ring of the trachea (*laryngotracheotomy*).

Laryngotomy is anatomically the more simple operation; it can readily be performed, and should be employed in those cases where the air passages require opening in an emergency for the relief of some sudden obstruction to respiration. The cricothyroid membrane is very superficial, being covered in the middle line only by the skin, superficial fascia, and the deep fascia. On each side of the middle line it is also covered by the Sternohyoid and Sternothyroid muscles, which diverge from each other at their upper parts, leaving a slight interval between them. On these muscles rest the anterior jugular veins. The only vessel of any importance in connection with this operation is the cricothyroid artery, which crosses the cricothyroid membrane, and which may be wounded, but rarely gives rise to any trouble. The operation is performed thus: The head being thrown back and steadied by an assistant, the finger is passed over the front of the neck, and the cricothyroid depression felt for. A vertical incision is then made through the skin, in the middle line over this spot, and carried down through the fascia until the cricothyroid membrane is exposed. A cross-cut is then made through the membrane, close to the upper border of the cricoid cartilage, so as to avoid, if possible, the cricothyroid artery, and a tracheotomy tube is introduced. It has been recommended, as a more rapid way of performing the operation, to make a transverse instead of a longitudinal cut, through both the superficial and deep structures, and thus to open at once the air passages. It will be seen, however, that in opening in this way the anterior jugular veins would be in danger of being wounded.

Tracheotomy may be performed either above or below the isthmus of the thyroid body, or this structure may be divided and the trachea opened behind it.

The isthmus of the thyroid gland usually crosses the second and third rings of the trachea; along its upper border is frequently to be found a large transverse communicating branch between the superior thyroid veins; and the isthmus itself is covered by a venous plexus formed between the thyroid veins of the opposite sides. Theoretically, therefore, it is advisable to avoid dividing this structure in opening the trachea.

Above the isthmus the trachea is comparatively superficial, being covered by the skin, superficial fascia, deep fascia, Sternohyoid and Sternothyroid muscles, and a second layer of the deep

fascia, which, attached above to the lower border of the hyoid bone, descends beneath the muscles to the thyroid body, where it divides into two layers and encloses the isthmus.

Below the isthmus the trachea lies much more deeply, and is covered by the Sternohyoid and the Sternothyroid muscles and a quantity of loose areolar tissue in which is a plexus of veins, some of them of large size; they converge to two trunks, the inferior thyroid veins, which descend on either side of the median line on the front of the trachea and open into the innominate vein. In the infant the thymus gland ascends a variable distance along the front of the trachea, and opposite the episternal notch the windpipe is crossed by the left innominate vein. Occasionally, also, in young subjects, the innominate artery crosses the tube obliquely above the level of the sternum. The thyroidea ima artery, when that vessel exists, passes from below upward along the front of the trachea.

From these observations it must be evident that the trachea can be more readily opened above than below the isthmus of the thyroid body.

Tracheotomy above the isthmus is performed thus: The patient should, if possible, be laid on his back on a table in a good light. A pillow is to be placed under the shoulders and the head thrown back and steadied by an assistant. The surgeon, standing on the right side of his patient, makes an incision from an inch and a half to two inches in length in the median line of the neck from the top of the cricoid cartilage. The incision must be made exactly in the middle line, so as to avoid the anterior jugular veins, and after the superficial structures have been divided the interval between the Sternohyoid muscles must be found, the raphé divided, and the muscles drawn apart. The lower border of the cricoid cartilage must now be felt for, and the upper part of the trachea exposed from this point downward in the middle line. Bosc has recommended that the layer of fascia in front of the trachea should be divided transversely at the level of the lower border of the cricoid cartilage, and, having been seized with a pair of forceps, pressed downward with the handle of the scalpel. By this means the isthmus of the thyroid gland is depressed, and is saved from all danger of being wounded, and the trachea is cleanly exposed. The trachea is now transfixed with a sharp hook and drawn forward in order to steady it, and is then opened by inserting the knife into it and dividing the two or three upper rings from below upward. If the trachea is to be opened below the isthmus, the incision to expose it must be made from a little below the cricoid cartilage to the top of the sternum.

In the child the trachea is smaller, more deeply placed, and more movable than in the adult. In fat or short-necked people, or in those in whom the muscles of the neck are prominently developed, the trachea is more deeply placed than in others.

A portion of the larynx or the whole of it has been removed for malignant disease, *laryngectomy*. Some surgeons do preliminary tracheotomy, insert a Trendelenburg cannula to prevent the flow of blood downward into the lungs, and then remove the larynx. Other surgeons do not employ preliminary tracheotomy. Perier's method of laryngectomy is as follows: Make a vertical incision in the median line from the level of the hyoid bone to below the level of the cricoid cartilage. Make a transverse incision at each end of the vertical incision. This makes an I-shaped wound. Separate the soft parts from the larynx and upper part of the trachea, and separate these two structures from the œsophagus. After arresting bleeding, divide the trachea below the cricoid cartilage, introduce a special cannula, complete the removal of the larynx, suture the opening of the trachea to the lower angle of the wound, and close the rest of the wound after securing drainage. In malignant disease of the larynx the associated lymph nodes must be removed. Partial laryngectomy, according to Sir F. Semon, is the removal of not less than one wing of the thyroid cartilage. Removal of a lesser piece of the thyroid or of a bit of the arytenoid or cricoid he considers with the operation of thyrotomy.

THE PLEURÆ (Figs. 879, 909).

Each lung is invested by an exceedingly delicate serous membrane, the **pleura**, which encloses the organ as far as its root, and is then reflected on to the pericardium, thoracic wall, and Diaphragm. The portion of the serous membrane investing the surface of the lung and dipping into the fissures between its lobes is called the **visceral layer of the pleura** (*pleura pulmonalis*) (Fig. 897), while that which lines the inner surface of the thorax is called the **parietal layer of the pleura** (*pleura parietalis*) (Fig. 897). The space between these two layers is called the **cavity of the pleura** (*cavum pleurae*), and contains a very little clear fluid. It must be borne in mind that in the healthy condition the two layers are in contact, and there is no real cavity. When the lung becomes collapsed a separation of it from the wall takes place and a cavity results. Each pleura is therefore a shut

sac, one occupying the right, the other the left half of the thorax, and they do not communicate with each other. The two pleuræ do not meet in the middle line

FIG. 897.—A transverse section of the thorax, showing the relative position of the viscera and the reflections of the pleuræ.

of the chest, excepting anteriorly opposite the second and third pieces of the sternum. The space left between them contains all the thoracic viscera excepting the lungs, and is named the **mediastinum**.

FIG. 898.—The dome of the pleura. (Poirier and Charpy.)

Different portions of the parietal pleura have received special names which indicate their position; thus, that portion which lines the inner surfaces of the ribs

and Intercostal muscles is the **costal pleura** (*pleura costalis*); that which covers the convex surface of the Diaphragm is the **diaphragmatic pleura** (*pleura diaphragmatica*); that which rises in the neck, over the apex of the lung, is the **cervical pleura** (*cupula pleuræ*); and that which is applied to the adjacent structures of the mediastinum is the **mediastinal pleura** (*pleura mediastinalis*).

Reflections of the Pleuræ (Fig. 897).—Commencing at the sternum, the pleura passes laterad, lines the costal cartilages, the inner surfaces of the ribs, and Internal intercostal muscles, and at the back part of the thorax passes over the gangliated cord of the sympathetic and its branches, and is reflected upon the sides of the bodies of the vertebræ where it is separated by a narrow interval, the **posterior mediastinum** (*cavum mediastinale posterius*), from the opposite pleura. From the vertebral column the pleura passes to the side of the pericardium, which it

FIG. 899.—The supports of the pleural dome. The oesophagus, trachea, and arteries have been cut and pulled aside to show the pleural reinforcements. (Poirier and Charpy.)

covers to a slight extent; it then covers the back part of the root of the lung, from the lower border of which a triangular sheet descends vertically by the side of the posterior mediastinum to the Diaphragm, but is not attached thereto. This sheet is the posterior layer of a wide fold, known as the **broad ligament** of the lung (*ligamentum pulmonale* or *ligamentum latum pulmonis*). From the posterior aspect of the lung root, the pleura may be traced over the convex surface of the lung, the apex, and base, and also into the fissures between the lobes, on to its inner surface and the front part of its root; it is continued from the lower margin of the root as the anterior layer of the broad ligament, and from this it is reflected on to the pericardium, and from it to the back of the sternum. Below, it covers the upper surface of the Diaphragm, and extends, in front, as low as the costal cartilage of the seventh rib; at the side of the thorax, to the lower border of the tenth rib on the left side and to the upper border of the same rib on the right side; and behind, it reaches as low as the twelfth rib, and sometimes even as low as the transverse process of the first lumbar vertebra. Above, its apex projects, through the superior aperture of the thorax into the neck, extending from one to two inches above the anterior extremity of the first rib; this portion of the sac is strengthened by a dome-like expansion of fascia (*Sibson's fascia*) (Fig. 899), attached in front to the inner border of the first rib, and behind to the anterior

border of the transverse process of the seventh cervical vertebra. This is covered and strengthened by a few spreading muscular fibres derived from the *Scaleni*.

In the front of the thorax, where the parietal layer of the pleura is reflected backward to the pericardium, the two pleural sacs are in contact for a short distance (Fig. 909). At the upper part of the thorax, behind the manubrium, they are not in contact, the point of reflection being represented by a line drawn from the sternoclavicular articulation to the midpoint of the junction of the manubrium with the body of the sternum. From this point the two pleuræ descend in close contact to the level of the fourth costal cartilages, and the line of reflection on the right side is continued downward in nearly a straight line to the lower end of the gladiolus, and then turns outward, while on the left side the line of reflection diverges outward and is continued downward, close to the left border of the sternum as far as the sixth costal cartilage. The inferior limit of the pleura is on a con-

FIG. 900.—Section of the wall of the thorax, showing the phrenicocostal sinus. (Poirier and Charpy.)

siderably lower level than the corresponding limit of the lung, but does not extend to the attachment of the Diaphragm, so that below the line of reflection of the pleura from the thoracic wall on to the Diaphragm the latter is in direct contact with the rib cartilages and the Internal intercostal muscles. In ordinary inspiration the thin margin of the base of the lung does not extend as low as the line of pleural reflection, with the result that the costal and diaphragmatic pleura are here in contact, the narrow slit between the two being termed the **costophrenic sinus** (*sinus phrenicocostalis*) (Fig. 900). A similar condition exists behind the sternum and rib cartilages, where the anterior thin margin of the lung falls short of the line of pleural reflection, and where the slit-like cavity between the two layers of pleura forms what is sometimes called the **costomediastinal sinus** (*sinus costomediastinalis*).

The line along which the right pleura is reflected from the thoracic wall to the Diaphragm starts in front, immediately below the seventh costosternal joint, and runs downward and backward behind the seventh costal cartilage so as to cross the tenth rib in the mid-axillary line, from which it is prolonged to the spine of the twelfth thoracic vertebra. The reflection

of the left pleura follows at first the ascending part of the sixth costal cartilage, and in the rest of its course is slightly higher than that of the right side.

The free surface of the pleura is smooth, polished, and moistened by a serous fluid; its attached surface is intimately adherent to the surface of the lung, and to the pulmonary vessels as they emerge from the pericardium; it is also adherent to the upper surface of the Diaphragm; throughout the rest of its extent it is somewhat thicker, and may be separated from the adjacent parts with extreme facility.

The right pleural sac is shorter, wider, and reaches higher in the neck than the left.

Ligamentum Latum Pulmonis.—From the above description it will be seen that the root of the lung is covered in front, above, and behind by the pleura, and that at its lower border the investing layers come into contact. Here they form a sort of mesenteric fold, the **ligamentum latum pulmonis** (*lig. pulmonale*), which extends

as far as the Diaphragm (but is not attached thereto) between the pericardium and the lower part of the inner surface of the lung, having a free falciform border below, between the lung and the Diaphragm. It serves to retain the lower part of the lung in position.

Structure of the Pleura.—The pleura is composed of fibroelastic connective tissue, its free surface being covered with a single layer of flat endothelial cells. It is fastened to adjacent structures by subserous areolar tissue. The subserous tissue of the visceral pleura is continuous with the areolar tissue of the lung.

Vessels and Nerves.—The arteries of the pleura are derived from the intercostal, the internal mammary, the musculophrenic, thymic, pericardiac, and bronchial arteries. The veins correspond to the arteries. The lymphatics are very numerous in the pleura and subserous tissue. The lymphatics of the visceral layer empty into the superficial pulmonary trunks; the lymphatics of the costal pleura empty into the intercostal trunks; of the diaphragmatic pleura, into the diaphragmatic trunks; of the mediastinal pleura, into the posterior mediastinal nodes. The nerves are derived from the phrenic and sympathetic (Luschka).

Applied Anatomy.—In operations upon the kidney it must be borne in mind that the pleura may sometimes extend below the level of the last rib, and may therefore be opened in these operations, especially when the last rib is removed, in order to give more room. It is best to keep the incision at least one inch below the last rib, enlarging the wound afterward, when the finger can be introduced as a guide.

In wounds of the Diaphragm the pleura may be injured. In operations about the root of the neck, especially in the removal of lymph nodes and the ligation of the first part of the subclavian artery, the pleura may be injured.

Punctured wounds of the root of the neck are apt to reach the pleura.

Empyema is a surgical disease. In acute empyema the treatment is drainage. A portion of the fifth or sixth rib in the axillary line is removed by subperiosteal resection, the pleura is opened, and a tube is introduced. In chronic empyema the lung is contracted and adherent and cannot expand; hence drainage will not cure it. It is necessary to perform multiple rib resection in order to permit the thoracic wall to sink in and obliterate the cavity, which, as the lung is unable to expand, it cannot do. The necessary operation may be the one of either Estlander, Schede, or Fowler (p. 168).

If a large wound admits suddenly a quantity of air into the pleura, dangerous or fatal pneumothorax arises, and the lung collapses. This is usually met during operations by using the Fell-O'Dwyer apparatus for artificial respiration, as advised by Matas.¹ This apparatus keeps the lung expanded, in spite of the entrance of air into the pleural sac. A surgeon can open the pleura widely without any fear of the lung collapsing if he operates in a Sauerbruch chamber. The pressure within this chamber is negative. The patient's head is outside of the chamber, his body is within it. The bronchioles are distended by the patient inhaling air at the ordinary pressure, but the exposed lung is subjected to negative pressure, hence the lung does not collapse in spite of a large wound in the pleura. In surgical pneumothorax the lung may be sutured to the thoracic wall, so as to block the opening. Sometimes, in order to arrest dangerous pulmonary bleeding, a surgeon deliberately induces pneumothorax, in the hope that the collapse of the lung will arrest bleeding.

When an abscess of the liver is posterior and on the dorsum, transpleural hepatotomy is performed. A portion of the tenth and eleventh ribs below the angle of the scapula is removed. As a rule, the pleura is found obliterated at this point. If it is opened, it is at once sutured or closed with gauze packing. The exposed Diaphragm is incised, and, as it is usually adherent to the liver, the abscess cavity is entered. If it is not adherent, the liver is exposed and the abscess sought for with an aspirating needle.

Grocco's sign is the presence of a triangular area of paravertebral dulness above the level of the twelfth rib on the side opposite to a pleural effusion. The dulness is believed to be due to a displacement of the contents of the posterior mediastinum by the fluid.

THE MEDIASTINUM, OR INTERPLEURAL SPACE.

The mediastinum is the space left in the median portion of the thorax by the non-apposition of the two pleuræ. It extends from the sternum in front to the vertebral column behind, and contains all the thoracic viscera excepting the lungs. The mediastinum may be divided for purposes of description into two parts—an

¹ Annals of Surgery, April, 1899.

upper portion, above the upper level of the pericardium, which is named the **superior mediastinum**; and a lower portion, below the upper level of the pericardium. This lower portion is again subdivided into three—that part which contains the pericardium and its contents, the **middle mediastinum**; that part which is in front of the pericardium, the **anterior mediastinum**; and that part which is behind the pericardium, the **posterior mediastinum**.

The **superior mediastinum** (Fig. 901) is that portion of the interpleural space which lies between the manubrium sterni in front and the upper thoracic vertebra behind. It is bounded below by a plane passing backward from the junction of the manubrium and gladiolus sterni to the lower part of the body of the fourth thoracic vertebra, and laterally by the lungs and pleuræ. It contains the origins of the Sternohyoid and Sternothyroid muscles and the lower ends of the Longus colli muscles; the arch of the aorta; the innominate, the thoracic portion of the left carotid and subclavian arteries; the upper half of the superior vena cava and

FIG. 901.—Transverse section through the second thoracic vertebra. (Braune.)

the innominate veins, and the left superior intercostal vein; the vagus, cardiac, phrenic, and left recurrent laryngeal nerves; the trachea, œsophagus, and thoracic duct; the remains of the thymus gland and some lymph nodes.

The **anterior mediastinum** (Fig. 897) is bounded in front by the sternum, laterally by the pleuræ, and behind by the pericardium. It is narrow above, but widens out a little below, and, owing to the oblique course taken by the left pleura, it is directed from above obliquely downward and to the left. Its anterior wall is formed by the left Triangularis sterni muscle and the fifth, sixth, and seventh left costal cartilages. It contains a quantity of loose areolar tissue, some lymphatic vessels which ascend from the convex surface of the liver, two or three lymph nodes (anterior mediastinal glands), and the small mediastinal branches of the internal mammary artery.

The **middle mediastinum** (Fig. 897) is the broadest part of the interpleural space. It contains the heart enclosed in the pericardium, the ascending aorta, the lower half of the superior vena cava, with the vena azygos major opening into

Applied Anatomy.—*Primary tumors* of the mediastinum are usually lymphomata or lymphosarcomata arising from the thymus or from the bronchial or posterior mediastinal lymph nodes; sarcomata, dermoid cysts, and embryomata, occur more rarely. These tumors give rise to pain, deformity of the thorax, and symptoms of pressure on the various nerves, bloodvessels, air passages, lymphatics, and on the œsophagus, as these various structures pass through the thorax. They may produce physical signs very much like those of an aortic aneurism, so that diagnosis between the two is often difficult. The prognosis is bad, life usually ending within a few months or a year of the onset of the symptoms.

Inflammation of the mediastinum due to wounds, or to the spread of inflammation from adjacent parts (*e. g.*, the œsophagus, the pericardium), is sometimes acute, leading to abscess formation. A more chronic form associated with adhesions and inflammation of the pericardium—the so-called chronic adhesive mediastinopericarditis—gives rise to obscure symptoms suggesting gradual heart failure, and leads to death slowly but surely.

THE LUNGS (PULMONES) (Figs. 903, 904).

The **lungs** are the essential organs of respiration; they are two in number, placed one on each side of the thorax, separated from each other by the heart and other contents of the mediastinum. A healthy lung hangs free within the pleural cavity. It is suspended by the root and by the ligamentum pulmonale. In many

FIG. 903.—The right lung. The inner or mediastinal surface, with the hilum laid bare by the removal of the structures forming the root of the lung. (Toldt.)

cases examined the lung does not hang free, but, as a result of former pleurisy, an area of the pulmonary pleura is adherent to the parietal pleura. Each lung is conical in shape, and presents for examination an **apex**, a **base**, three **borders**, and three **surfaces**.

The **apex** (*apex pulmonis*) is rounded, and extends into the root of the neck about an inch to two inches above the level of the anterior end of the first rib. A furrow produced by the subclavian artery as it curves outward in front of the pleura runs upward and outward immediately below the apex. The brachial plexus is in close proximity to this portion of the lung.

The **base** (*basis pulmonis*) is broad, concave, and rests upon the convex surface of the **Diaphragm**, which separates the right lung from the upper surface of the right lobe of the liver and the left lung from the upper surface of the left lobe of the liver, the fundus of the stomach, and the spleen. Since the Diaphragm extends higher on the right than on the left side, it follows that the concavity on the base of the right lung is deeper than that of the left. Laterally and behind, the base is bounded by a thin, sharp margin which projects for some distance into the costophrenic sinus of the pleura, between the lower ribs and the costal attachment of the Diaphragm. The base of the lung descends during inspiration and ascends during expiration; its relation to the thoracic wall is indicated in Figs. 909 and 910.

FIG. 904.—The left lung. The inner or mediastinal surface, with the root of the lung cut across. (Toldt.)

Surfaces.—The **external, costal, or thoracic surface** (*facies costalis*) (Figs. 907 and 908) is smooth, convex, of considerable extent, and corresponds to the form of the cavity of the thorax, being deeper behind than in front. It is in contact with the costal pleura, and presents, in a hardened specimen, slight grooves corresponding to the overlying ribs.

The **inner or mediastinal surface** (*facies mediastinalis*) (Figs. 903 and 904) is in contact with that portion of the pleura which forms the lateral boundary of the mediastinal space. It presents a deep concavity which accommodates the pericardial sac; this is larger and deeper on the left than on the right lung, on account of the heart projecting farther to the left than to the right of the mesal plane. Above and behind this concavity is a triangular depression named the **hilum** (*hilus pulmonis*), where the structures which form the root of the lung enter and leave the viscus.

On the **right lung** (Fig. 905) immediately above the hilum, is an arched furrow which accommodates the vena azygos major, while running upward, and then arching outward some little distance below the apex, is a wide groove for the superior vena cava and right innominate vein; and behind this, nearer the apex, is a second

furrow for the innominate artery. Along the back part of the inner surface is a vertical groove for the œsophagus; this groove becomes less distinct below, owing to the inclination of the lower part of the œsophagus to the left of the middle line. In front and to the right of the lower part of the œsophageal groove, the inner surface is applied to the pleural covering of the right and posterior aspects of the thoracic parts of the inferior vena cava; this vessel being accommodated in a deep concavity.

On the *left lung* (Fig. 904), immediately above the hilum, is a well-marked curved furrow produced by the arch of the aorta, and running upward from this toward the apex is a groove accommodating the subclavian artery; a slight impression in front of the latter and close to the margin of the lung lodges the left innominate vein. Behind the hilum and pericardial depression is a vertical furrow produced by the descending thoracic aorta, and in front of this, near the base of the lung, the lower part of the œsophagus causes a shallow depression.

FIG. 905.—Front view of the heart and lungs.

Borders.—The **posterior border** (*margo posterior*) is broad and rounded, and is received into the deep concavity on either side of the vertebral column. It is much longer than the anterior border.

The **inferior border** (*margo inferior*) is the margin of the base separating the costal and diaphragmatic surfaces. It projects, below, into the upper part of the costophrenic sinus.

The **anterior border** (*margo anterior*) is thin and sharp, overlaps the front of the pericardium, and is projected into the costomediastinal sinus of the pleura. The anterior border of the right lung is almost vertical; that of the left presents, below, an angular notch, the **incisura cardiaca**, into which the heart and pericardium are

received. A projection from the upper lobe comes forward beneath the cardiac notch; it is called the *lingula pulmonis*.

FIG. 906.—Pulmonary veins, seen in a dorsal view of the heart and lungs. The lungs have been pulled away from the median line, and a part of the right lung has been cut away to display the air ducts and bloodvessels. (Testut.)

FIG. 907.—The right lung. The outer or costal surface. (Toldt.)

FIG. 908.—The left lung. The outer or costal surface. (Toldt.)

Fissures and Lobes of the Lung.—The **left lung** is divided into two lobes, an upper and a lower, by an oblique fissure (*incisura interlobaris*), which extends

from the outer to the inner surface of the lung both above and below the hilum. As seen on the surface, this fissure commences on the inner aspect of the lung at the upper and posterior part of the hilum, and runs backward and upward to the posterior border, which it crosses about two and a half inches below the apex. It then extends downward and forward over the outer surface and reaches the lower border a little behind its anterior inferior extremity, and its further course can be followed upward and backward across the inner surface as far as the lower part of the hilum. The **upper lobe** (*lobus superior*) lies above and in front of this fissure, and includes the apex, the anterior border, and a considerable part of the outer surface and the greater part of the inner surface of the lung. The

FIG. 909.—Front view of chest, showing relations of pleurae and lungs to the chest wall. The blue lines indicate the lines of the reflection of the pleurae; the red, the outlines of the lungs and their fissures.

lower lobe (*lobus inferior*), the larger of the two, is situated below and behind this fissure, and comprises almost the whole of the base, a large portion of the outer surface, and the greater part of the posterior border.

The **right lung** is divided into three lobes, upper, middle, and lower, by an oblique and a horizontal fissure. The **oblique fissure** separates the lower from the middle and upper lobes, and corresponds closely with the fissure of the left lung. Its direction is, however, more vertical, and it cuts the lower border about three inches behind its anterior inferior extremity. The **horizontal fissure** separates the upper from the middle lobe. It begins in the oblique fissure near the posterior border of the lung and, running horizontally forward, cuts the anterior border at the level of the sternal end of the fourth costal cartilage; on the inner surface it may be traced

backward to the hilum. The **middle lobe** (*lobus medius*), the smallest of the lobes of the right lung, lies between the horizontal fissure and the lower part of the oblique fissure; it is wedge-shaped and includes the lower part of the anterior border and the anterior part of the base of the lung.

FIG. 910.—Lateral view of chest, showing relations of right pleura and lung to the chest wall. The blue line indicates the line of pleural reflection; the red lines, the outline of the lung and its fissures.

The right lung is the larger and heavier; it is broader than the left, owing to the inclination of the heart to the left side; it is also shorter by an inch, in consequence of the Diaphragm rising higher on the right side to accommodate the liver.

The Root of the Lung (*radix pulmonis*) (Figs. 903 and 904).—A little above the middle of the inner surface of each lung, and nearer its posterior than its anterior border, is its root, by which the lung is connected to the heart and the trachea. The root is formed by the bronchial tube, the pulmonary artery, the pulmonary veins, the bronchial arteries and veins, the pulmonary plexus of nerves, lymphatics, bronchial lymph nodes, and areolar tissue, all of which are enclosed by a reflection of the pleura. The root of the right lung lies behind the superior vena cava and ascending portion of the aorta, and below the vena azygos major. The root of the left lung passes beneath the arch of the aorta and in front of the descending aorta; the phrenic nerve and the anterior pulmonary plexus lie in front of each, and the vagus and posterior pulmonary plexus behind each; below each is the ligamentum latum pulmonis.

The chief structures composing the root of each lung are arranged in a similar manner from before backward on both sides—viz., the two pulmonary veins in front, the pulmonary artery in the middle, and the bronchus, together with the bronchial vessels, behind. From above downward, on the two sides, their arrangement differs, thus:

On the *right* side their position is—bronchus, pulmonary artery, pulmonary veins; but on the *left* side their position is—pulmonary artery, bronchus, pulmonary veins. It should be noted that the entire right bronchus does not lie above the right pulmonary artery, but only its eparterial branch (see p. 1179), which passes to the upper lobe of the right lung; the divisions of the bronchus for the middle and lower lobes lie below the artery.

Divisions of the Bronchi.—Just as the lungs differ from each other in the number of their lobes, so the bronchi differ in their mode of subdivision.

The *right* bronchus gives off, about an inch from the bifurcation of the trachea, a branch for the upper lobe. This branch arises above the level of the pulmonary artery, and is therefore named the *eparterial bronchus*. All the other divisions of the main stem come off below the pulmonary artery, and consequently are termed *hyparterial bronchi*. The first of these is distributed to the middle lobe, and the main tube then passes downward and backward into the lower lobe, giving off in its course a series of large ventral and small dorsal branches. The ventral and dorsal branches arise alternately, and are usually eight in number—four of each kind. The branch to the middle lobe is regarded as the first of the ventral series.

The *left* bronchus passes below the level of the pulmonary artery before it divides, and hence all its branches are *hyparterial*; it may therefore be looked upon as equivalent to that portion of the right bronchus which lies on the distal side of its eparterial branch. The first branch of the left bronchus arises about two inches from the bifurcation of the trachea, and is distributed to the upper lobe. The main stem then enters the lower lobe, where it divides into ventral and dorsal branches similar to those in the right lung. The branch to the upper lobe of the left lung is regarded as the first of the ventral series.

The true **weight** of the human lungs as ascertained in the bodies of criminals executed by electricity, in which the mode of death is attended by a nearly bloodless condition of the lungs, is 215 grams (7½ ounces) for the left lung and 240 grams (8½ ounces) for the right lung (E. A. Spitzka, *Amer. Jour. of Anat.*, iii, 1, p. v). Ordinarily, with the vascular channels more or less filled with blood and serum, the two lungs together weigh about 42 ounces, the right lung being 2 ounces heavier than the left, but much variation is met with according to the amount of blood or serous fluid they may contain. The lungs are heavier in the male than in the female. The specific gravity of the lung tissue varies from 0.345 to 0.746.

The **color** of the lungs at birth is a pinkish white; in adult life a dark slate-color, mottled in patches; and as age advances this mottling assumes a black color. The coloring matter consists of granules of carbonaceous substance deposited in the areolar tissue near the surface of the organ. It increases in quantity as age advances, and is more abundant in males than in females. The posterior surface of the lung is usually darker than the anterior.

The **surface** of the lung is smooth, shining, and marked out into numerous polyhedral spaces, indicating the lobules of the organ; the area of each of these spaces is crossed by numerous lighter lines.

The **substance** of the lung is of a light, porous, spongy texture; it floats in water and crepitates when handled, owing to the presence of air in the tissue; it is also highly elastic; hence the collapsed state of these organs when they are removed from the closed cavity of the thorax.

The Fetal Lung.—After respiration has been established, the lung fills the pleural cavity. In the fetus, as the lung has never been distended with air and has never received a large amount of blood, it is gathered into a small mass at the back of the thorax. It will sink in water and feels solid to the touch.

Structure.—The structure of the lung is such that the blood brought by the pulmonary artery comes into close relation with the air which enters from the bronchioles. The blood gives materials to the air, and the air gives elements to the blood, and the process of respiration causes the dark blood brought from the heart by the pulmonary artery to return to the heart as

red blood in the pulmonary veins. The lungs are composed of an **external serous coat**, a **subserous areolar tissue**, and the **pulmonary substance or parenchyma**.

The **serous coat** is thin, transparent, and invests the entire organ as far as the root. It is composed of a layer of endothelial cells resting upon a thin layer of fibroelastic tissue, and is continuous with the subserous tissue. It is known as the pulmonary pleura (p. 1183).

The **subserous areolar tissue** contains a large proportion of elastic fibres; it invests the entire surface of the lung, and extends inward between the lobules.

The **parenchyma** is composed of **lobules** which, although closely connected by an interlobular areolar tissue, are quite distinct from one another. The lobules vary in size from 0.3 cm. to 3 cm. ($\frac{1}{4}$ inch to $1\frac{1}{4}$ inches); those on the surface are large, of pyramidal form, with the bases turned toward the surface; those in the interior are smaller and of various forms. Each lobule is composed of one of the ramifications of a **bronchiole** (about 1 mm. in diameter) and its terminal air cells, and of the ramifications of the pulmonary and bronchial vessels, lymphatics, and nerves, all of these structures being connected by fibroelastic tissue.

The **bronchus** upon entering the lung divides like the ducts of a gland, the terminal tubules, about 1 mm. in diameter, constituting the **bronchioles**. Each bronchiole forms a lobule that is separated and closed from its neighbor. The bronchiole diminishes in diameter to about 0.5 mm. and divides into several tubules (0.3 to 0.4 mm. in diameter), the **respiratory bronchioles**, upon the sides of which some minute depressions, **alveoli**, may be seen. Each respiratory bronchiole further subdivides into several **alveolar ducts** (0.2 mm. in diameter), along which alveoli are numerous. The alveolar ducts lead into individual dilated spaces, the **alveol**, **air sacs**, or **infundibula** (0.3 to 5 mm. in diameter), upon the sides of which are **alveoli** or **sacculi** (0.05 to 0.1 mm. in diameter). The alveoli are partially separated from one another by low partitions or **septa**, of the same structure as the alveolar wall.

Changes in Structure of the Bronchus and Its Divisions.—Each main bronchus resembles the trachea in structure. Within the lung the bronchial tubes are circular in outline. As the bronchus divides and redivides monopodially, changes occur in the various coats. The mucous coat presents a corrugated appearance and the cartilage in the submucosa changes to a complete investing layer composed of a number of individual plates. With this change the smooth muscle tissue, internal to the cartilage, increases so as to form a complete layer. As the smaller tubes are approached the cartilage decreases in amount, while the muscle increases relatively. The mucous glands in mucosa disappear in those tubules of 1 mm. in diameter, while the cartilage persists until a diameter of about 0.5 mm. is reached.

Each **bronchiole** consists of a layer of simple columnar and goblet epithelial cells resting upon a basement membrane and a fibroelastic tunica propria; external to this is found a layer of smooth muscle tissue, and beyond this a layer of white fibrous tissue containing the main vessels and nerves of the tubules. The **respiratory bronchiole** is lined by simple ciliated cells, that gradually give way to nonciliated columnar and cuboidal cells, and lastly flattened epithelium (the **respiratory epithelium**). Some muscle tissue is still present, and the elastic tissue increases in quantity. The **alveolar ducts** are lined by simple epithelial plates resting upon a basement membrane supported by elastic tissue. At the end of this tubule the muscle tissue disappears. The **air sacs** are composed of the **alveoli** or **sacculi** lined by respiratory epithelium that rests upon a basement membrane supported by a meshwork of elastic tissue containing the densest capillary plexus of the body. This elastic tissue allows the alveoli to increase from two to three times their ordinary diameters. Separating one alveolus from another is a low **septum** that has the same structure as the alveolar wall.

Vessels of the Lungs.—The **pulmonary artery** (Figs. 905 and 906) conveys the venous blood to the lungs; it divides into branches which accompany the bronchial tubes, and terminates in a dense capillary network upon the walls of the air cells. In the lung the branches of the pulmonary artery are usually above and in front of a bronchial tube, the vein below. The pulmonary arteries are the nutrient vessels of the respiratory epithelium.

The **pulmonary capillaries** form plexuses which lie immediately beneath the epithelium of the walls and septa of the air cells and of the alveoli. In the septa between the air cells the capillary network forms a single layer. The capillaries form a very minute network, the meshes of which are smaller than the vessels themselves; their walls are also exceedingly thin. The arteries of neighboring lobules are independent of one another, but the veins freely anastomose.

The **pulmonary veins** commence in the pulmonary capillaries, the radicles coalescing into larger branches, which run along through the substance of the lung, independently from the minute arteries and bronchi. After freely communicating with other branches they form large vessels, which ultimately come into relation with the arteries and bronchial tubes, and accompany them to the hilum of the organ. Finally, they open into the left auricle of the heart, conveying oxygenated blood to be eventually distributed to all parts of the body by the aorta.

The **bronchial arteries** supply blood for the nutrition of bronchial tubes and vessels of the lung. The thoracic aorta usually gives off two left bronchial arteries. The single right bron-

¹ The meshes are only 0.002" to 0.008" in width, while the vessels are 0.003" to 0.005" (Kölliker, Human Microscopic Anatomy).

chial artery usually arises from the first right aortic intercostal, but sometimes from the superior left bronchial artery, or from the aorta. In the root of the lung they are posterior to the bronchus, they accompany the bronchial tubes, supply the bronchial tubes and surrounding interlobular tissue, and give branches to the walls of the larger pulmonary vessels, the œsophagus, pericardium, and bronchial lymph nodes. Those supplying the bronchial tubes form a capillary plexus in the muscular coat, from which branches are given off to form a second plexus in the mucous coat. This plexus anastomoses with branches of the pulmonary artery, and empties into the pulmonary vein. Others are distributed in the interlobular areolar tissue, and terminate partly in the deep, partly in the superficial, bronchial veins. Lastly, some ramify upon the surface of the lung beneath the pleura, where they form a capillary network. There may be but one bronchial artery; there may be three or four.

The **bronchial veins** are not found in the walls of the very small bronchi. The small bronchial veins run along by the front and back of the medium sized and larger tubes, and form two trunks at the root of each lung. These vessels terminate on the right side in the *vena azygos major*, and on the left side in the superior intercostal or left upper azygos vein. Tracheal and posterior mediastinal veins open into the bronchial veins. The venous blood from the smaller tubes passes to the pulmonary veins.

FIG. 911.—A pulmonary lobule. (Poirier and Charpy.)

FIG. 912.—The terminal bronchial tubes. The respiratory bronchiole and alveoli. (Poirier and Charpy.)

The **lymphatics** begin in networks about the lobules and form networks about the bronchi and beneath the bronchial mucous membrane. The superficial collecting trunks arise about the lobules and beneath the pleura. According to Sappey, the superficial trunks from the upper lobe begin on the costal surface; one set passes around the anterior border, another set around the posterior border, and a third into the incisura interlobaris. The same observer says that the superficial trunks from the middle lobe unite with the trunks from the upper and lower lobes; and the superficial trunks from the lower lobe, like those of the upper lobe, are in three sets. One set passes around the posterior margin, one around the anterior margin, and one into the interlobar fissure. All of the superficial trunks convey lymph to the nodes of the hilum. Some of the deep collecting trunks begin by the side of the small bronchi; others course along by the pulmonary veins or pulmonary arteries. All of them pass to the nodes of the hilum. The nodes of the hilum are in communication with the peritracheobronchial nodes.

Nerves.—The lungs are supplied from the **anterior and posterior pulmonary plexuses**, formed chiefly by branches from the **sympathetic** and **vagus**. The filaments from these plexuses accompany the bronchial tubes, and are lost upon them. Small ganglia are found upon these nerves.

Surface Form.—The apex of the lung is situated in the neck, behind the interval between the two heads of origin of the Sternomastoid muscle. The height to which it rises above the clavicle varies very considerably, but is generally about one inch. It may, however, extend as much as an inch and a half or an inch and three-quarters, or, on the other hand, it may scarcely project above the level of this bone. In order to mark out the anterior margin of the lung, a line is to be drawn from the apex point, one inch above the level of the clavicle, and rather nearer the

posterior than the anterior border of the Sternomastoid muscle, downward and inward across the sternoclavicular articulation and first piece of the sternum until it meets, or almost meets, its fellow of the other side opposite the articulation of the manubrium and gladiolus. From this point the two lines are to be drawn downward, one on either side of the mesal line and close to it, as far as the level of the articulation of the fourth costal cartilages to the sternum. From here the two lines diverge; the left is to be drawn at first passing outward with a slight inclination downward, and then taking a bend downward with a slight inclination outward to the apex of the heart, and thence to the sixth costochondral articulation. The direction of the anterior border of this part of the left lung is denoted with sufficient accuracy by a curved line with its convexity directed upward and outward from the articulation of the fourth right costal cartilage of the sternum to the fifth intercostal space, an inch and a half below and three-quarters of an inch internal to the left nipple in the male. The continuation of the anterior border of the right lung is marked by a prolongation of its line from the level of the fourth costal cartilages vertically downward as far as the sixth, when it slopes off along the line of the sixth costal cartilage to its articulation with the rib.

The lower border of the lung is marked out by a slightly curved line with its convexity downward from the articulation of the sixth costal cartilage to its rib to the spinous process of the tenth thoracic vertebra. If vertical lines are drawn downward from the middle of the clavicle, from the deepest part of the axilla, and from the apex of the scapula, while the arms are raised from the sides, they should intersect this convex line, the first at the sixth, the second at the eighth, and the third at the tenth rib. It will thus be seen that the pleura extends farther down than the lung, so that it may be wounded, and a wound may pass through its cavity into the Diaphragm, and the abdominal viscera may be injured without the lung being involved.

The posterior border of the lung is indicated by a line drawn from the level of the spinous process of the seventh cervical vertebra, down either side of the vertebral column, corresponding to the costovertebral joints as low as the spinous process of the tenth thoracic vertebra. The trachea bifurcates opposite the spinous process of the fourth thoracic vertebra, and from this point the two bronchi are directed outward.

"The position of the great fissure of the lungs may be indicated by a line drawn from the third thoracic spine obliquely downward in such a manner as to reach the sixth rib close to the mid-clavicular line. The interlobar fissure between the upper and middle lobes of the right lung corresponds to a line drawn from the apex of the axilla almost horizontally to the sternum, reaching the latter at about the level of the fourth costal cartilage" (Ehrendrath).

Applied Anatomy.—The lungs may be wounded or torn in three ways: (1) By compression of the thorax, without any injury to the ribs. (2) By a fractured rib penetrating the lung. (3) By stabs, gunshot wounds, etc.

The first form, where the lung is *ruptured by external compression* without any fracture of the ribs, is very rare, and usually occurs in young children, and affects the root of the lung—i. e., the most fixed part—and thus, implicating the great vessels, is frequently fatal. It would seem to be a most unusual injury, and the exact mode of its causation is difficult to understand. The probable explanation is that immediately before the compression is applied a deep inspiration is taken and the lungs are fully inflated; owing then to spasm of the glottis at the moment of compression, the air is unable to escape from the lung, the lung is not able to recede, and consequently gives way.

In the second variety, when the *wound* in the lung is produced by the *penetration of a broken rib*, both the pleura costalis and the pleura pulmonalis must necessarily be injured, and consequently the air taken into the wounded air cells may find its way through these wounds into the cellular tissue of the parietes of the thorax. This it may do without collecting in the pleural cavity; the two layers of the pleura are so intimately in contact that the air may pass straight through from the wounded lung into the subcutaneous tissue. *Emphysema* constitutes, therefore, an important sign of injury to the lung in cases of fracture of the ribs. *Pneumothorax*, or air in the pleural cavity, is much more likely to occur in injuries to the lung of the third variety; that is to say, from *external wounds*, from stabs and gunshot injuries, in which cases air passes either from the wound of the lung or from an external wound into the cavity of the pleura during the respiratory movements. In these cases there is generally no emphysema of the subcutaneous tissue unless the external wound is small and valvular, so that the air drawn into the wound during inspiration is then forced into the cellular tissue during expiration because it cannot escape from the external wound. Occasionally in wounds of the parietes of the thorax no air finds its way into the cavity of the pleura, because the lung at the time of the accident protrudes through the wound and blocks the opening. This occurs where the wound is large, and constitutes a so-called *hernia* of the lung. *True hernia* of the lung occurs, though very rarely, after wounds of the thoracic wall, when the wound has healed and the cicatrix subsequently yields from the pressure of the viscus behind. It forms a globular, elastic, crepitating swelling, which enlarges during expiratory efforts, falls during inspiration, and disappears on holding the breath. Wounds of the lung may produce dangerous or fatal *hemorrhage* into the pleural sac. In many cases the bleeding is spontaneously arrested; in others the surgeon must interfere to save life. In some cases air has been admitted by intercostal incision and the inser-

tion of a tube, and pulmonary collapse has arrested bleeding. In other cases it is necessary to resect portions of several ribs, and stop bleeding by ligatures or suture ligatures. J. Chalmers Da Costa reports a case in which a furious secondary hemorrhage followed a gunshot wound. He resected several ribs, packed the pleural cavity about the lung with sterile gauze, to obtain a base for support, and then arrested the bleeding by packing iodoform gauze against the firmly supported lung. This patient recovered.

Incision of the lung (*pneumotomy*) is performed for pulmonary abscess (either tuberculous or pyogenic), pulmonary gangrene, hydatid cysts, and bronchiectasis. In pulmonary abscess, locate the area by physical signs and the *x*-rays, resect a portion of a rib over it, and note if the pleura is adherent. If it is adherent, continue the operation. If it is not adherent, insert stitches of catgut through the two layers of pleura and the superficial part of the lung, so as to encircle a considerable area, and then wait several days for adhesions to form. Adhesions protect the pleura from infection, and, by keeping air from the pleural sac, prevent pneumothorax. When ready to continue the operation, locate the abscess with an aspirating needle and syringe, open it with a cautery at a dull red heat, and drain by means of a tube.

Pneumotomy is very unsatisfactory in tuberculous cavities and bronchiectasis. In tuberculosis, excision of the diseased area (*pneumectomy*) has been employed, but it is not to be advised.

Operations upon the lungs can be most safely performed with the patient in a Sauerbruch chamber. The danger of collapse of the lung is thus eliminated.

The routine methods of physical examinations—inspection, palpation, percussion, and auscultation—are nowhere more important than they are in the diagnosis of diseases of the lungs. It is essential, too, that in every case the two sides of the thorax should be compared with each other, and that the wide variations that may be met with under normal conditions in different persons and at different ages should be kept in mind when the thorax is being examined.

On *inspection* the thorax will be seen to be enlarged and barrel-shaped in emphysema, in which the volume of the lungs is increased by dilatation of their alveoli, or in an acute attack of asthma, or when a large pleural effusion or mediastinal tumor is present. The thoracic wall will be flattened or sunken, on the other hand, over an area of lung that has collapsed or become fibrosed, as often happens in chronic pulmonary tuberculosis. The respiratory movements of the thoracic wall will be lessened, or even absent, over a part or the whole of the affected side in such acute disorders as pleurisy, pneumonia, or pleural effusion, or in more chronic disease where the underlying lung is fibrosed, or is crushed to one side by a mediastinal tumor; and by the use of the *x*-rays a corresponding loss of movement or displacement of the Diaphragm on the affected side can often be observed. Under normal conditions the intercostal spaces are a little depressed: but they may be obliterated or even bulging on that side when a large effusion or newgrowth fills up one of the pleural cavities.

On *palpation*, the hand can be used to verify the eye's impressions as to the degree of movement on respiration of any part of the thoracic wall. The facility with which the vibrations produced by the voice are conducted from the larynx by the underlying lung to the hand (in the form of *vocal fremitus*) can also be tested. The vocal fremitus is commonly much increased over the consolidated area in pneumonia or in fibrosis of the lung, and much diminished over a pleural effusion when the lung is pushed up by the fluid toward the top of the pleural cavity. It is also diminished, but to a less extent, in emphysema, and in bronchitis when the bronchi are blocked by secretion. In bronchitis the bubbling of the secretion in the tubes can often be felt by a hand placed on the thoracic wall as the patient breathes; and in chronic pleurisy the friction of the two roughened pleural surfaces against each other can sometimes be felt in the same way.

On *percussion*, the normal resonance of the pulmonary tissue is found to be increased in emphysema, and in pneumothorax this hyperresonance may be still further increased. The resonance is lessened in any condition causing collapse or solidification of the lung tissue, or when its place is taken by fluid (pleural effusion) or some solid growth (mediastinal tumor). Thus, dullness on percussion at the bases of the lungs is common in the hypostatic congestion of the bases seen in heart failure; dullness at the right base is often due to compression of the lung by enlargement of the liver; some dullness at the apex of a lung is frequently met with in tuberculosis of that part, before the disease has progressed very far. Complete dullness over one side of the thorax, back and front alike, except at the apex, is common when a large pleural effusion has taken the lung's place. Von Kórányi, Grocco, and others, have drawn attention to a triangular patch of dullness along the vertebral column (the paravertebral triangle of dullness) on the unaffected side in pleural effusion; this triangle of dullness is said to be absent in other conditions causing loss of pulmonary resonance on percussion, and is due to shifting over of the contents of the posterior mediastinum toward the sound side. The apex of this triangle is in the middle line at the upper level of the fluid effusion; its base, some two to four inches in length, runs horizontally outward from the middle line at the level where the pulmonary resonance normally comes to an end.

On *auscultation* of the lungs, both in health and disease, the variety of sounds to be heard is very great. It is impossible to give adequate consideration to them here, and for further information reference should be made to the text-books dealing with the subject.

THE ORGANS OF DIGESTION.

THE Apparatus for the Digestion of the Food (*apparatus digestorius*) consists of the **alimentary canal** and of certain **accessory organs**.

The **alimentary canal** is a musculomembranous tube, about thirty feet, or nine meters, in length, extending from the mouth to the anus, and lined throughout the entire extent by mucous membrane. It has received different names in the various parts of its course; at its commencement, the **mouth**, we find provision made for the mechanical division of the food (*mastication*), and for its admixture with a fluid secreted by the salivary glands (*insalivation*); beyond this are the **pharynx** and the **œsophagus**, the organs which convey the food (*deglutition*) into that part of the alimentary canal, the **stomach**, in which the principal chemical changes occur, and in which the reduction and solution of the food take place; in the **small intestine** the nutritive principles of the food are separated, by its admixture with the bile, pancreatic and intestinal fluids, from that portion which passes into the **large intestine**, most of which is expelled from the system through the **rectum** and **anal canal**.

THE MOUTH, ORAL OR BUCCAL CAVITY (CAVUM ORIS).

The mouth is placed at the commencement of the alimentary canal; it is a nearly oval-shaped cavity, in which the mastication and insalivation of the food take place (Figs. 913 and 914).

The **aperture of the mouth** (*rima oris*) is bounded by the lips. The **angle of the mouth** (*angulus oris*) is formed on each side by the meeting of the upper and lower lips (*commissura labiorum*). When at rest with the lips in contact, the rima is a slightly curved line. Every movement which the lips make alters the shape of the rima. When the mouth is closed the floor and roof are usually in contact and its sides are approximated to the dental arches. The mouth consists of two parts—an outer, smaller portion, the **vestibule**, and an inner, larger part, the **cavity proper of the mouth**.

The **vestibule** (*vestibulum oris*) is a slit-like space, bounded in front and laterally by the lips and cheeks; behind and internally by the gums and teeth. Above and below it is limited by the reflection of the mucous membrane from the lips and cheeks to the gum covering the upper and lower alveolar arch respectively. It receives the secretion from the parotid, buccal, molar, and labial glands, and communicates, when the jaws are closed, with the *cavum oris* by an aperture on each side behind the wisdom teeth, and by narrow clefts between opposing teeth (interdental spaces).

The **cavity of the mouth proper** (*cavum oris proprium*) is bounded laterally and in front by the alveolar arches with their contained teeth; behind, it communicates with the pharynx by a constricted aperture termed the **isthmus faucium**. It is roofed in by the hard and soft palate. The greater part of the floor is formed by the tongue, the remainder being completed by the reflection of the mucous membrane from the sides and under surface of the tongue to the gum lining the inner aspect of the mandible. It receives the secretion from the submaxillary, sublingual, and lingual glands.

Floor of the Mouth.—If the tongue be lifted out of its resting-place, the true floor of the mouth, or sublingual region, may be examined. In the midline a fold of mucous membrane, the **frenum linguae**, extends from the under surface of the tongue to the floor. On each side of the frenum is a papilla, the **caruncula sublingualis**, on the summit of which is the small orifice of the submaxillary (Wharton's) duct. Extending backward from these caruncles, between the tongue and the alveolar arches on each side, is a carunculated fold, the **plica sublingualis**, which becomes lost posteriorly. The carunculated elevations, of variable number, present the orifices of the sublingual ducts.

Structure.—The *mucous membrane* lining the mouth is continuous with the integument at the free margin of the lips and with the mucous lining of the pharynx behind; it is of a rose-pink tinge during life, and very thick where it covers the hard parts bounding the cavity. It is covered by stratified squamous epithelium. In the subepithelial fibroelastic tissue are seen many small accessory salivary glands.

FIG. 913.—Diagram of the alimentary tube and its appendages. (Testut.)

The **Lips** (*labia oris*) are two fleshy folds which surround the orifice of the mouth, formed externally by integument and internally by mucous membrane, between which are found the Orbicularis oris muscle (Fig. 293), the labial vessels, some nerves (Fig. 442), areolar tissue, and fat, and numerous small labial glands. The upper lip is called the **labium superius**; the lower lip is called the **labium inferius**. The inner surface of each lip is connected in the middle line to the gum of the corresponding jaw by a fold of mucous membrane, the **frenulum** (*frenulum labii superioris* and *frenulum labii inferioris*), the upper being the larger of the two.

The **labial glands** (*glandulae labiales* (Fig. 442) are situated between the mucous membrane and the Orbicularis oris muscle around the orifice of the mouth. They

are circular in form, and of small size; their ducts open by minute orifices upon the surface of the mucous membrane. In structure they resemble the salivary glands.

The **Cheeks** (*buccae*) form the sides of the face and are continuous in front with the lips. They are composed externally of integument, internally of mucous membrane, and between the two of a muscular stratum, besides a large quantity of fat, areolar tissue, vessels, nerves, and buccal glands.

The Mucous Membrane.—The mucous membrane lining the cheek is reflected above and below upon the gums, where its color becomes lighter; it is continuous behind with the lining membrane of the soft palate. It is composed of stratified squamous epithelial cells that rest upon a basement membrane and papillated tunica propria that consists of fibroelastic tissue supporting the smaller vessels and nerves. Opposite the second molar tooth of the upper jaw is a **papilla**, the summit of which presents the aperture of the **parotid duct** (*ductus parotideus* [*Stenonis*]) (Fig. 946). The principal muscle of the cheek is the Buccinator, but numerous other muscles enter into its formation—viz., the Zygomatici, Risorius, and Platysma.

The Buccal Glands (*glandulae buccales*).—The buccal glands are placed in the submucous tissue between the mucous membrane and Buccinator muscle; they are similar in structure to the labial glands, but smaller. Four or five glands of larger size than the previously mentioned glands are placed beneath the mucous membrane in the neighborhood of the last molar tooth. They are called the **molar glands** (*glandulae molares*). Their ducts open into the mouth opposite the last molar tooth. The fat pad of the cheek (*corpus adiposum buccae*) has been described on page 376.

FIG. 914.—Antero-inferior surface of the soft palate. The tongue has been removed, so that the pharyngeal isthmus is distinctly seen. (Luschka.)

The **Gums** (*gingivae*) are composed of a dense fibrous tissue, closely connected to the periosteum of the alveolar processes and surrounding the necks of the teeth. They are covered by smooth and vascular mucous membrane, which is remarkable

for its limited sensibility. Around the necks of the teeth the fibroelastic portion presents numerous fine papillæ; and from this point it is reflected into the alveolus, where it is continuous with the periosteal membrane lining that cavity.

The **Palate** (*palatum*) forms the roof of the mouth; it consists of two portions, the **hard palate**, about two-thirds in front, the **soft palate**, about one-third behind.

The **hard palate** (*palatum durum*) (Figs. 914 and 915) is bounded in front and at the sides by the upper alveolar arches and gums; behind, it is continuous with the soft palate. It is formed by the palate processes of the maxillæ and the palate processes of the palate bones (Fig. 72). It is covered by a dense structure formed by the periosteum and mucous membrane of the mouth, which are intimately adherent, particularly to the front and sides, by means of a layer of fibrous

FIG. 915.—The palatine vault on the right side of the mucous membrane has been removed. The left side shows the mucous membrane and the glandular layer. (Poirier and Charpy.)

tissue. Along the middle line is a **linear ridge** or **raphé** (*raphe palati*), which terminates anteriorly in a small papilla, the **incisive papilla** (*papilla incisiva*), corresponding with the inferior opening of the anterior palatine fossa. On either side and in front of the raphé the mucous membrane is thick, pale in color, and corrugated; these corrugations, which are composed of fibrous tissue, are the **palatine¹ rugæ** (*plicæ palatinae transversæ*). In very young children the rugæ are distinct and definite. In the aged they are indistinct. Behind, it is thin, smooth, and of a deeper color; it is covered with stratified squamous epithelium, and the fibrous tissue beneath it contains many mucous glands, the **palatine glands** (*glandulae palatinae*). The palatine vessels and nerves lie in the fibrous tissue beneath the mucous membrane.

¹ Concerning the etymology of *palatal* and *palatine*, see footnote on page 109.

The **Soft Palate** (*palatum molle*) (Figs. 914 and 915) is a movable fold suspended from the posterior border of the hard palate, and forming an incomplete septum between the mouth and pharynx. It consists of a fold of mucous membrane enclosing muscle fibres, an aponeurosis, vessels, nerves, lymphoid tissue, and mucous glands. When occupying its usual position it is relaxed and pendent, and its oral surface is concave, continuous with the roof of the mouth, and marked by a **median ridge** or **raphé**, which indicates its original separation into two lateral halves. Its pharyngeal surface is convex, and continuous with the mucous membrane covering the floor of the posterior nares. Its anterior or upper border is attached to the posterior margin of the hard palate, and its sides are blended with the pharynx. Its posterior or lower border is free. The posterior portion of the soft palate (*velum palatinum*) terminates posteriorly and externally on each side in a free margin, the posterior arch of the palate, and bounds the isthmus of the pharynx.

Hanging from the middle of its lower border is a small, cone-shaped, pendulous process, the **uvula** (*uvula palatina*). The uvula varies greatly in length in different individuals. It is composed of glands and connective tissue, contains a prolongation of the Azygos uvulæ muscle and is covered with mucous membrane, and arching outward and downward from the base of the uvula on each side are two curved folds of mucous membrane, containing muscle fibres, called the **arches** or **pillars of the soft palate** or **pillars of the fauces** (*arcus palatini*).

The **anterior pillar** (*arcus glossopalatinus*) (Fig. 914) on each side runs downward, outward, and forward to the side of the base of the tongue, and is formed by the projection of the Palatoglossus muscle, covered by mucous membrane.

The **posterior pillar** (*arcus pharyngopalatinus*) (Fig. 914) is larger and projects farther inward than the anterior; it runs downward, outward, and backward to the sides of the pharynx, and is formed by the projection of the Palatopharyngeus muscle, covered by mucous membrane. The anterior and posterior pillars are separated below by a triangular interval (*tonsillar sinus*), in which the tonsil is lodged.

The aperture by which the mouth communicates with the pharynx is called the **isthmus of the fauces** (*isthmus faucium*). It is bounded, above, by the free margin of the soft palate; below, by the back of the tongue; and on each side, by the pillars of the fauces and the tonsils.

The **aponeurosis of the soft palate** is a thin but firm fibrous layer attached above to the posterior border of the hard palate, and becoming thinner toward the free margin of the soft palate. Laterally, it is continuous with the pharyngeal aponeurosis. It forms the framework of the anterior half of the soft palate, and is joined by the tendons of the Tensor palati muscles.

The **muscles of the soft palate** are found in its posterior half, and are six on each side—the **Levator palati**, **Tensor palati**, **Azygos uvulæ**, **Palatoglossus**, **Palatopharyngeus**, and **Salpingopharyngeus** (see p. 398). The following is the relative position of these structures in a dissection of the soft palate from the posterior or nasopharyngeal to the anterior or oral surface: Immediately beneath the pharyngeal mucous membrane is a thin stratum of muscle tissue, the posterior fasciculus of the **Palatopharyngeus muscle**, joining with its fellow of the opposite side in the middle line. This posterior fasciculus is joined by the Salpingopharyngeus muscle. Beneath this are the **Azygos uvulæ** and **Salpingopharyngeus muscles**, consisting of two rounded fleshy fasciculi, placed side by side in the median line of the soft palate. Next comes the aponeurosis of the **Levator palati**, joining with the muscle of the opposite side in the middle line. Fourthly, the anterior fasciculus of the **Palatopharyngeus**, thicker than the posterior, and separating the Levator palati from the next muscle, the **Tensor palati**. This muscle terminates in a tendon which, after winding around the hamular process of the internal pterygoid plate of the sphenoid bone, expands into a broad aponeurosis in the soft palate, anterior to the other muscles so far enumerated. Finally, we have a thin muscular stratum, the **Palatoglossus muscle**, placed in front of the aponeurosis of the Tensor palati, and separated from the oral mucous membrane by lymphoid tissue.

The **mucous membrane of the soft palate** is thin, and covered with stratified squamous epithelium on both surfaces, excepting near the orifice of the Eustachian tube, where its epithelium

is stratified and ciliated.¹ Beneath the mucous membrane on the oral surface of the soft palate is a considerable amount of lymphoid tissue. The palatine glands form a continuous layer on the pharyngeal surface and around the uvula.

The arteries supplying the palate are the **descending palatine branch of the internal maxillary artery** (*a. palatina descendens*), the **ascending or palatine branch of the facial artery** (*a. palatina ascendens*), and sometimes a palatine branch of the ascending pharyngeal. The **veins** terminate chiefly in the pterygoid and tonsillar plexuses. The **lymphatic vessels** pass to the deep cervical nodes.

Development of the Mouth.—The mouth is developed partly from the stomodeum, the depression between the head end of the embryo and the pericardial area, and partly from the floor of the extreme end of the foregut. The floor of the stomodeum is the thin, buccopharyngeal membrane, formed by the apposition of ectoderm and entoderm; this membrane wholly disappears after the second week of embryonic life, and a communication is established between the mouth and future pharynx. With the development of the face the nasal passages are separated from the mouth proper by the coalescence of the maxillary and palatal processes of the first visceral arch with the lateral nasal and globular processes forming the maxillæ and palate.

The development of the teeth is described on page 1214.

Applied Anatomy.—**Cleft palate** is by no means a rare congenital deformity, and may be partial or complete. Most of the cleft is in the middle line. It may be a mere cleft of the uvula, it may be limited to the soft palate, or it may involve the hard palate to but not include the alveolus. It may pass through the alveolus, but if it does so it ceases to be median at this point, and follows the line of suture between the incisive bone and the maxilla (pp. 106 and 152). Complete cleft palate is likely to be accompanied by *harelip*. This cleft in the lip is not median, but is at the termination of the palate cleft. If the cleft of a cleft palate runs along each side of the incisive bone, the bone is isolated from the maxilla and the cleft is Y-shaped. In such a case *double harelip* is present.

The **Teeth** (*dentes*).—The human subject is provided with two sets of teeth, which make their appearance at different periods of life.

Those of the first set appear in childhood, and are called the **temporary, deciduous, or milk teeth**. Those of the second set are named **permanent or succedaneous teeth**.

The **temporary teeth** are twenty in number—four incisors, two canines, and four molars in each jaw (Figs. 916 and 933).

The **permanent teeth** are thirty-two in number—four incisors (two central and two lateral), two canines, four bicuspid, and six molars in each jaw (Figs. 918 and 922).

The dental formulæ may be represented as follows:

Temporary Teeth.

	Molar.	Canine.	Incisor.	Incisor.	Canine.	Molar.	
Upper jaw . . .	2	1	2	2	1	2	} Total, 20.
Lower jaw . . .	2	1	2	2	1	2	

Permanent Teeth.

	Molar.	Bicuspid.	Canine.	Incisor.	Incisor.	Canine.	Bicuspid.	Molar.	
Upper jaw . . .	3	2	1	2	2	1	2	3	} Total, 32.
Lower jaw . . .	3	2	1	2	2	1	2	3	

General Characters (Fig. 923).—Each tooth consists of three portions—the **crown or body** (*corona dentis*), projecting above the gums; the **root or fang** (*radix dentis*), entirely concealed within the alveolus; and the **neck** (*collum dentis*), the constricted portion between the root and crown, covered by the gum.

The **roots** of the teeth are firmly implanted within the **sockets or alveoli of the jaws** (*alveoli dentales*) (see pp. 104 and 117). These depressions are lined with periosteum, which is reflected on to the tooth at the apex of the root and covers

¹ According to Klein, the mucous membrane on the nasal surface of the soft palate in the fetus is covered throughout by columnar ciliated epithelium, which subsequently becomes squamous; and some anatomists state that it is covered with columnar ciliated epithelium, except at its free margin, throughout life.

it as far as the neck. This is the **root**-, or **pericemental membrane** (*periosteum alveolare*). At the margin of the alveolus the periosteum becomes continuous with the fibrous structure of the gums.

Surfaces.—In consequence of the curve of the dental arch, such terms as anterior, posterior, internal, and external, as applied to the teeth, are misleading and confusing. Special terms are therefore applied to the different surfaces of a tooth: That which looks toward the lips and cheek is the **labial** or **buccal surface** (*facies*

FIG. 916.—Deciduous teeth of left side. Labial view.

FIG. 917.—Deciduous teeth. Lingual view.

labialis); that toward the tongue is the **lingual surface** (*facies lingualis*); that surface which is directed toward the mesal plane, supposing the teeth were arranged in a straight line outward from the central incisor, is known as the **proximal surface**, looks toward predecessor; while that directed away from the mesal plane is called the distal surface, looks toward successor. The surface which comes in contact with the teeth of the opposite jaw is the **grinding, masticating, or occlusal surface** (*facies masticatoria*).

FIG. 918.—Permanent teeth, right side. (Burchard.)

The **Temporary, Deciduous, or Milk Teeth** (*dentes decidui*) (Figs. 916 and 917) are smaller, but resemble in form those of the permanent set. The neck is more marked, owing to the greater degree of convexity of the labial and lingual surfaces of the crown. The last of the two temporary molars is the largest of all the deciduous teeth, and is succeeded by the second bicuspid. The first upper molar has only three cusps—two labial, one lingual; the second upper molar has four cusps. The first lower molar has four cusps; the second lower molar has five.

The roots of the temporary molar teeth are smaller and more diverging than those of the permanent set, but in other respects bear a strong resemblance to them.

Permanent Teeth (*dentes permanentes*) (Fig. 918).—The **incisors** or **cutting teeth** (*dentes incisivi*) are so named from their presenting a sharp cutting edge, adapted for incising the food. They are eight in number, and comprise the four front teeth in each jaw.

The **crown** is directed vertically and is chisel-shaped, being bevelled at the expense of its lingual surface, so as to present a sharp horizontal cutting edge. Before being subjected to attrition this edge presents three small elevations. The **labial surface** is convex, smooth, and highly polished. The **lingual surface** is concave, and is marked by two marginal ridges extending from an encircling ridge at the neck to the angles of the cutting edge of the tooth. The ridge at the neck is termed the **cingulum** or **basal ridge**. The **neck** of the tooth is constricted. The **root** is long, single, conical, transversely flattened, thicker before than behind, and slightly grooved on either side in the longitudinal direction. The root may be curved.

FIG. 919.—Right half of upper jaw (from below), with the corresponding teeth. The letters and numbers point to the classes of teeth and the numbers in classes.

FIG. 920.—Right half of lower jaw, with the corresponding teeth. The letter and numbers point to the various cusps or their modifications on the different teeth. (Burchard.)

The **incisors of the upper jaw** are altogether larger and stronger than those of the lower jaw, the central incisors being larger and flatter than the lateral incisors. They are directed obliquely downward and forward.

The **incisors of the lower jaw** are smaller and flatter than the upper, and the elevations upon their lingual faces are not marked. The two central are smaller than the two lateral incisors, being the smallest of all the teeth. The **roots** of these teeth are flattened laterally.

The **Canine Teeth** (*dentes canini*) are four in number, two in the upper, two in the lower jaw—one being placed distal to each lateral incisor. They are larger and stronger than the incisors, especially in the roots, which are deeply implanted and each causes a well-marked prominence of the process at the place of insertion.

The **crown** is large, of spear-head form, and its very convex labial surface is marked by three longitudinal ridges. The concave lingual surface is also marked by three ridges which unite at a basal ridge. The **point** or **cusp** is longer than in the other teeth, and is the point of division between a short proximal and a long distal cutting edge. These two edges form an obtuse angle with each other.

The **root** is single, oval, or elliptical on transverse section, and is longer and more prominent than the roots of the incisors.

The **upper canines**, popularly called the **eye teeth**, are larger and longer than the two lower, and in occlusion are distal to them to the extent of half the width of the crown.

The **lower canines**, popularly called the **stomach teeth**, have the general form of the upper canines, but their lingual surfaces are much more flattened, owing to the absence of the elevations marking the upper teeth. Their roots are more flattened and may be bifid at their apices.

The **bicuspid teeth**, or the **premolars** (*dentes premolares*), are eight in number, four in each jaw; they are placed distal to the canine teeth, two upon each side of the jaw.

The **crown** is surmounted by two cusps, one buccal and one lingual, separated by a groove, the buccal being more prominent and larger than the lingual. The lower bicuspid is not truly bicuspid, the first having but a primitive lingual cusp, the second having the lingual cusp divided into two sections—i. e., it is usually tricuspid. The **necks** of the teeth are oval; the **roots** are single and laterally compressed, that of the first upper bicuspid being frequently bifid. The first upper bicuspid is usually the largest of the series. The roots of the lower bicuspid are less compressed and more rounded.

The **Molar Teeth** (*dentes molares*) are the largest and strongest teeth of the permanent set, and are adapted by their forms for the crushing and grinding of the food. They are twelve in number, six in each jaw, three being placed posterior to each second bicuspid.

The **crowns** are cuboidal in form, are convex buccally and lingually; they are flattened proximally and distally. They are formed by the fusion of three primitive cuspids in the upper and four in the lower. To these are added in the first and second upper molars a **distolingual tubercle**, and in the first and third molars of the lower jaw a **distobuccal tubercle**. The unions of the primitive forms are marked by sulci. The necks of these teeth are large and rhomboidal in form. The **roots** of the upper molars are three in number—one large **lingual** or **palatal root**, and two smaller **buccal roots**. In the lower molars, two roots are found, a proximal and a distal, each of which is much flattened from before backward.

The **first molar teeth** are the largest of the dental series; they have four cusps on the upper and five in the lower—three buccal and two lingual. The **second molars** are smaller; the crowns of the upper are compressed until the distolingual cusp is reduced. The crowns of the lower are almost rectangular, with a cusp at each angle. The **third molars** are called the wisdom teeth, or *dentes sapientiae* (*dentes serotini*), from their late eruption; they have three cusps upon the upper and five upon the lower. The three roots of the upper are frequently fused together, forming a grooved cone, which is usually curved backward. The roots of the lower, two in number, are compressed together, and curve backward.

Of the permanent teeth, all but the molars represent succedaneous teeth, that is, teeth that succeed those of the temporary set. The molars are primary teeth, as they possess no forerunners in the temporary set.

Arrangement of the Teeth.¹—The human teeth are arranged in two parabolic arches, the **upper row** or **arch** (*arcus dentalis superior*) being larger, its teeth overlapping the **lower row** or **arch** (*arcus dentalis inferior*). The average distance between the centres of the condyles of the mandible is about four inches, which is also the distance from either of these points to the line of junction between the lower incisor teeth. Whether the jaw be large or small, the equilateral triangle

¹ After Dr. W. G. A. Bonwill.

indicated is included in it; the range of size is between three and one-half and four and one-half inches.

FIG. 921.—View of teeth *in situ*, with the external plates of the alveolar processes removed. (Cryer.)

Owing to the smaller sizes of the lower incisors, the teeth of the mandible are each one-half a tooth in advance of its upper fellow, so that each tooth of the dental

FIG. 922.—Front and side views of the teeth and jaws. (Cryer.)

series has two antagonists, with the exception of the lower central incisors and upper third molars (Figs. 921 and 922).

The grinding faces of the upper bicusps and molars curve progressively upward and point outward, the first molar being at the lowest point of the curve, the third molar at the highest. The curve of the lower dental arch is the reverse, the first molar at its deepest part, the third molar at its extremity. The greater the depth to which the upper incisors overlap the lower, the more marked this curve and the more pointed are the cusps of the grinding teeth.

The movement of the human mandible is forward and downward, the resultant of these directions being an oblique line, upon an average of 35 degrees from the horizontal plane.¹

When the mandible is advanced until the cutting edges of the incisors are in contact, the jaws are separated, but at the highest point of the lower arch its third molar advances, and meets and rests upon a high point, the second molar of the upper arch, and thus undue strain upon the incisors is obviated.

In the lateral movements of the mandible but one side is in effective action at one time; the oblique positions of the cusps of the opposite teeth are such that when either side is in action the other is balanced at two or more points.

FIG. 923.—Vertical section of a molar tooth.

FIG. 924.—Vertical section of a tooth *in situ* (15 diameters). *c* is placed in the pulp cavity, opposite the cervix, or neck of the tooth; the part above is the crown, that below is the root (fang). 1. Enamel with radial and concentric markings. 2. Dentine with tubules and incremental lines. 3. Cementum or crusta petrosa, with bone corpuscles. 4. Pericemental membrane. 5. Bone of mandible.

There is an anatomical correspondence between the forms and arrangement of the teeth, the form of the condyle of the mandible, and the muscular arrangement. Individuals who have teeth with long cusps have the head of the bone much rounded from before backward, and have a preponderance of the direct over the oblique muscles of mastication, and *vice versa*; teeth with short or no cusps are associated with a flattened condyle and strong oblique muscles.

Very great aberrations in the dental arrangement are frequently followed by accommodative changes in the condyles of the mandible.

Structure of the Teeth.—A longitudinal section of a tooth will show the presence of a central chamber having the general form of the crown of the tooth, and called the **pulp chamber** or **pulp cavity** (*cavum dentis*). The solid portion of the tooth exhibits three hard tissues: one, the

¹ W. E. Walker, *Dental Cosmos*, 1896.

proper dental substance, called **dentine** or **ivory**, sheathed upon the exposed crown by a layer called the **enamel**, while the dentine of the root is enclosed in a distinct tissue, the **cementum** or **crusta petrosa**. Both enamel and cementum are thinnest at the neck and thickest upon their distal portions.

The **enamel** (*substantia adamantina*) (Figs. 924, 925, and 928) is the hardest and most compact part of a tooth, and forms a thin crust over the exposed part of the crown, as far as the commencement of the root. It is thickest on the grinding surface of the crown until worn away by attrition, and becomes thinner toward the neck. It consists of a congeries of minute hexagonal rods, columns, or prisms, known as **enamel fibres** or **prisms** (*prismata adamantina*) (Fig. 928). In general they lie parallel with one another, resting by one extremity upon the dentine, which presents a number of minute depressions for their reception, and forming the free surface of the crown by the other extremity. There are additional shorter (*supplemental*) prisms filling in the spaces between the long diverging prisms. There are occasional collections of prisms which run diagonally. The prisms are directed vertically on the summit of the crown, horizontally at the sides; they are about the $\frac{1}{3500}$ of an inch in diameter, and pursue a more or less wavy course. By reflected light radial striations are visible, best marked near the dentine. These are **Schreger's lines**, and are due to the fact that the prisms take an undulatory course

FIG. 925.—Longitudinal ground section through the apex of a canine tooth from a three-and-a-half-year-old boy. The entrance of the dental canaliculi between the enamel prisms and the course taken by the latter are shown. $\times 135$. (Szymonowicz.)

and those of two layers may have opposite directions. Another series of lines, having a brown appearance from pigmentation, and denominated the **parallel striæ** or **brown striæ of Retzius**, or the **colored lines**, are seen on a section of the enamel. These lines are concentric, and cross the enamel rods. They are caused by the mode of enamel deposition. Inasmuch as the enamel columns, when near the dentine, cross each other and only become parallel farther away, a series of radial markings, light and dark alternately, is obtained (Fig. 924). The enamel prisms are themselves calcified and are fixed to each other by a very small amount of cement substance. Numerous minute interstices intervene between the enamel fibres near their dentinal surface. It is noted that some of the dentinal canals at the crown penetrate a certain distance between the rods of the enamel; this is considered pathological by some (Fig. 925). No nutritive canals exist in the enamel, except the very few dentinal canals which at the crown penetrate a short distance, and these are found only in a small area.

Chemical Composition.—According to Bibra, enamel consists of 96.5 per cent. of earthy matter and 3.5 per cent. of animal matter. The earthy matter consists of the phosphate and

he carbonate of calcium, with traces of fluoride of calcium, phosphate of magnesia, and other salts.

The **enamel** of a recently erupted tooth is covered by a membrane, the thickness of which is $\frac{1}{100}$ of an inch. It is known as **enamel cuticle** or **Nasmyth's membrane** (*cuticula dentis*). It is probably the remains of the enamel organ, though some consider it the continuation of the cementum.

The **dentine** or **ivory** (*substantia eburnea*) (Fig. 927) forms the principal mass of the tooth. It represents modified bone, but differs from the latter in that its cells are upon the surface of the pulp and not in the substance of the dentine. The important parts are: dentinal tubules, dentinal sheaths, matrix, and dentinal fibres.

The **dentinal tubules** are minute canals which have a spiral course, more or less perpendicular to the pulp cavity, and extending from this cavity to the enamel or to the cementum. The diameter at the pulpal end is about $\frac{1}{100}$ of an inch, and this diminishes as the tubules branch. The tubules usually end blindly near the enamel; some, however, terminate in the interglobular spaces or anastomose with other tubules. The dentinal tubules contain the **dentinal fibres**, which represent the peripheral processes of the odontoblastic cells, and their branches follow the divisions of the tubules. The tubule branches are most numerous near the enamel or the cementum.

FIG. 926.—Ground section through the root of a human premolar. D, Dentine. K, Cement corpuscles. O, Osteoblasts. Ep, Remains of Hertwig's epithelial sheath, 200 diameters. J, Interglobular spaces. (Röse.)

FIG. 927.—From a ground section through the parts of a dentine, near the pulp, of a human canine tooth which has been impregnated with pigment. The dental canaliculi are cut across and are joined together by side branches. $\times 400$.

The **dentinal sheaths**, or **Neumann's sheaths**, are tubes of markedly resistant dentine surrounding and bounding the dentinal tubules. They branch and curve as do the tubules.

The **matrix**, or **intertubular dentine**, is less dense than that of the sheaths. It fills the spaces between the sheaths, and seems to be composed of lamellæ that run parallel to the pulp chamber. Fibrils have been found in the matrix. Scattered in the matrix, and especially near the enamel, are numerous spaces filled with a gelatinous substance; these are the **interglobular spaces** (*spatia interglobulares*), representing areas of incomplete calcification. Between the dentine and cementum the spaces are very numerous, but small; these constitute **Tomes' granular layer**.

In a **dry** tooth a section of dentine often displays a series of lines—the **incremental lines of Salter**—which are parallel with the laminae above mentioned. These lines are caused by two facts: (1) The imperfect calcification of the dentinal laminae immediately adjacent to the line. (2) The drying process, which reveals these defects in the calcification. These lines are wide or narrow according to the number of laminae involved, and along their course, in consequence of the imperfection in the calcifying process, little irregular cavities are left, which are the **interglobular spaces** already referred to. They have received their name from the fact that they are surrounded by minute nodules or globules of dentine. Other curved lines may be seen parallel to the surface. These are the **concentric lines of Schreger**, and are due to the optical effect of simultaneous curvature of the dentinal tubules.

Chemical Composition.—According to Berzelius and Bibra, dentine consists of twenty-eight parts of animal and seventy-two of earthy matter. The animal matter is resolvable by boiling into gelatin. The earthy matter consists of phosphate and carbonate of calcium, with a trace of fluoride of calcium, phosphate of magnesia, and other salts.

The **cementum**, or **crusta petrosa** (*substantia ossea*) (Fig. 924), is disposed as a thin layer on the roots and neck of a tooth, from the termination of the enamel as far as the apex of the root, where it is usually very thick. At the neck it overlies a slight margin of enamel. In structure and chemical composition it is true bone. It consists of a number of lamellæ that are thicker near the apex than the neck of the tooth in young teeth. In older teeth there are additional shorter supplemental lamellæ at the apex. Between the lamellæ are the lacunæ and canaliculi, and it is claimed that in thick cementum even Haversian systems may be found. It is composed of about 66 per cent. organic matter and 34 per cent. inorganic matter. The teeth of the young usually contain Haversian systems in the thicker portions of the cementum. The neck of the tooth does not contain lacunæ. Sharpey's fibres (p. 38) are very numerous. Some of the lacunæ of the cementum receive dentinal tubes from the dentine.

As age advances the cement increases in thickness, and gives rise to those bony growths, or exostoses, so common in the teeth of the aged; the pulp cavity becomes also partially filled up by a hard substance intermediate in structure between dentine and bone (the *osteodentine* of Owen; the *secondary dentine* of Tomes). It is formed by the odontoblasts, the dental pulp lessening in volume.

FIG. 928.—Enamel prisms (350 diameters). A. Fragments and single fibres of the enamel isolated by the action of hydrochloric acid. B. Surface of a small fragment of enamel, showing the hexagonal ends of the fibres.

The **pulp** (*pulpa dentis*) occupies the **pulp cavity** or **chamber**. This chamber communicates with the outside through a minute canal in the apex of each fang, called the **root canal** (*canalis radialis dentis*). The foramen at the apex is called the **apical foramen** (*foramen apicis dentis*). The **pulp** is a highly vascular and sensitive mass of mucous connective tissue connected with the nutrition and sensitiveness of the tooth. It consists of a network of delicate fibrils supporting spindle-shape, stellate, and spheroidal cells, and, lastly, the **odontoblasts**, which are arranged in a single row upon the surface of the pulp; each odontoblast is a cylindrical or flask-shaped cell possessing several processes, of which the peripheral becomes the **dentinal fibre**. The bloodvessels of the pulp break up into innumerable capillary loops which lie beneath the layer of odontoblasts. The nerve fibrils break up into numberless amyelinic filaments, which spread out beneath the odontoblasts, and probably send terminal filaments to the extreme periphery of the pulp outside the odontoblasts. The matrix cells and their processes are irregularly arranged in the body of the pulp, but in the canal portion the fibrillæ are in the direction of the axis of the root.

The **peridental membrane** (*pericementum*) is a vascular and sensitive fibrous tissue membrane that holds the tooth in place. Upon its internal surface it forms cementum, while upon its outer surface it forms the bone of the alveolar process of maxilla or mandible. It is thickest at the apical and gingival regions of the tooth and thin in the middle. Upon its inner surface are seen cementoblasts, and upon its outer surface are found osteoblasts. The **arteries** are derived from the apical artery, and ultimately form a capillary plexus beneath the cemental and alveolar surfaces of the membrane. The venous channels converge at the apex to empty into the apical vein.

Lymphatics are said to be absent.

Development of the Teeth (Figs. 929 to 935).—The teeth are an evolution from the dermoid system, and not of the bony skeleton; they are developed from two of the blasto-

germ layers, the ectoderm and mesoderm. From the former the enamel is developed; from the latter the dentinal pulp, dentine, cementum, and peridental membrane. It is customary to view the development of the permanent and temporary teeth as separate studies.

The earliest evidence of tooth formation in the human embryo is observed about the sixth week. The epithelium covering the embryonic jaws is seen to rise as a ridge along the summit of each jaw. This ridge is the **maxillary rampart of Kölliker and Waldeyer**. A transverse section through the jaw will show the elevation to be due to a linear and outlined activity of the germinal epithelial layer; a corresponding epithelial growth is seen to sink as a band into the mesodermal tissue beneath. This band is called the **dental lamina** or **dental shelf**. The local

FIG. 929.—Anlage of the enamel germ connected with the oral epithelium by the enamel ledge. $\times 110$.

FIG. 932.—Budding from the enamel ledge of the anlage of the enamel germ, which later goes to form the enamel of a permanent tooth; at the periphery of the papilla the odontoblasts are beginning to differentiate. $\times 40$.

FIGS. 929 to 932.—Four stages in the development of a tooth in a sheep embryo (from the lower jaw). (From Böhm and Davidoff.)

cell activity continues, and in its descent the band appears to meet with a resistance which causes a flattening of its extremity into a continuous lamina. From the outer or labial surface of the shelf epithelial buds are given off successively, ten in number, one for each temporary tooth; the earliest (central incisors) appear about the seventh to the eighth week.

The growth of each bud continues, and each expands into a flask-like form, the walls covered by a layer of germinal cells, its interior composed of stellate cells. The bulb is now seen to flatten upon its deep surface, as though it had met with an outlined resistance from the mesodermal

tissue beneath. The mesoderm at the base of each enamel organ condenses, and seems to force the adjacent part of the enamel germ toward the apex of the organ, producing thus a sac-like structure, the **enamel organ**; the latter now consists of three layers, outer columnar layer, middle, stellate reticulum, and inner, enamel-forming cells, the **membrana adamantina**. The papilla-like mass of mesoderm that extends into the enamel organ is called the **dental papilla**.

FIG. 933.—Vertical section of the mandible of an early human fetus. (Magnified 25 diameters.)

The mesoderm peripheral to the enamel organ condenses to form a sheath called the **dental sac** or **follicle**. In the meantime the dental shelf becomes attenuated and tends to disappear, and bone is being deposited in the intervals around and between the teeth, so that the latter soon lie in a gutter of bone.

The cells of the enamel organ now undergo a series of differentiations. The inner layer, arranged as columnar epithelium, are the **enamel cells**, or **ameloblasts**. The layer is called the

FIG. 934.—Section through tooth follicle—human canine seven and one-half months. A. Follicular wall. B. Outer epithelial coat. C. Stellate reticulum. D. Stratum intermedium. E. Ameloblasts. F. Odontoblasts. G. Pulp.

ameloblastic or **enamel-forming layer** (Figs. 934, 935, and 936). The cells of the outer wall remain cuboidal; the cells which lie between become much distended, and on account of their appearance when seen in section this portion of the organ is called the **enamel jelly** or the **stellate reticulum**. The layer of cells immediately contiguous to the ameloblasts form a layer called the **stratum intermedium** (Fig. 934, D).

The enclosed **mesoblastic papilla** (the *future dental pulp*) has its peripheral cells, which are called **odontoblasts**, differentiated into columnar bodies disposed as a layer, each cell having a large nucleus. The vascular supply of the pulp is now well marked. A section of a follicle at this period will exhibit the follicular wall springing from the base of the dental papilla and having a well-marked blood supply. The bony alveolar walls are well outlined, and evidences of periosteum appear (Figs. 933, 934, and 935).

Development of Enamel (Fig. 935).—In point of time, the deposition of dentine actually begins before that of enamel, so that the first-formed layer of enamel is deposited against a layer of immature dentine, and is formed from within outward, so that the youngest enamel is upon the surface of the tooth. The enamel is built up of two distinct substances—globules of uniform size which are formed by the ameloblasts, and a cementing substance, probably an albuminate of calcium (calcoglobulin), the basis of all the calcified tissues. In the ends of the ameloblasts, next to the dentine, the secretion of calcoglobulin is deposited, and into the plastic mass the enamel globules are extruded, each globule remaining connected with the ameloblasts by plasmic strings, which also join the globules laterally.¹

The first deposit of enamel begins in the tips of the cusps, and is quickly followed by a disappearance of the stellate reticulum at that point; the stellate reticulum appears to atrophy, so that the vascular follicular wall is brought into direct apposition with the stratum intermedium, which becomes differentiated into a glandular (secreting) tissue which elaborates the calcic albuminous basis of the enamel. The secretion passes from the cells of the stratum intermedium through a membrane into the ameloblasts, where it is in part combined with the cellular globules, and irregular masses of it are extruded as cementing substance. The deposition continues until the enamel cap has its typical form. The deposition of the layers of globules is indicated by parallel lines transverse to the axes of the enamel rods. At the completion of amelification the ameloblasts are partially calcified and form the **enamel cuticle** or **Nasmyth's membrane** (*cuticula dentis*).

Formation of Dentine.—The layer of columnar cells bounding the periphery of the pulp, the **odontoblasts**, are in apposition with a plexus of capillary vessels (Fig. 936). Each cell is a secreting body which selects the material for dentine building. Against the layer of ameloblasts, the *membrana eboris*, covering the dental papilla, the odontoblasts deposit globules of the calcium albuminate, and receding as the deposits are made, leave one or more protoplasmic processes in the calcic deposit. These are known as **Tomes'** or **dental fibres**. The process continues until the normal dentine thickness is formed. The deposit is laid down in a scaffolding of finely fibrillated tissue, and begins about the sixteenth week. The layer of formative cells remains constant. The remains of the dental papilla constitute the **pulp** and lie in the pulp cavity (p. 1214).

Formation of Cementum.—As the enamel organ continues to grow the dental follicle covering atrophies, while that over the future root region continues to grow. Upon its dentinal surface the stellate cells constitute the **cementoblasts**. Upon its outer surface the stellate cells are **osteoblasts** that form the alveolar bone. The cementum of the tooth is not formed until the dentine has extended below the enamel cap, while the cementum of the apex is not completed until after the eruption of the tooth.

Formation of Alveoli.—By the time the crowns of the teeth have formed, each is enclosed in a loculus of bone which has developed around it and at some distance from it; the developing permanent tooth is contained in the same loculus, but is later separated from the temporary tooth by a growth of bone. The alveolar process is not completed until after the eruption of the teeth. During eruption that portion of the process overlying the crown undergoes absorption, and as soon as the immature tooth is erupted the alveolar process has developed about the root, whose formation is also completed after eruption.

Development of the Permanent Teeth.—The permanent teeth as regards their development may be divided into two sets: (1) Those which replace the temporary teeth, and which, like them, are ten in number; these are the **successional permanent teeth**; and (2) those which have no temporary predecessors, but are superadded at the back of the dental series. These are three in number on either side in each jaw, and are termed the **superadded permanent teeth**. They are the three molars of the permanent set, the molars of the temporary set being replaced by the premolars or bicuspsids of the permanent set.

FIG. 936.—Part of section of developing tooth of young rat, showing the mode of deposition of the dentine (highly magnified). a. Outer layer of fully calcified dentine. b. Uncalcified matrix with a few nodules of calcareous matter. c. Odontoblasts with processes extending into the dentine. d. Pulp. The section is stained with carmine, which colors the uncalcified matrix, but not the calcified part.

The **Development of the Successional Permanent Teeth**—the ten anterior ones in either jaw—will be first considered. The germs for these teeth are developed from the lingual side of the dental shelf, opposite to the corresponding temporary teeth. The germ for the central incisor appears at about the *seventeenth week*, and the others follow successively in order of their eruption. The deposition of enamel, dentine, and cementum occurs as in the temporary teeth. The sac of each permanent tooth is also connected with the fibrous tissue of the gum by a slender band of the *gubernaculum*, which passes to the margin of the jaw behind the corresponding milk tooth (see above).

The **Superadded Permanent Teeth**—three on each side in each jaw—develop as primary teeth. The enamel germ for the first molar tooth appears during the *sixteenth week from the end of the dental shelf*. The enamel germ for the second molar tooth appears about the *fourth month after birth* from the neck of the enamel sac of the first molar tooth, while that for the third molar or wisdom tooth does not appear until the *third year after birth*, from the enamel sac of the second molar tooth.

Eruption.—When the teeth are ready to erupt the bone between them and the gum is absorbed as well as that covering the labial surface of the crown, until one-half of the enamel is exposed. The bone covering the lingual surface is more slowly absorbed, as it protects the permanent tooth germ beneath. As a result of this process the tooth is exposed by the removal of the bone around the crown, and not by a growth upward of the tooth itself. In the replacement of the temporary teeth by the permanent set the roots of the temporary teeth are gradually absorbed until merely the enamel cap and contained dentine remain. The hold of the tooth upon the jaw is weakened so that it may readily be removed or lost.

FIG. 937.—The milk teeth in a child aged about four years. The permanent teeth are seen in their alveoli. (Cryer.)

Calcification of the permanent teeth proceeds in the following order: First molar, soon after birth; the central incisor, lateral incisor, and canine, about six months after birth; the bicuspsids, at the second year or later; second molar, end of second year; third molar, about the twelfth year.

The **Eruption of the Temporary Teeth** commences at the seventh month, and is complete about the end of the second year.

The periods for the eruption of the temporary set are (C. S. Tomes):

Lower central incisors	6 to 9 months.
Upper incisors	8 to 10 "
Lower lateral incisors and first molars	15 to 21 "
Canines	16 to 20 "
Second molars	20 to 24 "

The Eruption of the Permanent Teeth takes place at the following periods, the teeth of the lower jaw preceding those of the upper by a short interval:

6½ years, first molars.	10th year, second bicuspid.
7th year, two middle incisors.	11th to 12th year, canine.
8th year, two lateral incisors.	12th to 13th year, second molars.
9th year, first bicuspid.	17th to 21st year, third molars.

THE TONGUE (LINGUA) (Fig. 938).

The tongue is a very mobile muscular organ, undergoing changes in length and width at every contraction of its muscle. It is one of the organs of the special sense of taste, and is also an organ of speech, and assists in insalivation, mastication, and deglutition. It is situated in the floor of the mouth, in the interval between the two lateral portions of the body of the mandible, and when at rest is about three and one-half inches (8.75 cm.) in length. We describe the **body**, **base**, **apex**, **dorsum**, **margin**, and **inferior surface**.

The **body** (*corpus linguae*) forms the great bulk of the organ and is composed of striated muscle.

The **base** or **root** (*radix linguae*) is directed backward and connected with the hyoid bone by the Hyoglossi and Geniohyoglossi muscles and the hyoglossal membrane; with the epiglottis by three folds, **glossoepiglottic folds**, of mucous membrane; with the soft palate by means of the anterior pillars of the fauces; and with the pharynx by the Superior constrictor muscles and the mucous membrane.

The **apex** or **tip** (*apex linguae*) is free, thin, and narrow, and is directed forward against the inner surface of the lower incisor teeth.

The **dorsum** of the tongue (*dorsum linguae*) of a living person, when at rest, is markedly arched from before backward. On the dorsum is a **median longitudinal raphe** (*sulcus medianus linguae*). This slight depression terminates posteriorly in the depression known as the **foramen cecum** (*foramen caecum linguae* [*Morgagnii*]), from which a shallow-shaped groove, the **sulcus terminalis** of His, runs outward and forward on each side to the lateral margin of the tongue. The part of the dorsum of the tongue in front of this groove, known as the **anterior**, **apical**, or **oral part**, forming about two-thirds of its upper surface, looks upward, is practically horizontal, and is rough and covered with papillæ; the posterior or **basal** third of the dorsum is vertical and looks backward, is smoother, and contains numerous muciparous glands and lymphoid follicles.

The **margin** of the tongue (*margo lateralis linguae*) is free in front of the anterior arch of the palate. Just in front of the arch are several vertical folds, the **folia linguae**.

The **under** or **inferior surface** (*facies inferior linguae*) of the tongue is connected with the mandible by the Geniohyoglossi muscles; from its sides the mucous membrane is reflected to the inner surface of the gums, and from its under surface on to the floor of the mouth, where, in the middle line, it is elevated into a distinct vertical fold, the **frenum linguae** (*frenulum linguae*). To each side of the frenum is a slight fold of the mucous membrane, the **plica fimbriata**, the free edge of which exhibits a series of fringe-like processes.

The tip of the tongue, part of the under surface, its sides, and dorsum are free.

Structure of the Tongue.—The tongue is partly invested by mucous membrane and a sub-mucous fibrous layer surrounding the central muscle tissue. It consists of symmetrical halves, separated from each other, in the middle line, by a fibrous septum. Each half is composed of muscle fibres arranged in various directions (p. 394), containing many glands and much interposed fat, and supplied by vessels and nerves.

The **mucous membrane** (*tunica mucosa linguae*) invests the entire extent of the free surface of the tongue. On the dorsum it is thicker behind than in front, and is continuous with the

sheath of the muscles attached to it, through the submucous fibrous layer. On the under surface of the organ, where it is thin and smooth, it can be traced on each side of the frenum through the ducts of the submaxillary and the sublingual glands. As it passes over the borders of the organ it gradually assumes a papillary character. That covering the under surface of the organ is thin, smooth, and identical in structure with that lining the rest of the oral cavity. The mucous membrane covering the tongue behind the foramen cecum and sulcus terminalis is thick and freely movable over the subjacent parts.

The mucosa consists of stratified squamous epithelial cells resting upon a basement membrane, and this upon a papillated tunica propria of fibroelastic tissue containing the capillary loops and nerves. Upon the apical two-thirds of the dorsum of the tongue the projections of the mucosa are seen, and these are the papillæ. They vary in number, size, form, and location; they are the **filiform papillæ**, **fungiform papillæ**, and **circumvallate papillæ**.

FIG. 938.—Upper surface of the tongue.

The **filiform** or **conical papillæ** (*papillae filiformes*) are small and scattered over the apical two-thirds (dorsum and margin) of the tongue, and are arranged in parallel lines that are directed outward and forward, especially posteriorly. Minute *secondary papillæ* of a whitish color project from these filiform structures.

The **fungiform papillæ** (*papillae fungiformes*) (Fig. 939) are scattered sparingly over the dorsum of the tongue, and are more numerous at the sides and apex. They are larger in size but less numerous than the preceding, and are readily recognized by their large size and deep red color. Their bases are narrow and constricted, while the free ends are large and blunt; the whole papilla is above the general epithelial surface of the tongue. These papillæ possess secondary papillæ, and in their epithelium *taste buds* are at times seen.

The **circumvallate papillæ** (*papillae vallatae*) (Fig. 939) are of large size, but only eight to twelve in number. They are arranged like a letter V at the junction of the apical two-thirds and basal one-third of the dorsum, with the apex at the foramen cecum and the arms directed out-

ward and forward just in front of the sulcus terminalis. These papillæ are partially or wholly submerged, that is, lie in depressions. Each consists of a narrow base, attached at the bottom of the depression, while the remainder is surrounded by the vallum or ditch. Each papilla is from $\frac{1}{8}$ to $\frac{1}{4}$ inch in width and possesses secondary papillæ. In the epithelium of the sides are found the taste buds.

The **foramen cecum**, according to His, represents the remains of the evagination that formed the middle lobe of the thyroid body and the upper end of the supposed **thyroglossal duct** (*ductus thyroglossus*). This may exist as a canal, at times extending toward the hyoid bone.

FIG. 939.—Three kinds of papillæ, magnified.

Upon the posterior or basal one-third of the dorsum of the tongue papillæ are not found. The surface is irregular, however, due to the presence of follicular collections of lymphoid tissue, that produce rounded elevations of the mucosa. Each follicle possesses a little pit or crypt, and collectively the follicles are termed the **lingual tonsil** (*tonsilla lingualis*). Each crypt is lined by stratified squamous epithelial cells upon basement membrane and tunica propria; in the latter are numerous solitary follicles arranged around the pit, and each group is isolated from the neighboring collection.

Beneath the tunica propria of the mucosa is the **muscle tissue of the tongue**. This muscle tissue is of the voluntary striated variety and is divided into two sets of muscles—Intrinsic and Extrinsic (described on p. 395).

Scattered throughout the tongue, but especially located in definite areas, are glands of a mucous and serous character. The mucous glands are found behind the circumvallate papillæ and along the margins, and an especial group at the apex, called the **apical glands** or **glands of Nuhn and Blandin** (*glandulæ linguales anteriores of Nuhn and Blandin*) (Fig. 941). Each gland is situated at the side of the frenulum and is covered by a fasciculus of muscle fibres derived from the Styloglossus and Inferior lingualis muscles. Each gland is from one-half inch to nearly an inch in length (1 to 2 cm.) and about one-third of an inch broad (8 mm.). Each gland has from four to six ducts, which open on the under surface of the apex. The **serous glands**, or **glands of von Ebner**, occur in the basal part of the tongue, the ducts opening chiefly into the fossæ around the circumvallate papillæ. Both mucous and serous glands resemble the other salivary glands in structure (p. 1228).

The Vessels of the Tongue.—The arteries of the tongue are derived from the **lingual**, the **facial**, and **ascending pharyngeal**. The veins of the tongue open into the **internal jugular**.

The **lingual artery** (Fig. 943) on each side passes forward beneath the Hyoglossus muscle and courses to the apex of the tongue, between the Genioglossus and the Inferior lingual muscles, about one-eighth of an inch from the surface. It divides into the **ranine** (Fig. 941) and **sublingual** (Fig. 943). Near the apex a branch is given off from the ranine artery, which pene-

FIG. 940.—Circumvallate papillæ of tongue of rabbit, showing position of taste goblets. *a*, Duct of gland. *d*, Serous gland. *p*, Taste buds. *l*, Primary septa, and *l'*, secondary septa, of papillæ. *n*, Myelinated nerve. *M*, Muscle fibres. (Stöhr.)

trates the septum and joins a like branch from the other side. The **dorsalis linguae** is a branch of the lingual supplying the posterior part of the tongue, and rami from the **tonsillar branch of the facial** go to the same region. A network of capillary vessels is placed beneath the epithelium.

The **ranine veins** lie to the side of the frenum underneath the mucous membrane. Each ranine vein runs backward, superficial to and upon the Hyoglossus muscle and near to the

FIG. 941.—Under surface of tongue, showing position and relations of gland of Blandin or Nuhn. (From a preparation in the Museum of the Royal College of Surgeons of England.)

hypoglossal nerve. The venae comites of the lingual artery usually join the ranine vein, and the trunk opens into the internal jugular vein, but the vessels may open separately into the jugular vein (Fig. 496).

The Lymphatic Vessels of the Tongue (Fig. 559).—The lymphatic vessels from the anterior half of the tongue pass to the **submaxillary lymph nodes**.

Lymph vessels from the posterior half of the tongue are connected with satellite **nodes** on the Hyoglossus muscle and terminate in the **deep cervical nodes**. The last-named lymph vessel accompanies the ranine vein. The lingual lymphatics arise from a network beneath the

FIG. 942.—Frontal section through the body of the tongue of a newborn babe. $\times 3$. (Spalteholz.)

epithelium. Across the anterior two-thirds of the tongue there is little or no lymphatic connection between the two sides; in the posterior one-third there is free connection, due to absence of septum here.

The Nerves of the Tongue (Fig. 943).—The nerves of the tongue are five in number in each half—the **lingual branch of the inferior maxillary division of the trigeminal**, which is distributed

to the **papillæ** at the fore part and sides of the tongue, and forms the nerve of ordinary sensibility for its anterior two-thirds; the **chorda tympani**, which runs in the sheath of the lingual, is generally regarded as the nerve of taste for the same area (p. 1000); the **lingual branch** of the **glossopharyngeal**, which is distributed to the mucous membrane at the base and sides of the tongue, and to the **papillæ circumvallatæ**, and which supplies both sensor and gustatory filaments to this region; the **hypoglossal nerve**, which is the motor nerve to the muscular substance of the tongue; and the **internal laryngeal branch** of the **superior laryngeal**, which sends some fine branches to the root near to the epiglottis. **Sympathetic** filaments also pass to the tongue from the *nervi molles* on the lingual and other arteries supplying it. Some of the nerves end free between the cells of epithelium; others terminate as end organs (Meissner's corpuscles and the end-bulbs of Krause), and in taste buds as sensor dendrites (p. 1151).

FIG. 943.—Under surface of tongue, showing the distribution of nerves to this organ. (From a preparation in the Museum of the Royal College of Surgeons of England.)

The Development of the Tongue (Figs. 944 and 945).—The tongue is developed in the floor of the pharynx. The rudiment of the anterior or buccal portion appears during the third week as a rounded elevation, immediately behind the ventral ends of the mandibular arches. This elevation is named the **tuberculum impar** (Figs. 944 and 945); it extends forward on the oral surface of the mandibular arch, and increases markedly in size by the development of a pair of lateral tongue elevations, which raise themselves from the inner surfaces of the mandibular arches, and, blending with the tuberculum impar, form the tip and greater portion of the buccal part of the tongue. These lateral growths correspond with similar structures which were described by E. Kallius in the development of the tongue of the lizard. From the ventral ends of the fourth arch there arises a second and larger elevation, in the centre of which is a median groove or furrow. This elevation is named the **furcula** (Fig. 944), and is at first separated from the tuberculum impar by a depression, but later by a ridge formed by the forward growth and fusion of the ventral ends of the second and third arches. The posterior or pharyngeal part of the tongue is developed from this ridge, which extends forward in the form of a V, so as to embrace between its two limbs the tuberculum impar (Figs. 944 and 945). At the apex of the V a pit-

like invagination occurs, to form the middle thyroid rudiment, and this depression is represented in the adult by the *foramen cecum* of the tongue. In the adult the union of the anterior and posterior parts of the tongue is marked by a V-shaped depression (*sulcus terminalis*), the apex of which is at the foramen cecum, while the two limbs run outward and forward, parallel to, but a little behind, the circumvallate papillæ. The prominent anterior part of the furcula forms the epiglottis; the furrow behind it is the entrance to the larynx; and the anterior parts of its lateral margins constitute the arytenoepiglottidean folds.

FIG. 944.—The floor of the pharynx of a human embryo about twenty-three days old. $\times 30$. (From His.)

Applied Anatomy.—The diseases to which the tongue is liable are numerous, and its applied anatomy is of importance, since any or all the structures of which it is composed—muscles, connective tissue, mucous membrane, glands, vessels, nerves, and lymphatics—may be the seat of morbid changes. It is not often the seat of congenital defects, though a few cases of *vertical cleft* have been recorded, and it is occasionally, though much more rarely than is commonly supposed, the seat of *tongue-tie*, from shortness of the frenum.

There is, however, one condition which must be regarded as congenital, though not uncommonly it does not exhibit the significant changes until a year or two after birth. This is an enlargement of the tongue which is due primarily to a dilatation of the lymph channels and a greatly increased development of the lymphatic tissue throughout the tongue (*macroglossia*). This is often aggravated by inflammatory changes induced by injury or exposure, and the tongue may

FIG. 945.—Floor of mouth of an embryo slightly older than that shown in Fig. 944. $\times 16$. (From His.)

assume enormous dimensions and hang out of the mouth, giving the child an imbecile expression. The treatment consists in excising a V-shaped portion and bringing the cut surfaces together with deeply placed silver sutures. Acute inflammation of the tongue (*acute glossitis*) may be caused by injury or the introduction of some septic or irritating matter, and it is attended by great swelling from infiltration of the connective tissue of the tongue; this connective tissue is present in considerable quantity. The great swelling renders the patient incapable of swallowing or speaking, and may seriously impede respiration. The condition may eventuate in suppuration and the formation of an *acute abscess*. *Chronic abscess*, which has been mistaken for cancer, may also occur in the substance of the tongue.

The mucous membrane of the tongue may become chronically inflamed, and presents different appearances in different stages of the disease, to which the terms *leukoplakia*, *psoriasis*, and *ichthyosis* have been given.

The tongue, being very vascular, is often the seat of *nevroid growths*, and these have a tendency to grow rapidly.

The tongue is frequently the seat of *ulceration*, which may arise from many causes, as from the irritation of jagged teeth, dyspepsia, *tuberculosis*, *syphilis*, and *cancer*. Of these, the cancerous ulcer is the most important, and probably also the most common. The variety is the *squamous epithelioma*, which soon develops into an ulcer with an indurated base. It produces great pain which speedily extends to all parts supplied with sensation by the trigeminal nerve, especially to the region of the ear. The pain in these cases is conducted to the ear and temporal region by the lingual nerve, and from this nerve pain radiates to the other branches of the inferior maxillary nerve, especially the auriculotemporal. Possibly pain in the ear itself may be due to implication of the fibres of the glossopharyngeal nerve, which by its tympanic branch reaches the tympanic plexus. Cancer of the tongue spreads through the organ very rapidly because of the almost constant muscular movements.

Cancer of the tongue may necessitate removal of a part or the whole of the organ, and many different methods have been adopted for its excision. The better method is by the scissors, usually known as Whitehead's method. The mouth is widely opened with a gag, the tongue is transfixed with a stout silk ligature, by which to hold and make traction on it and the reflection of mucous membrane from the tongue to the jaw, and the insertion of the Geniohyoglossi first divided with a pair of curved blunt scissors. The Palatoglossi are also divided. The tongue can now be pulled well out of the mouth. The base of the tongue is cut through by a series of short snips, each bleeding vessel being dealt with as soon as divided, until the situation of the ranine artery is reached. The remaining undivided portion of tissue is to be seized with a pair of Wells' forceps, the tongue removed, and the vessel secured. In the event of the ranine artery being accidentally injured early in the operation, hemorrhage can be at once controlled by passing two fingers over the dorsum of the tongue as far as the epiglottis and dragging the root of the tongue forcibly forward.

In cases where the disease is confined to one side of the anterior portion of the tongue this operation may be modified by splitting the tongue down the centre and removing only the affected half. If the posterior portion of the tongue is attacked by cancer the entire tongue must be removed, even if but one side of the organ is *apparently* involved. The exchange of lymph between the halves of the posterior portion of the tongue makes it certain that the opposite half becomes involved soon after the origin of the disease. Whatever operation is performed for cancer of the tongue, the lymph nodes must be removed from *both sides of the neck*. This is to be done, even if but one side of the tongue is removed.

Finally, where both sides of the floor of the mouth are involved in the disease, or where very free access is required on account of the extension backward of the disease to the pillars of the fauces and the tonsil, or where the mandible is involved, the operation recommended by Syme must be performed. This is done by an incision through the central line of the lip, across the chin, and down as far as the hyoid bone. The mandible is sawed through at the symphysis, and the two halves of the bone forcibly separated from each other. The mucous membrane is separated from the bone, the Geniohyoglossi detached from the bone, and the Hyoglossi divided. The tongue is then drawn forward and removed close to its attachment to the hyoid bone. Adjacent lymph nodes can be removed, and if the bone is implicated in the disease, it can also be removed by freeing it from the soft parts externally and internally, and making a second section with the saw beyond the diseased part.

THE SALIVARY GLANDS (Fig. 946).

The principal salivary glands communicating with the mouth, and pouring their secretion into its cavity, are the **parotid**, **submaxillary**, and **sublingual**.

The **Parotid Gland** (*glandulae parotis*) is the largest of the three salivary glands, varying in weight from half an ounce to an ounce. It lies upon the side of the face, immediately below and in front of the external ear. The main portion of the gland is superficial, somewhat flat and quadrilateral in form, and is placed between the ramus of the mandible in front and the mastoid process and Sternomastoid muscle behind, overlapping, however, both boundaries. Above, it is limited by the zygoma; below, it extends to about the level of a line joining the tip of the mastoid process to the angle of the mandible. The remainder of the gland is wedge-shaped, and extends deeply inward toward the pharyngeal wall.

The gland is enclosed within a capsule continuous with the deep cervical fascia; the layer covering the outer surface is dense and closely adherent to the gland;

a portion of the fascia, attached to the styloid process and the angle of the mandible, is thickened to form the stylomandibular ligament which intervenes between the parotid and submaxillary glands.

The *anterior surface* of the gland is moulded on the posterior border of the ramus of the mandible with the attached Internal pterygoid and Masseter muscles, and advances forward between the two Pterygoid muscles and overlaps the Masseter. A part of the overlapping portion, immediately below the zygoma, is usually detached, and is named the *socia parotidis* (*gl. parotis accessoria*).

The *outer or superficial surface*, slightly lobulated, is covered by the integument, the superficial fascia containing the facial branches of the great auricular nerve and some small lymph nodes, and the fascia which forms the capsule of the gland.

FIG. 946.—The salivary glands.

The *inner or deep surface* extends inward by means of two processes, one of which lies on the styloid process and the styloid group of muscles and projects under the mastoid process and Sternomastoid muscle; the other is situated in front of the styloid process and passes into the posterior part of the glenoid fossa behind the temporomandibular joint. The deep surface is in contact with the internal and external carotid arteries, the internal jugular vein and the vagus and glossopharyngeal nerves.

The *anterior border* lies on the superficial surface of the Masseter; the *posterior* abuts on the external auditory meatus and the mastoid process, and overlaps the anterior edge of the Sternomastoid. The *superior border* is in contact with the zygomatic arch, and the *inferior* overlaps the posterior belly of the Digastric. The *inner border* at the junction of the anterior and inner surfaces is in relation with the styloid process and styloid muscles, and is separated from the pharyngeal wall by some loose connective tissue.

Structures within the Gland.—The *external carotid artery* lies at first in contact with the deep surface, and then in the substance of the gland. The artery gives

off its *posterior auricular* branch which emerges from the gland behind; it then divides into its terminal branches, the *internal maxillary* and *superficial temporal*; the former runs inward behind the neck of the mandible; the latter runs upward across the zygoma and gives off its *transverse facial* branch which emerges from the front of the gland. Superficial to the arteries are the *temporal* and *internal maxillary veins*, uniting to form the *temporomaxillary vein*; in the lower part of the gland this vein divides into anterior and posterior divisions. The anterior division emerges from the gland to join the facial vein; the posterior unites in the gland with the posterior auricular vein to form the external jugular vein. On a still more superficial plane is the *facial nerve*, the *branches* of which emerge at the upper and anterior borders of the gland. Branches of the *great auricular nerve* pierce the gland to join the facial, and the *auriculotemporal branch* of the inferior maxillary nerve emerges from the upper part of the gland.

Lymph nodes, known as the **parotid nodes**, are in and about the parotid gland, some being embedded in the outer surface of the parotid fascia, others being in the inner surface of the fascia, others in the gland itself, particularly along the temporomaxillary vein and external carotid artery (see p. 779).

The **Duct of the Parotid Gland**, or **Stenson's Duct** (*ductus parotideus* [*Stenonis*]) (Fig. 946), is about two inches and a half (6.25 cm.) in length. It commences by numerous branches from the anterior part of the gland, crosses the Masseter muscle, and at its anterior border turns inward nearly at a right angle and passes into the substance of the Buccinator muscle, which it pierces; it then runs for a short distance obliquely forward between the Buccinator muscle, and the mucous membrane of the mouth, and opens upon the inner surface of the cheek by a small orifice, opposite the second upper molar tooth (Fig. 926). While crossing the Masseter it receives the duct of the *socia parotidis*. In this position it has the transverse facial artery above it and some branches of the facial nerve below it.

The parotid duct is dense, it is of considerable thickness, and its canal is about the size of a crowquill; but at its orifice on the inner aspect of the cheek its lumen is greatly reduced in size. The duct corresponds to the middle third of a line drawn across the face from the lower margin of the external auditory meatus to midway between the red margin of the upper lip and the ala of the nose.

Vessels and Nerves.—The **arteries** supplying the parotid gland are derived from the external carotid, and from the branches given off by that vessel in or near its substance. The **veins** empty into the external jugular through some of its tributaries. The **lymphatics** terminate in the superficial cervical and the deep cervical nodes, passing in their course through two or three lymph nodes placed on the surface and in the substance of the parotid. The **nerves** are derived from the plexus of the **sympathetic** on the external carotid artery, the **nervus intermedius**, the **auriculotemporal**, and the **great auricular nerves**. It is probable that the branch from the auriculotemporal nerve is derived from the **glossopharyngeal** through the **otic ganglion**. At all events, in some of the lower animals this has been proved experimentally to be the case.

The **Submaxillary Gland** (*glandula submaxillaris*) (Fig. 946) is irregular in form and weighs about two drams (eight to ten grams). A considerable part of it is situated in the submaxillary triangle, reaching forward to the anterior belly of the Digastric and backward to the stylohyoid ligament which intervenes between it and the parotid gland. Above, it extends under cover of the body of the mandible; below, it usually overlaps the intermediate tendon of the Digastric and the insertion of the Stylohyoid, while from its deep surface a tongue-like **deep process** extends forward and inward above the Mylohyoid muscle.

The **deep surface** is in relation with the Mylohyoid, Hyoglossus, Styloglossus, Stylohyoid, and posterior belly of the Digastric muscles; in contact with it are the mylohyoid nerve and the mylohyoid and submental vessels.

The facial artery is embedded in a groove in the posterior border of the gland.

The *deep process* of the gland extends forward and inward between the Mylohyoid below and externally, and the Hyoglossus and Styloglossus internally; above it is the lingual nerve; below it, the hypoglossal nerve and ranine vein.

The duct of the submaxillary gland, or Wharton's duct (*ductus submaxillaris (Whartoni)*), is about two inches in length, and its wall is much thinner than that of the parotid duct. It begins by numerous branches from the deep portion of the gland which lies on the upper surface of the Mylohyoid muscle, and runs forward and inward between the Mylohyoid and the Hyoglossus and Geniohyoglossus muscles, then between the sublingual gland and the Geniohyoglossus muscle, and opens by a narrow orifice on the summit of a small papilla (*caruncula sublingualis*) at the side of the frenum linguae. On the Hyoglossus muscle it lies between the lingual and hypoglossal nerves, but at the anterior border of the muscle it is crossed by the lingual nerve.

Vessels and Nerves.—The arteries supplying the submaxillary glands are branches of the facial and lingual. Its veins follow the course of the arteries. The lymphatics drain into the submaxillary lymph nodes. The nerves are derived from the submaxillary ganglion, through which it receives filaments from the chorda tympani and from the lingual branch of the inferior maxillary, sometimes from the mylohyoid branch of the inferior dental and from the sympathetic.

The Sublingual Gland (*glandula sublingualis*) (Fig. 946) is the smallest of the salivary glands. It is situated beneath the mucous membrane of the floor of the mouth, at the side of the frenum linguae, in contact with the inner surface of the mandible, close to the symphysis. It is narrow, flattened, in shape somewhat like an almond, and weighs about a dram. It is in relation, *above*, with the mucous membrane; *below*, with the Mylohyoid muscle; in *front*, with the mandible and its fellow of the opposite side; *behind*, with the deep part of the submaxillary gland; and *internally*, with the Geniohyoglossus, from which it is separated by the lingual nerve and submaxillary duct. Its excretory ducts or ducts of Rivinus (*ductus sublingualis minores*) are from eight to twenty in number; some join the submaxillary duct, others open separately into the mouth, on the elevated crest of mucous membrane (*plica sublingualis*) caused by the projection of the gland on either side of the frenum linguae. One or more join to form a tube which opens into the submaxillary duct; this is called the duct of Bartholin (*ductus sublingualis major*).

Vessels and Nerves.—The sublingual gland is supplied with blood from the sublingual and submental arteries. Its nerves are derived from the lingual.

Structure of Salivary Glands (Fig. 947).—The salivary glands are compound tubuloracemose or racemose glands, surrounded by a capsule of white fibrous connective tissue that divides the gland into numerous lobes and lobules. The tissue between the lobules supports blood-vessels, nerves, lymphatics, and ducts. Each lobule consists of the ramifications of a single duct, dividing frequently like the branches of a tree, the branches terminating in either rounded or tubular ends, the *acini* or *alveoli*, around which the capillaries are distributed. Each alveolus or acinus consists of a single layer of columnar or pyramidal epithelial cells resting upon a basement membrane, further supported by the fibroelastic *tunica propria*, in which the capillaries and nerves are found. Within the lobule are found intralobular ducts that collect the secretion from the alveoli and empty it into the interlobular ducts between the lobules. The latter join, to ultimately form the excretory duct of the gland.

The main or excretory duct of each gland consists of mucous, muscle, and fibrous coats. The mucous coat is composed of either simple columnar or stratified columnar epithelial cells that rest upon a basement membrane, and fibroelastic tunica propria. The muscle coat consists of circularly arranged smooth muscle tissue. The fibrous coat consists of fibroelastic tissue and serves to support the other coats.

The salivary glands are mucous, serous, and mixed. The mucous glands secrete a thick viscid fluid and the cells of the acini stain lightly. The alveoli are tubular in form and the cells large and of a columnar shape, cloudy to transparent, and may even be striated in appearance. At intervals peculiar, darkly staining crescent-shaped cells or cell groups are seen between the above epithelium and the basement membrane; these are the demilunes of Heidenhain or crescents of Gianuzzi (Fig. 947), by some regarded as mucous cells in the resting stage, and by others as distinctly separate cells. These glands are the small unnamed glands of lips, cheek, pharynx, oesophagus, and tongue (especially the glands of Nuhn and Blandin).

Serous glands are those that secrete a thin, watery fluid, and the cells of the acini stain darkly. The acini are grape-like and the cells are somewhat pyramidal in form, smaller than mucous cells, and possess richly granular protoplasm. These glands are the parotid and many small unnamed glands in the tongue and lips.

Mixed glands are those in which some of the alveoli are tubular (mucous) and others grape-like (serous), representing both of the above varieties in one capsule. Here belong the sublingual and submaxillary glands.

The **arteries** enter the capsule and divide into branches that enter the interlobular tissues; from these vessels branches enter the lobules and form capillary plexuses around the alveoli in close proximity to the basement membrane. The **veins** return the blood in vessels parallel to the arteries.

The **nerves** enter with the vessels and ultimately form plexuses in the interlobular and intra-lobular tissue, the latter sending filaments that end in relation to the epithelial cells and blood-vessels. In the submaxillary gland small ganglia are found in connection with the interlobular nerve plexus.

Development of the Salivary Glands.—The salivary glands arise as diverticula from the epithelial lining of the mouth, and their rudiments appear in the following order—viz., the parotid during the fourth week, the submaxillary in the sixth week, and the sublingual during the ninth week (Hammar).

FIG. 947.—A highly magnified section of the submaxillary gland of the dog, stained with carmine. (Kölliker.)

Surface Form.—The orifice of the mouth is bounded by the *lips*, two thick, fleshy folds covered externally by integument and internally by mucous membrane, and consisting of muscles, vessels, nerves, areolar tissue, and numerous small glands. The size of the orifice of the mouth varies considerably in different individuals, but seems to bear a close relation to the size and prominence of the teeth. Its corners correspond pretty accurately to the outer border of the canine teeth. In the Ethiopian tribes the front teeth are large and inclined forward, the mouth is large; and this, combined with the thick and everted lips which appear to be associated with prominent teeth, gives to the negro's face much of the peculiarity by which it is characterized. The smaller teeth and the slighter prominence of the alveolar arch of the more highly civilized races render the orifice of the mouth much smaller, and thus a small mouth is an indication of intelligence, and is regarded as an evidence of the higher civilization of the individual.

Upon looking into the mouth, the first thing we may note is the tongue, the upper surface of which will be seen occupying the floor of the cavity. This surface is convex, and is marked along the middle line by a *raphé* which divides it into two symmetrical portions. The anterior two-thirds is rough and studded with papillae; the posterior third, smooth and tuberculated, contains numerous lymphoid structures which project from the surface. Upon raising the tongue the mucous membrane which invests the upper surface may be traced covering the sides of the under surface, and then reflected over the floor of the mouth on to the inner surface of the mandible, a part of which it covers. As it passes over the borders of the tongue it changes its character, becoming thin and smooth and losing the papillae which are to be seen on the upper surface. In the middle line the mucous membrane on the under surface of the tip of the tongue forms a distinct fold, the *frenum linguae*, by which this organ is connected to the symphysis of the mandible. Occasionally it is found that this frenum is rather shorter than natural, and, acting as a bridle, prevents the complete protrusion of the tongue. When this condition exists and an attempt is made to protrude the organ, the tip will be seen to remain buried in the floor of the mouth, and the dorsum of the tongue is rendered very convex, and more or less extruded from the mouth; at the same time a deep furrow will be noticed to appear in the middle line of the anterior part of the dorsum. Sometimes, a little external to the frenum, the ranine

vein may be seen immediately beneath the mucous membrane. The corresponding artery, being more deeply placed, does not come into view, nor can its pulsation be felt with the finger. On either side of the frenum, in the floor of the mouth, is a longitudinal elevation or ridge, produced by the projection of the sublingual gland, which lies immediately beneath the mucous membrane. And close to the attachment of the frenum to the tip of the tongue may be seen on either side the slit-like orifices of the *submaxillary ducts*, into which a fine probe may be passed without much difficulty. By everting the lips the smooth mucous membrane lining them may be examined, and may be traced from them on to the outer surface of the alveolar arch. In the middle line, both of the upper and lower lip, a small fold of mucous membrane passes from the lip to the bone, constituting the *frena*; these are not so large as the frenum linguae. By pulling outward the angle of the mouth, the mucous membrane lining the cheeks can be seen, and on it may be perceived a little papilla which marks the position of the orifice of the *parotid duct*. The exact position of the orifice of the duct will be found to be opposite the second upper molar tooth. The introduction of a probe into this duct is attended with considerable difficulty. The teeth are the next objects which claim our attention upon looking into the mouth. These are, as stated above, ten in either jaw in the temporary set, and sixteen in the permanent set. The gums, in which they are implanted, are dense, firm, and vascular.

At the back of the mouth is seen the *isthmus of the fauces*, or, as it is popularly called, "the throat;" this is the space between the pillars of the fauces on either side, and is the means by which the mouth communicates with the pharynx. Above, it is bounded by the soft palate, the anterior surface of which is concave and covered with mucous membrane, which is continuous with that lining the roof of the mouth. Projecting downward from the middle of its lower border is a conical-shaped projection, the *uvula*. On either side of the isthmus of the fauces are the anterior and posterior pillars, formed by the Palatoglossus and Palatopharyngeus muscles, respectively, covered over by mucous membrane. Between the two pillars on either side is situated the *tonsil*.

When the mouth is wide open a prominent tense fold of mucous membrane may be seen and felt, extending upward and backward from the position of the fang of the last molar tooth to the posterior part of the hard palate. This is caused by the *pterygomaxillary ligament*, which is attached by one extremity to the apex of the internal pterygoid plate, and by the other to the posterior extremity of the mylohyoid ridge of the lower jaw. It connects the Buccinator with the Superior constrictor of the pharynx. The fang of the last molar tooth indicates the position of the *lingual* (gustatory) nerve where it is easily accessible, and can with readiness be divided in cases of cancer of the tongue (see p. 996). On the inner side of the last molar tooth we can feel the hamular process of the internal pterygoid plate of the sphenoid bone, around which the tendon of the Tensor palati plays. The exact position of this process is of importance in performing the operation of *staphylorrhaphy*. About one-third of an inch (8 mm.) in front of the hamular process, and the same distance directly inward from the last molar tooth, is the situation of the opening of the posterior palatine canal, through which emerges the posterior or descending palatine branch of the internal maxillary artery and one of the descending palatine nerves from Meckel's ganglion. The exact position of the opening on the subject may be ascertained by driving a needle through the tissues of the palate in this situation, when it will be at once felt to enter the canal. The artery emerging from the opening runs forward in a groove in the bone just internal to the alveolar border of the hard palate, and may be wounded in the operation for the cure of cleft palate. Under these circumstances the palatine canal may require plugging. By introducing the finger into the mouth the anterior border of the coronoid process of the mandible can be felt, and it is especially prominent when the jaw is dislocated. By throwing the head well back a considerable portion of the posterior wall of the pharynx may be seen through the isthmus faucium, and on introducing the finger the anterior surface of the bodies of the upper cervical vertebrae may be felt immediately beneath the thin muscular stratum forming the wall of the pharynx. The finger can be hooked around the posterior border of the soft palate, and by turning it forward the posterior nares, separated by the septum, can be felt, or the presence of any adenoid or other growths in the nasopharynx can be ascertained.

Applied Anatomy.—The duct of a salivary gland may be blocked by a *calculus*, and the condition is often productive of severe pain.

A wound of the parotid duct or of the parotid gland may be followed by a *salivary fistula*.

The parotid recess is completely lined by fascia, except above. "Between the anterior edge of the styloid process and the posterior border of the External pterygoid muscle there is a gap in the fascia, through which the parotid space communicates with the connective tissue about the pharynx."

This explains why there is frequently swelling of the parotid region in postpharyngeal abscess. A *parotid abscess* rarely bursts through the skin; it may pass into the temporal fossa, may enter the zygomatic fossa, may advance toward the mouth, pharynx, or neck. Because of the situation of the gland, a parotid abscess may cause inflammation of the temporomandibular joint or periostitis of the bone about the meatus, and may even burst into the external auditory meatus (Treves).

The facial nerve passes through the gland, and inflammation or tuberculosis of the gland may cause *facial palsy*. Some enlargements of the parotid region are due to inflammation of the parotid lymph nodes, and these nodes may become *tuberculous*.

Mumps is characterized by acute inflammation of the parotid gland.

Various tumors occur in the parotid (fibroma, sarcoma, carcinoma, enchondroma, etc.). Most parotid tumors contain more or less cartilage. Complete extirpation of the parotid gland surgically is certainly extremely difficult, and Treves and others maintain that it is impossible

THE PHARYNX (Figs. 950, 951).

The **pharynx** is that part of the alimentary canal which is placed behind, and communicates with the nose, mouth, and larynx. It is a musculomembranous tube, somewhat conical in form, with the base upward and the apex downward, extending from the under surface of the skull to the level of the cricoid cartilage in front and that of the sixth cervical vertebra behind.

The cavity of the pharynx (*cavum pharyngis*) is about four inches and a half in length, and broader in the transverse than in the antero-posterior diameter. Its greatest breadth is opposite the cornua of the hyoid bone; its narrowest part is at its termination in the œsophagus. It is attached, *above*, to the periosteum of the petrous portion of the temporal bone and of the basilar process of the occipital bone. To the pharyngeal tubercle of the basilar process of the occipital bone the raphe of the Constrictor muscles is attached. It is limited above by the body of the sphenoid as well as by the basilar process of the occipital; *below*, it is continuous with the œsophagus; *posteriorly*, it is connected by loose areolar tissue with the cervical portion of the vertebral column and the Longus colli and Rectus capitis anticus muscles; this areolar tissue is contained in what is called the **retropharyngeal space**; *anteriorly*, it is incomplete, and is attached in succession to the Eustachian tube, the internal pterygoid plate, the pterygomandibular ligament, the posterior termination of the mylohyoid ridge of the mandible, the mucous membrane of the mouth, the base of the tongue, hyoid bone, the thyroid and cricoid cartilages; *laterally*, it is connected to the styloid processes and their muscles, and is in contact with the common and internal carotid arteries, the internal jugular veins, and the glossopharyngeal, vagus, hypoglossal, and sympathetic nerves, and above with a small part of the Internal pterygoid muscles. Seven openings communicate with it—viz., the two posterior nares, the two Eustachian tubes, the mouth, larynx, and œsophagus. The cavity of the pharynx may be subdivided from above downward into three parts—**nasal, oral, and laryngeal**.

The **Nasal Part**, or **Nasopharynx** (*pars nasalis pharyngis*) (Fig. 950), lies behind the nose and above the level of the soft palate; it differs from the two lower parts of the tube in that its cavity always remains patent. In front it communicates through the **posterior nares** (*choanae*) (Fig. 951) with the nasal fossæ. On its lateral wall is the **pharyngeal orifice of the Eustachian tube** (*ostium pharyngeum tubæ auditivæ*) (Figs. 948 and 949), somewhat triangular in shape and bounded behind by a firm prominence, the **Eustachian cushion** (*torus tubarius*), caused by the inner extremity of the cartilage of the tube which elevates the mucous membrane (Fig. 949). The orifice is about one-third to one-half inch behind the inferior turbinated bone. A vertical fold of mucous membrane, the **salpingopharyngeal fold** (*plica salpingopharyngea*) (Fig. 949), stretches from the lower part of the cushion to the pharynx; it contains the Salpingopharyngeus muscle. A second and smaller fold, the **salpingopalatine fold** (*plica salpingopalatina*) (Fig. 949) stretches from the upper part of the cushion to the palate. Behind the orifice of the Eustachian tube is a deep recess, the **lateral recess or fossa of Rosenmüller** (*recessus pharyngeus*) (Fig. 949), which represents the remains of the upper part

of the second branchial cleft. The posterior wall of the nasopharynx is directed upward and forward, and it meets the superior wall at an angle constituting the **vault of the pharynx** (*fornix pharyngis*). On the posterior wall, above the level of the orifices of the Eustachian tubes, is a prominence, best marked in childhood, produced by a mass of lymphoid tissue which is known as the **pharyngeal tonsil** (*tonsilla pharyngea*) (Fig. 948). In the pharyngeal vault, in the middle line, an irregular flask-shaped depression of the mucous membrane is sometimes seen extending up as far as the basilar process of the occipital bone. It is known as the *pharyngeal bursa*, a possible vestige of the pharyngeal tonsil. The floor of the nasopharynx is formed by the upper surface of the sloping soft palate; in front the floor is continuous with that of the nasal cavities, while behind it ends at the free margin of the soft palate, which bounds the **isthmus of the pharynx** (*isthmus pharyngonasalis*).

The **Oral Part** (*pars oralis pharyngis*) of the pharynx reaches from the under surface of the soft palate to about the level of the hyoid bone. It opens anteriorly, through the **isthmus faucium**, into the mouth, while in its lateral wall, between the two pillars of the fauces, is the tonsil.

FIG. 948.—Pharyngeal tonsil in an adult (Eecat.)

FIG. 949.—The posterior lateral cavity of the nasopharynx. (Fscat.)

The **Tonsils** (*tonsilla palatina*) (Figs. 914 and 950) are two prominent bodies situated one on each side of the fauces, between the anterior and posterior pillars of the soft palate. They are of a rounded form, and vary considerably in size in different individuals. A recess, the **supratonsillar fossa** (*fossa supratonsillaris*), may be seen, directed upward and backward above the tonsil, the recess being the remains of the lower part of the second visceral cleft. It is covered by a fold of mucous membrane termed the **plica triangularis**. Externally the tonsil is covered with a fibrous capsule which joins the aponeurosis of the pharynx. The outer surface of the capsule is in relation with the inner surface of the Superior constrictor muscle of the pharynx, to the outer side of which is the Internal pterygoid muscle, the **ascending palatine artery**, the Superior constrictor muscle of the pharynx, and the **tonsillar artery**. The internal carotid artery lies behind and to the outer side of the tonsil, and nearly an inch (20 to 25 mm.) distant from it. It corresponds in position to the angle of the mandible. The surface of the tonsil which looks toward the pharynx presents from twelve to fifteen orifices, each leading into small recesses or **crypts** (*fossulae tonsillares*). From the crypts numerous follicles branch out into the substance of the tonsil by means of very irregular channels.

Structure.—The tonsil is covered externally by a capsule of white fibrous tissue that separates it from the surrounding organs and tissues. This capsule sends in trabeculae that divide the

organ into irregular compartments. Within the compartments is the delicate framework and reticulum in the meshes of which are found diffuse lymphoid tissue and solitary nodules or follicles. The internal surface presents twelve to fifteen depressions or **crypts** (*fossulae tonsillares*), that extend into the organ in the form of irregular, blindly ending, tortuous channels or follicles. The internal surface of the tonsils and the crypts and follicles are lined by stratified squamous cells, exhibiting in places marked degenerative changes, and in others leukocytes that are passing through the epithelial layer to the crypts. The tonsils seem to present a hilus at the anterior margin just under cover of the anterior pillar of the soft palate, as here the vessels seem to enter and leave.

The arteries supplying the tonsils are the **dorsalis linguae** from the lingual, the **ascending palatine** and **tonsillar** from the facial, the **ascending pharyngeal** from the external carotid, the **descending palatine** branch of the internal maxillary, and a twig from the **small meningeal**. The veins terminate in the **tonsillar plexus**, on the outer side of the tonsil, and the tonsillar plexus joins the pharyngeal plexus, which communicates with the pterygoid plexus of the internal jugular or facial vein. They seem to enter and leave at the hilus.

Surrounding each follicle is a close plexus of *lymphatic vessels*. From these plexuses the lymphatic vessels pass to the submaxillary lymph nodes below the angle of the mandible. From the submaxillary nodes lymph passes to the deep cervical nodes.

The Nerves of the Tonsil.—A branch from the **glossopharyngeal nerve** by uniting with branches of the **pharyngeal plexus** forms the **tonsillar plexus**.

Development.—The tonsils are developed from the lower parts of the second visceral clefts, immediately behind the anterior pillars of the fauces. The entoderm which lines these clefts grows in the form of a number of solid buds into the surrounding mesoderm. These buds become hollowed out by the degeneration and casting off of their central cells, and by this means the tonsillar crypts are formed. Lymphoid cells accumulate around the crypts, and become grouped to form the lymphoid follicles; the latter, however, are not well defined until after birth.

Applied Anatomy.—When a *tonsil* enlarges it projects inward. The *deafness* which so often attends hypertrophy of the tonsil is not due to blocking of the Eustachian orifice by the tonsil, but is due to thickening of the mucous membrane lining the tube itself. The *profuse bleeding* which sometimes follows an operation for the removal of the tonsil is very seldom due to injury of the internal carotid artery, but is due to *injury of the ascending pharyngeal artery* (p. 600) or one of the palatine arteries.

The Laryngeal Part of the pharynx (*pars laryngea pharyngis*) is that division which lies behind the larynx; it is wide above where it is continuous with the oral portion, while below at the lower border of the cricoid cartilage it becomes continuous with the œsophagus. In front it presents the triangular aperture of the larynx, the base of which is directed forward and is formed by the epiglottis, while its lateral boundaries are constituted by the arytenoepiglottic folds. On either side of the laryngeal orifice is a recess, termed the **sinus pyriformis** (*recessus pyriformis*) (Fig. 950); it is bounded internally by the arytenoepiglottic fold, externally by the thyroid cartilage and thyrohyoid membrane. In the anterior part of the sinus pyriformis is a fold (*plica nervi laryngei*), which passes downward and inward. Extending outward from the epiglottis on each side is a fold, the **pharyngoepiglottic fold** (*plica pharyngoepiglottica*). This ascends in the lateral wall of the pharynx, nearly to the posterior arch of the fauces.

Structure.—The pharynx is composed of **mucous, fibrous, and muscular coats**.

The **mucous coat** (*tunica mucosa*) is continuous with that lining the Eustachian tubes, the nasal fossæ, the mouth, and the larynx. In the nasopharynx it is covered by stratified ciliated epithelium; in the buccal and laryngeal portions the epithelium is of the stratified squamous variety. In the tunica propria considerable diffuse lymphoid tissue, pharyngeal, tonsil, and **mucous glands** (*glandulae pharyngeae*) are found; the latter are especially numerous at the upper part of the pharynx around the orifices of the Eustachian tubes.

The **pharyngeal aponeurosis** or **fibrous coat** is situated between the mucous and the muscle layers, and consists of large bundles of white fibrous connective tissue. It is thick above, where the muscle fibres are wanting, and is firmly connected to the periosteum of the basilar process of the occipital and petrous portion of the temporal bones. As it descends it diminishes in thickness, and is gradually lost. It is strengthened posteriorly by a strong fibrous band, which is attached above to the pharyngeal spine on the under surface of the basilar portion of the occipital bone, and passes downward, forming a **median raphe**, which gives attachment to the Constrictor muscles of the pharynx.

The **muscular coat** has been already described (pp. 395 to 398).

The **motor nerves** are derived chiefly from the pharyngeal plexus; the Tensor palati, however, receives a special branch from the otic ganglion. The **sensor** filaments are derived from the descending palatine and nasopalatine, and from the glossopharyngeal nerve.

The Lymphatic Pharyngeal Ring.—This name was applied by Waldeyer to the lymphatic structures gathered into a sort of ring about the pharynx. There are three chief collections of this tissue on each side. The first is known as the **lingual tonsil** (p. 1221); the second as the **palatal tonsil** (p. 1232); and the third as the **pharyngeal tonsil** (p. 1232).

FIG. 950.—Sagittal median section of the head and neck. The head is thrown backward into complete extension, which explains the relations between the lower jaw and the hyoid bone as seen in the figure. (Luschka.)

Development of the Pharynx.—The pharynx develops from the cephalic portion of the foregut, flanked by the five branchial (visceral) arches, with four intervening branchial clefts (visceral pouches). These have become retrogressively modified in that they have lost their respiratory function (as gills), but recur in the development of each individual for the purpose of forming organs not entirely vestigial. Thus, the first or most cephalic branchial arch assists in the formation of the jaws, the malleus, incus, sphenomandibular ligament, and part of the external ear. The second arch forms the styloid process, lesser cornu of hyoid and the intervening stylohyoid ligament, the stapes, a part of the external ear, and a part of the posterior one-third of the tongue. From the third arch are formed the body and greater cornu of the hyoid bone, and part of the posterior one-third of the tongue. The fourth and fifth arches share in forming the thyroid cartilage. The inner furrows or clefts, lined by entoderm, contribute to

the formation of important structures. Thus, the first inner furrow becomes the middle-ear cavity and Eustachian tube, the "closing membrane" persisting as the tympanic membrane separating the inner from the outer furrow, which becomes the external auditory meatus. The second inner furrow becomes the lateral recess of the pharynx, and its entodermal lining gives rise to the tonsil. From the third inner furrow are developed the thymus and the inferior parathyroid gland, while the fourth gives rise to the lateral lobes of the thyroid and the superior parathyroid glands. The isthmus of the thyroid is derived by a median ventral evagination of the entoderm arising between the tuberculum impar and the second visceral bar. Another median ventral evagination occurs at the level of the fourth visceral arch to form the respiratory apparatus.

Applied Anatomy.—The *internal carotid artery* is in close relation with the pharynx, so that its pulsations can be felt through the mouth. It has been occasionally wounded by sharp-pointed instruments introduced into the mouth and thrust through the wall of the pharynx.

FIG. 951.—The anterior surface of the pharynx. (Sappey.)

In *aneurism* of this vessel in the neck the tumor necessarily bulges into the pharynx, as this is the direction in which it meets with the least resistance, nothing lying between the vessel and the mucous membrane except the thin Constrictor muscle, whereas on the outer side there is the dense cervical fascia, the muscles descending from the styloid process, and the margin of the Sternomastoid muscle.

The mucous membrane of the pharynx is very vascular, and is often the seat of *inflammation*, frequently of a septic character, and dangerous on account of its tendency to spread to the larynx. On account of the tissue which surrounds the pharyngeal wall being loose and lax, the inflammation is liable to spread through it far and wide, extending downward into the posterior mediastinum along the oesophagus. *Abscess* may form in the connective tissue behind the pharynx, between it and the vertebral column, constituting what is known as *retropharyngeal abscess*. This is most commonly due to caries of the cervical vertebrae, but may also be caused by supuration of a lymph node which is situated in this position opposite the axis, and which receives lymphatics from the nares, or by *gumma* or by *acute pharyngitis*. In these cases the pus may

be easily evacuated by an incision, with a guarded bistoury, through the mouth, but, for aseptic reasons, it is desirable that the abscess should be opened from the neck. In some instances this is perfectly easy; the abscess can be felt bulging at the side of the neck and merely requires an incision for its relief; but this is not always so, and then an incision should be made along the posterior border of the Sternomastoid and the deep fascia should be divided. A director is now to be inserted into the wound, the forefinger of the left hand being introduced into the mouth and pressure made upon the swelling. This acts as a guide, and the director is to be pushed onward until pus appears in the groove. A pair of sinus forceps are now inserted along the director and the opening into the cavity dilated.

Foreign bodies not infrequently become lodged in the pharynx and most usually at its termination at about the level of the cricoid cartilage, just beyond the reach of the finger, as the distance from the arch of the teeth to the commencement of the oesophagus is about six inches.

Hypertrophy of the lymphoid tissue of the nasopharynx produces groups of hypertrophic masses known as *adenoids*. A child with adenoids has a cough, and when awake or asleep, breathes noisily and with the mouth open. The voice is muffled, the hearing is impaired, the expression is vacant, the mind is dull, and the tonsils are enlarged.

Hypertrophy of the lymphoid tissue of the nasopharynx produces groups of hypertrophic masses known as *adenoids*. A child with adenoids has a cough, and when awake or asleep, breathes noisily and with the mouth open. The voice is muffled, the hearing is impaired, the expression is vacant, the mind is dull, and the tonsils are enlarged.

THE OESOPHAGUS (Figs. 952, 953).

The *oesophagus*, or *gullet*, is a musculomembranous canal, about nine or ten inches in length, extending from the pharynx to the stomach. It commences at the upper border of the cricoid cartilage, opposite the sixth cervical vertebra, descends along the front of the vertebral column through the posterior mediastinum, passes through the Diaphragm, and, entering the abdomen, terminates at the cardiac orifice of the stomach, opposite the eleventh thoracic vertebra, about an inch to the left of the median plane. The general direction of the oesophagus is vertical, but it presents two or three slight curves in its course. At its commencement it is placed in the median line, but it inclines to the left side as far as the root of the neck, gradually passes to the middle line again, and finally deviates to the left as it passes forward to the oesophageal opening of the Diaphragm (*hiatus oesophageus*). The oesophagus also presents antero-posterior flexures, corresponding to the curvature of the cervical and thoracic portions of the vertebral column. It is the narrowest part of the alimentary canal, being most contracted at its commencement, at about the level of the third thoracic vertebra, and at the point where it passes through the Diaphragm (Fig. 952).

FIG. 952.—Contour of the oesophagus. On the left the distances of the constrictions from the incisor teeth are given in centimeters; on the right are given the diameters in millimeters. (Half natural size.)

When empty, the oesophagus is collapsed so that its anterior and posterior walls come in contact and the lumen is stellate on account of the longitudinal foldings of the inelastic mucous membrane loosely held by the submucosa. The calibre

of the lumen varies between half an inch to an inch or more, depending upon the absence or presence of swallowed substances. The average distance from the upper incisor teeth to the beginning of the gullet is about six inches (15 cm.); the average distance from the incisor teeth to the cardiac opening of the stomach is fifteen or sixteen inches (40 cm.). The portion of the œsophagus which is in the neck is called the **cervical portion** (*pars cervicalis*); the portion in the thorax, the **thoracic portion** (*pars thoracalis*); and the portion which lies in the œsophageal groove of the liver, and therefore below the Diaphragm, is the **abdominal portion**. The **abdominal portion of the œsophagus** (*pars abdominalis*) is not over half an inch in length, and is limited to the small portion of the anterior and left lateral surface observed when a stomach which is completely empty is drawn downward with considerable force. The abdominal portion of the œsophagus is covered by perito-

FIG. 953.—Pleural cul-de-sac of the posterior mediastinum.

FIG. 954.—The relations of œsophagus, trachea, and aorta in an infant. (Poirier and Charpy.)

neum only on its ventral and left aspects. It is somewhat conical, with its base toward the stomach, and is known as the *antrum cardiacum*.

Relations.—The **cervical portion** of the œsophagus is in relation, *in front*, with the trachea, and at the lower part of the neck, where it projects to the left side, with the thyroid gland; *behind*, it rests upon the vertebral column and Longus colli muscles; *on either side*, it is in relation with the common carotid artery (especially the left, as it inclines to that side) and part of the lateral lobe of the thyroid gland; the recurrent laryngeal nerves ascend between it and the trachea; to its left side is the thoracic duct.

The **thoracic portion** of the œsophagus is at first situated a little to the left of the median line; it then passes behind the aortic arch, separated from it by the trachea, and descends in the posterior mediastinum, along the right side of the aorta, then runs in front and a little to the left of the aorta, and enters the abdomen through the Diaphragm at the level of the tenth thoracic vertebra. Just before it passes through the Diaphragm it presents a distinct dilatation or *bulb*. It is in relation, *in front*, with the trachea, the left bronchus, the pericardium, and the Diaphragm; *behind*, it rests upon the vertebral column, the Longus colli muscles, the right intercostal arteries, the thoracic duct, and the vena azygos minor veins; and *below*, near the Diaphragm, upon the

front of the aorta. On its *left* side, in the superior mediastinum, are the terminal part of the arch of the aorta, the left subclavian artery, the thoracic duct, and left pleura, while running upward in the angle between it and the trachea is the left recurrent laryngeal nerve; below, it is in relation with the descending thoracic aorta. On its *right* side are the right pleura and the vena azygos major, which it overlaps. The vagus nerves descend in close contact with it, the right nerve passing down behind, and the left nerve in front of it; the two nerves uniting to form a plexus (*plexus gulæ s. œsophageus*) around the tube.

In the lower part of the posterior mediastinum the thoracic duct lies to the right side of the œsophagus; higher up, it is placed behind it, and, crossing about the level of the fourth thoracic vertebra, is continued upward on its left side.

FIG. 955.—The position and relation of the œsophagus in the cervical region and in the posterior mediastinum. Seen from behind. (Poirier and Charpy.)

Structure.—The œsophagus has four coats—an **external** or **fibrous**, a **muscular**, a **sub-mucous**, and an **internal** or **mucous** coat.

The **fibrous coat** consists of white fibrous connective tissue that supports the other coats and assists in connecting the œsophagus to the surrounding tissues or organs.

The **muscular coat** (*tunica muscularis*) is composed of two planes of considerable thickness, an **external longitudinal** and an **internal circular**.

The **longitudinal fibres** are arranged, at the commencement of the tube, in three fasciculi—one in front, which is attached to the vertical ridge on the posterior surface of the cricoid cartilage, and one at each side, which is continuous with the fibres of the Inferior constrictor of the pharynx; as they descend they blend together and form a uniform layer, which covers the outer surface of the tube.

Accessory slips of muscle tissue pass between the œsophagus and the left pleura, where the latter covers the thoracic aorta, or the root of the left bronchus, or the back of the pericardium.

The **circular fibres** are continuous above with the Inferior constrictor of the pharynx; their direction is transverse at the upper and lower parts of the tube, but oblique in the intermediate part. Below, the circular fibres pass into the circular and oblique fibres of the stomach.

The muscle fibres in the upper part of the œsophagus are of a red color, and consist chiefly of the striped variety, but below they consist for the most part of involuntary muscular fibres.

The **submucous coat** (*tela submucosa*) connects loosely the mucous and muscular coats.

The **mucous coat** (*tunica mucosa*) is thick, of a reddish color above and pale below. It is disposed in longitudinal folds, which disappear on distention of the tube. Its surface is studded with minute papillæ, and is covered throughout with a thick layer of stratified pavement epithelium. Beneath the mucous membrane, between it and the submucous coat, is a layer of longitudinally arranged nonstriped muscle tissue. This is the **muscularis mucosæ** (*lamina muscularis mucosæ*). At the commencement of the œsophagus it is absent, or only represented by a few scattered bundles; lower down it forms a considerable stratum.

The **œsophageal glands** are small compound racemose glands of the mucous type; they are lodged in the submucous tissue and each opens upon the mucous surface by a long excretory duct.

Vessels and Nerves.—The larger vessels are in the submucosa and send branches to the mucosa and muscularis. The **arteries** supplying the œsophagus are derived from the **inferior thyroid branch of the thyroid axis of the subclavian**, from the **descending thoracic aorta** and the **bronchial arteries**, and from the **gastric branch of the celiac axis**, and from the **left inferior phrenic of the abdominal aorta**. They have for the most part a longitudinal direction. The **veins** are gathered into a plexus on the outer surface of the œsophagus. This plexus receives the venous blood from the walls of the tube. From the lower portion of the plexus branches go to the **coronary vein of the stomach**. Higher up branches go to the **azygos veins** and **thyroid veins**. In this manner a communication is opened between the portal veins and the systemic veins.

The **lymphatics** drain into the inferior deep cervical nodes and the nodes of the posterior mediastinum.

The **nerves** are derived from the **vagus** and from the **sympathetic**; they form a plexus in which are groups of ganglion cells between the two layers of the muscular coat. From this fibres pass to supply the muscle, and others go to the submucous tissue to form a secondary plexus. It is usual to regard the plexus as consisting of two parts, an **anterior œsophageal plexus**, derived from the left vagus, and a **posterior œsophageal plexus**, derived from the right vagus. These two plexuses are in the posterior mediastinum; they communicate with each other and contain sympathetic fibres.

Applied Anatomy.—The relations of the œsophagus are of considerable practical interest to the surgeon, as he is frequently required, in cases of *stricture* of this tube, to dilate the canal by a bougie, when it is of importance that the direction of the œsophagus and its relations to surrounding parts should be remembered. In cases of *malignant disease* of the œsophagus, where its tissues have become softened from infiltration of the morbid deposit, the greatest care is requisite in directing the bougie through the strictured part, as a false passage may easily be made, and the instrument may pass into the mediastinum, or into one or the other pleural cavity, or even into the pericardium.

One should also remember that obstruction of the œsophagus, and consequent symptoms of stricture, are occasionally produced by *aneurism* of some part of the aorta pressing upon the tube. In such a case the passage of a bougie could only hasten the fatal issue.

In passing a bougie the left forefinger should be introduced into the mouth and the epiglottis felt for, care being taken not to throw the head too far backward. The bougie is then to be passed beyond the finger until it touches the posterior wall of the pharynx. The patient is now asked to swallow, and at the moment of swallowing the bougie is passed gently downward, all violence being carefully avoided.

It occasionally happens that a *foreign body* becomes impacted in the œsophagus and can neither be brought upward nor moved downward. When all ordinary means for its removal have failed, and the body is lodged above the lower one-third of the gullet, external *œsophago-*

FIG. 956.—Accessory muscle slips between the œsophagus and pleura, and œsophagus and trachea. (From a preparation in the Museum of the Royal College of Surgeons of England.)

gotomy is performed. If the foreign body is lodged in the lower one-third of the gullet, the stomach is opened (*gastrotomy*) and the foreign body is extracted. If the foreign body is allowed to remain lodged in the œsophagus, extensive inflammation and ulceration may ensue. In one case the foreign body ultimately penetrated the intervertebral substance, and destroyed life by inflammation of the membranes and substance of the spinal cord.

The operation of *œsophagotomy* is thus performed: The patient being placed upon his back, with the head and shoulders slightly elevated, an incision, about four inches in length, should be made on the left side of the trachea, from the thyroid cartilage downward, dividing the skin, Platysma, and deep fascia. The edges of the wound being separated, the Omohyoid muscle should, if necessary, be divided, and the fibres of the Sternohyoid and Sternothyroid muscles drawn inward; the sheath of the carotid vessels, being exposed, must be drawn outward, and retained in that position by retractors; the œsophagus will now be exposed, and should be divided over the foreign body, which can then be removed. Great care is necessary to avoid wounding the thyroid vessels, the thyroid gland, and the laryngeal nerves.

The œsophagus may be obstructed not only by foreign bodies, but also by changes in its coats, producing *stricture*, or by pressure on it from without of *neurogrowths* or *aneurisms*, etc.

The different forms of *stricture* are: (1) the *spasmodic*, occurring in neurotic individuals, and intermittent in character, so that the dysphagia is not constant. Spasmodic stricture of the œsophagus sometimes occurs in cases of cancer of the stomach and cancer of the liver; (2) *fibrous*, due to cicatrization after injuries, such as swallowing corrosive fluids or boiling water; and (3) *malignant*, usually epitheliomatous in its nature. Cancer is most common either at the upper end of the tube, opposite to the cricoid cartilage, or at its lower end at the cardiac orifice. Cicatricial stricture may be treated by gradual dilatation. If a stricture is impassable from above, the stomach may be opened, an instrument passed from below, and a string used to divide the stricture. The operation of *œsophagostomy* has occasionally been performed, but if any operative interference is undertaken for stricture, with the idea of forming an orifice for the introduction of food, it is better to perform *gastrostomy*. In malignant stricture, *gastrostomy* is the only operation to be thought of.

THE ABDOMEN.

The **abdomen** is that portion of the trunk which lies below the Diaphragm, and it contains the largest cavity in the body. It is of an oval form, the extremities of the oval being directed upward and downward; the upper one is formed by the under surface of the Diaphragm, the lower end is limited by the structures

FIG. 957.—Schematic outlines of the abdomen.

which clothe the inner surface of the bony pelvis, principally the Levatores ani and the Coccygei muscles on either side. These muscles are sometimes termed the **Diaphragm of the pelvis**. In order to facilitate description, it is artificially divided into two parts, an upper and larger part, the **abdomen proper**, and a lower and smaller part, the **pelvis**. The cavities of these divisions are not separated from each other, but the limit between them is marked by the brim of the true pelvis. The cavity is wider above than below, and measures more in the vertical than in the transverse diameter.

The **abdomen proper** differs from the other great cavities of the body in being bounded for the most part by muscles and fasciæ, so that it can vary in capacity and shape according to the condition of the viscera which it contains; but, in

addition to this, the abdomen varies in form and extent with age and sex (Fig. 957). In the adult male, with moderate distention of the viscera, it is oval or barrel-shaped, but at the same time flattened from before backward. In the adult female, with a fully developed pelvis, it is conical with the apex above, and in young children it is conical with the apex below.

FIG. 958.—Topography of thoracic and abdominal viscera.

Boundaries.—The boundary between the thorax and abdomen is the Diaphragm, which extends as a dome over the abdomen, so that the cavity extends high into the bony thorax, reaching on the *right* side, in the midclavicular line, to the upper border of the fifth rib; on the *left* side it falls below this level by about half an inch or more. The abdomen proper is bounded *in front* and *at the sides* by the lower ribs, the abdominal muscles, and the iliac fossæ; *behind*, by the vertebral column and the Psoas and Quadratus lumborum muscles; *above*, by the Diaphragm; *below*, by the plane of the inlet or brim of the pelvis. The muscles forming the boundaries of the cavity are lined upon their inner surface by a layer of fascia, differently named, according to the part which it covers.

The abdomen contains (Fig. 958) the greater part of the alimentary canal; some of the accessory organs to digestion—viz., the liver and pancreas; the spleen, the kidneys, and adrenals, or *suprarenal* capsules. Most of these structures, as well as the wall of the cavity in which they are contained, are covered by an extensive and complicated serous membrane, the **peritoneum** (Fig. 988).

The Apertures in the Walls of the Abdomen.—The apertures found in the walls of the abdomen, for the transmission of structures to or from it, are the **umbilicus**, for the transmission (in the fetus) of the umbilical vessels; the **caval opening** in the Diaphragm, for the transmission of the inferior vena cava; the **aortic opening**, for the passage of the aorta, vena azygos major, and thoracic duct; and the **oesophageal opening**, for the oesophagus and vagus nerves. *Below*, there are two apertures on each side, one for the passage of the femoral vessels, and the other for the transmission of the spermatic cord in the male, and the round ligament in the female.

FIG. 959.—The regions of the abdomen and their contents. Edges of costal cartilages in dotted outline.

Regions (Fig. 959).—For convenience of description of the viscera, as well as of reference to the morbid conditions of the contained parts, the abdomen is artificially divided into nine regions by imaginary planes, two horizontal and two sagittal, passing through the cavity, the edges of the planes being indicated by lines drawn on the ventral surface of the body. Of the horizontal planes, the upper or *infracostal* is indicated by a line encircling the body at the level of the lowest points of the tenth costal cartilages, the lower by a line carried around the trunk at the level of the summits of the iliac crests. The lower plane closely corresponds to the *intertubercular plane* passing through the trunk at the level of the prominent and easily defined tubercle on the iliac crest about two inches behind

the anterior superior iliac spine. By means of these imaginary planes the abdomen is divided into three zones, which are named, from above downward, *subcostal*, *umbilical*, and *hypogastric* zones. Each of these is further subdivided by two sagittal planes, which are indicated on the surface by lines drawn vertically through points half way between the anterior superior iliac spines and the symphysis pubis. The regions as outlined by the BNA Commission are shown in Fig. 960.¹

The middle region of the upper zone is called the *epigastric*, and the two lateral regions, the *right* and *left hypochondriac*. The central region of the middle zone is the *umbilical*; and the two lateral regions, the *right* and *left lumbar*. The middle region of the lower zone is the *hypogastric* or *pubic region*; and the lateral regions are the *right* and *left iliac* or *inguinal*.

FIG. 960.—Regions of the abdomen, according to the BNA Commission.

The **pelvic cavity** is that part of the abdominal cavity which lies below and behind a plane passing through the promontory of the sacrum, the iliopectineal lines and the pubic crests. It is bounded behind by the sacrum, coccyx, Pyriformis muscles, and the great sacrosclatic ligaments; in front and laterally by the pubes and ischia and Obturator internus muscles; above, it communicates with the cavity of the abdomen; below, it is closed by the Levatores ani and Coccygei muscles and the triangular ligament. The pelvic cavity contains the urinary bladder, the sigmoid colon, the rectum, a few coils of small intestine, and some of the generative organs.

If the anterior abdominal wall is reflected in the form of four triangular flaps by means of vertical and transverse incisions—the former from the ensiform cartilage to the symphysis pubis, the latter from flank to flank at the level of the umbilicus—the abdominal or peritoneal cavity is freely opened and the contained

¹ Anatomists are far from agreed as to the best method of subdividing the abdominal cavity. Addison (Journal of Anatomy and Physiology, vols. xxxiv and xxxv), in a careful analysis of the abdominal viscera in forty subjects, adopts the following lines: (1) a median, from the symphysis pubis to the ensiform cartilage; (2) two lateral lines drawn vertically through a point midway between the anterior superior iliac spine and the symphysis pubis; (3) an upper transverse line half way between the symphysis pubis and the suprasternal notch; and (4) a lower transverse line midway between the last and the upper border of the symphysis pubis. The upper transverse line corresponds with what he has termed the *transpyloric plane*, from the fact that in most cases this plane traverses the pylorus.

viscera are in part exposed. Above and to the right side is the **liver**, situated chiefly under the shelter of the right ribs and their cartilages, but extending across the middle line, and reaching for some distance below the level of the ensiform cartilage. To the left of the liver is the **stomach**, from the lower border of which an apron-like fold of peritoneum, the **greater omentum**, descends for a varying distance, and obscures, to a greater or less extent, the other viscera (Fig. 986). Below it, however, some of the coils of the **small intestine** can generally be seen, while in the right and left iliac regions respectively the **cecum** and the **sigmoid flexure** of the colon are exposed. The **bladder** occupies the anterior part of the pelvis, and, if distended, will project above the symphysis pubis; the **rectum** lies in the concavity of the sacrum, but is usually obscured by the coils of the small intestine. The sigmoid colon lies between the rectum and the bladder.

If the stomach is followed from left to right it will be found to be continuous with the first part of the small intestine, or **duodenum**, the point of continuity being marked by a thickened ring which indicates the position of the **pyloric sphincter**. The duodenum passes toward the under surface of the liver, and then, curving downward, is lost to sight. If, however, the great omentum be thrown upward over the thorax, the terminal part of the duodenum will be observed passing across the vertebral column toward the left side, where it becomes continuous with the coils of the **small intestine**. These measure some twenty feet in length, and if followed downward will be seen to end in the right iliac fossa by opening into the **cecum**, the commencement of the **large intestine**. From the cecum the large intestine takes an arched course, passing at first upward on the right side, then across the middle line and downward on the left side, and forming respectively the **ascending**, **transverse**, and **descending parts of the colon**. In the left iliac region it assumes the form of a loop, the **sigmoid flexure**, then follows the curve of the sacrum and terminates in the **rectum** and **anal canal**.

The **spleen** lies behind the stomach in the left hypochondriac region, and may be in part exposed by pulling the stomach over toward the right side.

The glistening appearance of the deep surface of the abdominal wall and of the exposed viscera is due to the fact that the former is lined and the latter more or less completely covered by a serous membrane, the **peritoneum**.

THE PERITONEUM (TUNICA SEROSA).

The **peritoneum** is the largest serous membrane in the body, and consists, in the male, of a closed sac, a part of which is applied against the abdominal parietes, while the remainder is reflected more or less completely over the contained viscera. In the female the peritoneum is not a closed sac, since the free extremities of the Fallopian tubes open directly into the peritoneal cavity. The part which lines the parietes is named the **parietal peritoneum**; that which is reflected over the viscera, the **visceral peritoneum**. The *free surface* of the membrane is smooth, covered by a layer of flattened endothelium, and lubricated by a small quantity of serous fluid. Hence the viscera can glide freely against the wall of the cavity or upon one another with the least possible amount of friction. The *attached surface* is rough, being connected to the viscera and inner surface of the parietes by means of areolar tissue termed the **subserous areolar tissue** (*tela subserosa*). The parietal portion is loosely connected with the fascia lining the abdomen and pelvis, but more closely to the under surface of the Diaphragm and also in the middle line of the abdomen.

The space between the parietal and visceral layers of the peritoneum is named the **peritoneal cavity**; but it must be remembered that under normal conditions this cavity is a potential one, since the parietal and visceral layers are in contact.

The peritoneal "cavity" is subdivided into a **greater** and a **lesser cavity** or **sac**, which communicate through the foramen of Winslow (*foramen epiploicum*). The greater sac is opened when the ventral abdominal wall is pierced; the lesser is situated behind the stomach and adjoining structures, and may be regarded as a diverticulum of the greater sac.

The disposition of the peritoneum as it is applied to the parietes and also reflected over the viscera contained in the abdominal cavity is best understood after tracing the developmental (*embryologic*) history of the peritoneum and the alimentary tract.

Development of the Peritoneum and Alimentary Tract.¹—The segmenting ovum, at an early stage, becomes a blastodermic vesicle with two layers of cells composing its wall, named, from without inward, ectoderm and entoderm. The cavity of the vesicle is filled with the nutritive yolk (*vitellus*). Only a part of the ovum is destined to form the embryo, the remainder being used up in the formation of membranes and other appendages which are concerned in protection and nutrition; the ovum may, therefore, be divided into its *embryonic area* and *extra-embryonic portion*. In the embryonic area, in its caudal part, appears the transitory *primitive streak* and *groove* produced by an axial thickening of the ectoderm. From the sides of the primitive streak a third layer of cells,

the *mesoderm*, extends in all directions between ectoderm and entoderm, extending alongside the neural tube and notochord. The extension of the mesoderm takes place throughout the whole of the embryonic and extra-embryonic areas of the ovum except in certain regions. One such area, devoid of mesoderm, is seen immediately cephalad of the neural tube. This is named the *buccopharyngeal area*, since it afterward forms the temporary septum between the primitive mouth and primitive pharynx. This membrane extends from the head to the pericardial area. A similar area devoid of mesoderm is seen immediately caudad of the embryonic area, and is named the *cloacal membrane*, since it afterward forms the temporary septum between the anal pit and the primitive hindgut.

While the paraxial mesoderm extends along the neural tube and notochord and in all directions, its lateral portion splits into two concentric layers; the outer or *somatic* layer becomes applied to the ectoderm, and with it forms the *somatopleure* or body wall; the inner or *splanchnic* layer adheres to the entoderm, and with it forms the *splanchnopleure*, from which the greater portion of the digestive tract is formed. The space created between the layers of the mesoderm is termed the *cœlom* or *body cavity*. A portion of this space is later enclosed within the embryo, and is called the embryonic cœlom, while the portion of the cœlomic

¹ In the preparation of this chapter the editor has consulted several original treatises, notably G. S. Huntington's "Anatomy of the Human Peritoneum and Abdominal Cavity," 1903.

cavity left outside the embryo, the *extra-embryonic cœlom*, envelops the vitelline or yolk sac.

FIG. 962.—Diagram of a longitudinal section of a mammalian embryo. Very early. (After Quain.)

The relatively slow growth of the margin of the embryonic area and the relatively rapid growth of the axial parts soon come to form a ring of constriction between the embryo and the yolk sac, and a part of the latter—that is, a part of its splanchnopleural wall and part of the cavity—becomes enclosed within the embryo to form the primitive alimentary canal (Fig. 962). At the same time a part of the cœlom becomes enclosed within the embryo by the relative approximation of the lateral, cephalic, and caudal folds, and the embryonic cœlom cavity forms the rudiment of the pleural, pericardial, and peritoneal cavities. The abdominal cavity is separated from the other cavities by the septum transversum, the proton of the Diaphragm. The embryo grows more rapidly in length than in width, and its cephalic and caudal extremities are bent ventrad; the forward growth of the head tilts the areas situated cephalad so that the positions of the buccopharyngeal and

pericardial areas become reversed; the same inversion takes place with regard to the cloacal membrane.

are bent ventrad; the forward growth of the head tilts the areas situated cephalad so that the positions of the buccopharyngeal and

The alimentary tube, now in its simplest form, is nearly straight and may be divided into three portions: (a) the *foregut* between the pericardium and noto-

chord; (b) the *midgut*, opening directly into the yolk sac; and (c) the *hindgut*, contained within the caudal fold. The passage between the midgut and the

FIG. 965.—Front view of two successive stages in the development of the alimentary canal. (His.)

yolk sac is at first relatively wide, but it is subsequently narrowed and lengthened to become the tubular *vitelline duct* (to wholly disappear eventually).

In its course from the head to the tail the primitive alimentary canal is held to the body axis (notochord) by a broad mass of mesoderm, from which the common

mesentery of the gut is subsequently developed. The foregut¹ is also held by a ventral mesentery, the thoracic portion of which becomes modified by the de-

¹ The junction of the foregut with the midgut is generally understood to be at the level of the orifice of the common bile duct, or site of origin of the liver diverticulum.

velopment of the heart and lungs, while the abdominal portion serves as a matrix for the developing liver, and ultimately becoming the falciform ligament and gastro-hepatic omentum. The mesoderm lining the body cavity as well as the free surfaces of the mesenteries soon assumes the character of a serous membrane, and is then called the peritoneum. Topographically, this membrane may be subdivided into: (a) *Parietal peritoneum*, investing the inner surface of the abdominal cavity; (b) *visceral peritoneum*, investing the alimentary tube and its derivatives; (c) *mesenteric peritoneum*, connecting the two former, as a suspensory support for the alimentary tract, and carrying the vessels and nerves to it.

The pharynx, œsophagus, stomach, and part of the duodenum are developed from the foregut; the descending and sigmoid parts of the colon, the rectum, and the tubular diverticulum of the allantois are developed from the hindgut; the midgut gives origin to the remainder of the alimentary tube.

FIGS. 968 and 969.—Illustrating two stages in the development of the human alimentary canal and its mesentery. The arrow indicates the entrance to the bursa omentalis. (Hertwig.)

The upper part of the foregut becomes dilated in the form of branchial pouches to form the pharynx; the succeeding part remains tubular¹ and with the descent of the stomach becomes elongated to form the œsophagus. About the fifth week a fusiform dilatation, the future stomach, makes its appearance. The stomach, together with a succeeding part of the duodenum, has a ventral mesentery, called the *ventral mesogastrium*, in addition to its dorsal attachment, the *dorsal mesogastrium*. In the base of the dorsal mesogastrium courses the aorta which supplies a series of branches, embedded in the mesoderm, to the alimentary tube. The stomach undergoes a further dilatation, and its two curvatures can be recognized, the greater directed dorsad and the lesser ventrad, while its two surfaces look to the right and left respectively. The midgut undergoes great elongation and forms a loop which projects downward and forward; from the arch of the loop the vitelline duct passes to the umbilicus. For a time a part of the loop extends beyond the abdominal cavity into the umbilical cord, but is withdrawn into the cavity by the end of the third month.

About the sixth week a lateral diverticulum makes its appearance on the caudal part of the loop a short distance from the vitelline duct, and indicates the future cecum and appendix. The part of the loop on the distal side of the cecal diverticulum increases in diameter and forms the future ascending and transverse portions of the large intestine. The cecal diverticulum shares only partially in this increase in calibre, its pendant portion remaining rudimentary and forming the appendix.

¹ The epithelium of the œsophagus and certain other portions of the gut increases so greatly in thickness by active proliferation of the cells that the lumen is nearly or wholly closed during the second month, to be restored about one month later (Congenital stenosis).

The stomach and intestine, with their mesenteries, undergo changes of position determined by several growth factors, such as the elongation of the intestine, and the development of such organs as the liver, pancreas, and spleen. Such developmental changes, with subsequent displacements, adhesions, and absorptions, serve to form all the mesenteries, omenta, and peritoneal folds of the adult, so that, while in the primitive condition the intestinal tube is suspended by a dorsal mesentery and freely movable, certain portions of it become later, by secondary adhesion, firmly connected with the parietes (retroperitoneal) or with other portions of the tract.

Rotation of Stomach and Intestine.—The stomach rotates so that its greater (dorsal) curvature with the attached dorsal mesogastrium is carried downward and to the left, so that the right surface of the stomach is now directed backward and the left surface forward (ventrad)—a change in position which explains why the left vagus nerve is found on the front of the stomach and the right vagus on the back of it. As the stomach rotates, the dorsal mesogastrium is necessarily elongated; this elongation is, however, augmented in further development, so that a large pouch, the *bursa omentalis* or *lesser sac* is formed. The entrance to this pouch constitutes the future *foramen of Winslow*. The duodenum, developed from that part of the tube which immediately succeeds the stomach, undergoes

FIG. 970.—The primitive mesentery of a six weeks' human embryo, half schematic. (Kollmann.)

FIG. 971.—Final disposition of the intestines and their vascular relations. A. Aorta. H. Hepatic artery. S. Splenic artery. M. Col. Branches of superior mesenteric artery. m, m'. Branches of inferior mesenteric artery. (Jonnescio.)

little elongation. It is at first suspended by a mesentery (mesoduodenum) and projects forward in the form of a loop. The loop is subsequently displaced backward by the transverse colon, so that the right surface of the mesoduodenum is swung back, and, adhering to the parietal peritoneum partly in front of the right kidney, is obliterated; in this way the duodenum, together with the pancreas which has invaded the dorsal mesoduodenum, become retroperitoneal. It is further fixed in position by the liver and pancreas which arise as diverticula from it. The liver, developing between the layers of the ventral mesogastrium, comes to occupy the upper right portion of the abdominal cavity, and thus reduces the entrance to the omental bursa to the small foramen of Winslow.

The remainder of the alimentary canal becomes elongated, and as a consequence the tube becomes complexly coiled on itself, and this elongation demands a corresponding increase in the width of the intestinal attachment of the mesentery, which becomes folded.

Rotation of the Intestine.—At an early stage the small and large intestines are attached to the dorsal wall of the abdomen by a common mesentery, the coils of the small intestine falling to the right, while the large intestine lies on the left side.¹

The gut now becomes rotated upon itself, so that the large intestine is carried over in front of the small intestine, and the cecum is placed immediately below the liver; about the sixth month the cecum descends into the right iliac fossa,² and the large intestine now forms an arch consisting of the ascending, transverse, and descending portions of the colon—the transverse portion crossing in front of the duodenum and lying just below the greater curvature of the stomach; within this arch the coils of the small intestine are disposed (Figs. 968 and 969). The

FIG. 972.—Torsion of the umbilical loop. Initial position. (Jonnesco.)

FIG. 973.—Torsion of the umbilical loop. Acquired position. (Jonnesco.)

intestine in its rotation twists the mesentery in a funnel-shaped manner, so that the original right leaf of the mesentery of the small intestine has become the left, and *vice versa*. The mesentery of the small intestine assumes the oblique attachment characteristic of its adult conditions. All divisions of the large intestine are at first freely movable, being suspended by a free mesocolon; but subsequently the ascending and descending portions become fixed retroperitoneal structures in consequence of adhesion of the opposed surfaces of the ascending and descending mesocolons and of the dorsal parietal peritoneum. Occasionally the descending mesocolon, more rarely the ascending, persists so that the bowel is more or less movable in these divisions. The sigmoid colon usually remains movable throughout life.

The omental bursa, which at first reaches only as far as the greater curvature of the stomach, grows downward as a double-layered, pouch-like fold, the interior layer derived from the right leaf of the primitive mesogastrium, its exterior layer

¹ Sometimes this condition persists throughout life, and it is then found that the duodenum does not cross from the right to the left side of the vertebral column, but lies entirely on the right side of the mesal plane, where it is continued into the jejunum; the arteries to the small intestine (*rami intestini tenuis*) also arise from the right instead of the left side of the superior mesenteric artery.

² Sometimes the downward progress of the cecum is arrested, so that in the adult it may be found lying immediately below the liver instead of in the right iliac region.

FIG. 974.—Illustrating the development of the bursa omentalis, cavity of the greater omentum or lesser sac. Fetal stage. * Lesser sac. (Hertwig.)

FIG. 975.—Development of bursa omentalis. Infantile stage. Greater omentum covers the intestines and has fused with the transverse mesocolon. Pancreas is free from peritoneum posteriorly. (Hertwig.)

FIG. 976.—Schematic figure of the bursa omentalis, etc. Human embryo of eight weeks. (Kollmann.)

from the left leaf. This omental sac or **greater omentum** extends downward as an apron-like fold in front of the transverse colon and the coils of the small intestine. The anterior layer of the transverse mesocolon is at first quite distinct from the posterior layer of the bursa omentalis, but ultimately the two blend, and hence the greater omentum appears as if attached to the transverse colon (Figs. 974, 975, and 976).

The **lesser omentum** is formed by a thinning of the mesoderm of the ventral mesogastrium which attaches the stomach and part of the duodenum to the ventral abdominal wall. By the subsequent growth of the liver this leaf is divided into two parts—viz., the falciform and coronary ligaments between the liver and the abdominal wall and Diaphragm; and the lesser or gastrohepatic omentum, between the liver and the stomach.

FIG. 977.—Abdominal part of alimentary canal and its attachment to the primitive or common mesentery. Human embryo of six weeks. (Kollmann.)

Vertical Disposition of the Greater Sac (Fig. 979).—It is convenient to trace the greater sac from the back of the abdominal wall at the level of the umbilicus.

On following the parietal peritoneum upward from this level it is seen to be reflected around a fibrous cord, the **ligamentum teres** or **impervious umbilical vein** (Figs. 982 and 1067), which reaches from the umbilicus to the under surface of the liver. This reflection forms a somewhat triangular fold, the **falciform** or **suspensory ligament of the liver** (*ligamentum falciforme hepatis*), attaching the upper and anterior surfaces of the liver to the Diaphragm and abdominal wall. With the exception of the line of attachment of this ligament the peritoneum covers the whole of the under surface of the anterior part of the Diaphragm and is continued from it on to the upper surface of the right lobe of the liver as the **superior layer of the coronary ligament**, and on to the upper surface of the left lobe as the superior layer of the **left lateral ligament** of the liver. Covering the upper and anterior surfaces of the liver it is continued around its sharp margin on to its under surface, where it presents the following relations: (a) It covers

the under surface of the right lobe and is reflected from the back part of this to the upper extremity of the right kidney, forming in this situation the **inferior layer of the coronary ligament**; from the kidney it is carried downward to the duodenum and hepatic flexure of the colon and inward to the inferior vena cava, where it is continuous with the posterior wall of the lesser sac. Between the two layers of the coronary ligament there is a triangular surface of the liver which is devoid of peritoneal covering; this is named the **bare area of the liver**, and is attached to the Diaphragm by areolar tissue. Toward the right margin of the liver the two layers of the coronary ligament gradually approach each other, and ultimately fuse to form a small triangular fold connecting the right lobe of the liver to the Diaphragm, and named the **right lateral ligament** of the liver. The

FIG. 978.—Posterior view of the anterior abdominal wall in its lower half. The peritoneum is in place, and the various cords are shining through. (After Joessel.)

apex of the triangular bare area corresponds to the point of meeting of the two layers of the coronary ligament, its base with the fossa of the inferior vena cava. (b) It covers the lower surface of the quadrate lobe, the under and lateral surfaces of the gall-bladder, and the under surface of the posterior border of the left lobe; it is then reflected from the upper surface of the liver to the Diaphragm as the **inferior layer of the left lateral ligament**, and from the transverse fissure and the fissure for the ductus venosus to the lesser curvature of the stomach as the anterior layer of the **gastrohepatic, or lesser omentum**. If this layer of the lesser omentum be followed to the right it will be found to turn around the hepatic artery, bile duct, and portal vein and become continuous with the anterior wall of the lesser sac, forming a free folded edge of peritoneum.

Traced downward it covers the antero-superior surface of the stomach and the commencement of the duodenum, and is carried down from the greater curvature of the stomach into a large free fold, the **gastrocolic** or **greater omentum** (Figs. 980 and 986). Reaching the free edge of this fold, it is reflected upward to cover the under and posterior surfaces of the transverse colon, and thence to the posterior abdominal wall as the inferior layer of the **transverse mesocolon** (Fig. 979). It reaches the abdominal wall at the upper border of the third part of the duodenum, and is then carried down on the superior mesenteric vessels to the small intestine as the anterior layer of the **mesentery**. It encircles the intestine, and

FIG 979.—Diagram showing the vertical disposition of the peritoneum Lesser sac in red; greater sac in blue

subsequently may be traced, as the posterior layer of the mesentery, upward and backward to the abdominal wall. From this it sweeps down over the aorta into the pelvis, where it invests the sigmoid colon, its reduplication forming the **sigmoid mesocolon** (Fig. 988). Leaving first the sides and then the front of the rectum, it is reflected on to the base of the bladder, and, after covering the upper surface of that viscus, is carried along the urachus and impervious hypogastric arteries to the back of the abdominal wall, from which a start was made.

Between the rectum and the bladder the peritoneum forms, in the *male*, a pouch, the **rectovesical pouch** (*excavatio rectovesicalis*), bounded on the sides by two

crenate or semilunar folds (*plicae rectovesicales*), which pass from the posterior surface of the bladder to the sides of the rectum; the bottom of this pouch is about on a level with the middle of the seminal vesicles—i. e., three inches or so from the orifice of the anus. When the bladder is distended the peritoneum is carried up with the expanded viscus, so that a considerable part of the anterior surface of the latter lies directly against the abdominal wall without the intervention of the peritoneal membrane. When the bladder is empty the peritoneum forms a transverse fold over its upper surface (*plica vesicalis transversa*).

In the *female* the peritoneum is reflected from the rectum to the upper part of the posterior vaginal wall, forming the **rectovaginal pouch** or **pouch of Douglas** (*excavatio rectouterina*) (Fig. 980). It is continued over the posterior surface and fundus of the uterus on to its anterior surface, which it covers as far as the junction of the body and cervix uteri, forming here a second but shallower depression, the **utero-vesical pouch** (*excavatio vesicouterina*). It is also reflected from the sides of the uterus to the lateral wall of the pelvis on each side as two expanded folds, the **broad ligaments of the uterus** (*ligamenta lata uteri*), in the free margin of each of which is the Fallopian tube.

Vertical Disposition of the Lesser Sac (Fig. 979).—A start may be made in this case on the posterior abdominal wall above the pancreas. From this region the peritoneum may be followed upward on to the inferior surface of the Diaphragm, and thence on to the Spigelian and caudate lobes of the liver to the fissure for the ductus venosus and the transverse fissure; this *cul-de-sac* is the **Spigelian recess**. Traced laterally, it is continuous over the inferior vena cava with the posterior wall of the greater sac. From the liver it is carried downward to the lesser curvature of the stomach as the posterior layer of the gastrohepatic omentum, and is continuous on the right, around the hepatic artery, bile duct, and portal vein, with the greater sac. The posterior layer of the gastrohepatic omentum is carried down to the greater curvature of the stomach as a covering for the postero-inferior surface of this viscus, and from the greater curvature is continued downward as the deep layer of the greater or gastrocolic omentum. From the free margin of this fold it is reflected upward on itself to the anterior and superior surfaces of the transverse colon and thence as the superior layer of the transverse mesocolon to the upper border of the third part of the duodenum, from which it may be followed over the front of the pancreas to the level at which a start was made. It will be seen that the loop formed by the wall of the lesser sac below the transverse colon follows, and is closely applied to, the deep surface of that formed by the greater sac, and that the greater omentum or large fold of peritoneum which hangs in front of the small intestine therefore consists of four layers, two anterior and two posterior, separated by the potential cavity of the lesser sac though inseparably blended, as a rule, in the adult.

Horizontal Disposition of the Peritoneum.—Below the transverse colon the arrangement is extremely simple, as it includes only the greater sac (Fig. 981); above the level of the transverse colon it is more complicated on account of the existence of the two sacs. Below the transverse colon it may be considered in in three regions—viz., in the pelvis and in the abdomen proper, upper and lower portions.

1. *In the Pelvis.*—The peritoneum here follows closely the surfaces of the pelvic viscera and the irregularities of the pelvic walls and presents important differences in the two sexes: (a) *In the male* it encircles the sigmoid flexure, from which it is reflected to the posterior wall as a fold, the *sigmoid mesocolon*. It then leaves the sides and, finally, the front of the rectum, and is continued to the bladder; on either side of the rectum it forms a fossa, the *pararectal fossa*, which varies in size with the distention of the rectum. In front of the rectum the peritoneum forms the rectovesical pouch, which is limited laterally by peritoneal folds extending

from the sides of the bladder to the rectum and sacrum. These folds are known from their position as the *rectovesical* or *sacrogenital folds*. The peritoneum of the anterior pelvic wall covers the superior surface of the bladder, and on either side of this viscus forms a depression, termed the *paravesical fossa*, and limited externally by the fold of peritoneum covering the vas deferens. The size of this fossa is dependent on the state of distention of the bladder; when the bladder is empty, a variable fold of peritoneum, the *plica vesicalis transversa*, divides the fossa into two portions. On the peritoneum between the paravesical and pararectal fossæ the only elevations are those produced by the ureters and the internal iliac vessels. (b) In the female, pararectal and paravesical fossæ similar to those in the male are present; the outer limit of the paravesical fossa is the peritoneum investing the round ligament of the uterus. The rectovesical pouch is, however,

FIG. 980.—Diagrammatic mesal section of the female body, to show the peritoneum on vertical tracing. The greater sac of the peritoneum is black and is represented as being much larger than in nature; the lesser sac is very darkly shaded; the peritoneum on section is shown as a white line, and a white arrow is passed through the foramen of Winslow from the greater into the lesser sac. (Cunningham.)

divided by the uterus and vagina into a small anterior *utero-vesical* and a large, deep, posterior *recto-vaginal pouch* or *pouch of Douglas*. The sacrogenital folds form the margins of the latter, and are continued on to the back of the uterus to form a transverse fold, the *torus uterinus*. The *broad ligaments* extend from the sides of the uterus to the lateral walls of the pelvis; they contain in their free margins the Fallopian tubes, and on their posterior surface the ovaries attached by the mesovaria. Below, the broad ligaments are continuous with the peritoneum on the lateral walls of the pelvis. On the lateral pelvic wall behind the attachment of the broad ligament, in the angle between the elevations produced by the diverging internal and external iliac vessels, is a slight fossa, the *ovarian fossa*, in which the ovary normally lies.

2. *In the Lower Abdomen* (Fig. 981).—Starting from the linea alba, below the level of the transverse colon, and tracing the continuity in a horizontal direction to the right, the peritoneum covers the inner surface of the abdominal wall almost as far as the outer border of the *Quadratus lumborum*; it encloses the cecum and appendix, and is reflected over the sides and anterior surface of the ascending colon; it may then be traced over the *Psoas* muscle and the inferior vena cava toward the middle line, whence it passes along the mesenteric vessels to invest the small intestine, and back again to the large vessels in front of the vertebral column, forming the **mesentery**, between the layers of which are contained the mesenteric bloodvessels, nerves, lacteals, and lymph nodes. It is then continued over the left *Psoas* muscle; it covers the sides and anterior surface of the descending colon, and, reaching the abdominal wall, is continued on it to the middle line.

3. *In the Upper Abdomen* (Fig. 982).—Above the transverse colon the peritoneum can be traced, forming the greater and lesser sacs, and their communication through the foramen of Winslow can be demonstrated.

FIG. 981.—Peritoneal reflection in transverse section of lumbar region below the transverse colon. Seen from above. Schematic. (Tillaux.)

(a) **Greater Sac.**—Commencing on the posterior abdominal wall at the inferior vena cava, the membrane may be followed to the right over the front of the upper part of the right kidney on to the antero-lateral abdominal wall. From the middle of the anterior wall a backwardly directed fold encircles the impervious umbilical vein and forms the falciform ligament of the liver. Continuing to the left, the peritoneum lines the lateral abdominal wall and covers the outer part of the front of the left kidney, and is reflected to the posterior border of the hilus of the spleen as the posterior layer of the lienorenal ligament (Fig. 985). It can then be traced over the surface of the spleen to the front of the hilus, and thence to the cardiac extremity of the stomach as the anterior layer of the gastrosplenic omentum. It covers the antero-superior surface of the stomach and first part of the duodenum and extends up from the lesser curvature of the stomach to the liver, the latter portion forming the anterior layer of the gastrohepatic omentum.

(b) **Lesser Sac.**—On the posterior abdominal wall the peritoneum of the greater sac is continuous with that of the lesser sac in front of the inferior vena cava.

Starting from here, the lesser sac may be traced across the aorta and over the inner part of the front of the left kidney to the hilus of the spleen as the anterior layer of the lienorenal ligament. From the spleen it is reflected to the stomach as the posterior layer of the gastrosplenic omentum. It covers the postero-inferior surfaces of the stomach and commencement of the duodenum, and from the lesser curvature of the stomach extends upward to the liver as the posterior layer of the gastrohepatic omentum; the right margin of this layer is continuous around the hepatic artery, bile duct, and portal vein with the wall of the greater sac.

The **foramen of Winslow** (*foramen epiploicum*) is the passage of communication between the greater and lesser sacs. It is bounded in front by the free border of the gastrohepatic omentum, with the hepatic artery, common bile duct, and portal vein between its two layers; behind by the peritoneum covering the inferior vena cava; above by the peritoneum on the caudate lobe of the liver, and below by the peritoneum covering the commencement of the duodenum and the hepatic artery, the latter passing forward below the foramen before ascending between the two layers of the gastrohepatic omentum (Fig. 982).

FIG. 982.—Transverse section of peritoneum above the transverse colon. The arrow points to the lesser sac and passes through the foramen of Winslow.

The *boundaries of the lesser sac* will now be evident. It is bounded *in front*, from above downward, by the Spigelian lobe of the liver, the gastrohepatic omentum, the stomach, and the anterior two layers of the greater omentum; *behind*, it is limited, from below upward, by the two posterior layers of the greater omentum, the transverse colon, and the ascending layer of the transverse mesocolon, the upper surface of the pancreas, the left suprarenal gland, and the upper end of the left kidney. *Laterally*, the lesser sac extends from the foramen of Winslow to the spleen (*recessus lienalis*) (Fig. 985), where it is limited by the lienorenal ligament and the gastrosplenic omentum.

In the fetus the lesser sac reaches as far as the free margin of the great omentum, but in the adult its vertical extent is usually more limited, owing to adhesions between the layers of the omentum. It should be stated that during a considerable part of fetal life the transverse colon is suspended from the posterior abdominal wall

by a mesentery of its own—the two posterior layers of the greater omentum passing, at this stage, in front of the colon (Fig. 974). This condition sometimes persists throughout adult life, but as a rule adhesion occurs between the mesentery of the transverse colon and the posterior layer of the greater omentum, with the result that the colon appears to receive its peritoneal covering by the splitting of the two posterior layers of the latter fold. In the adult the lesser sac intervenes between the stomach and the structures on which that viscus lies, and performs, therefore, the functions of a serous bursa for the stomach.

Numerous peritoneal folds extend between the various organs or connect them to the parietes. They serve to hold them in position, and, at the same time, enclose the vessels and nerves proceeding to them. Some of these folds which connect certain viscera with the parietes are called **ligaments**, such as the ligaments

FIG. 983.—Bursa omentalis, or lesser sac, opened from the front by an incision through the gastrocolic omentum. A probe passes through the foramen of Winslow and rests on the gastropancreatic fold. (Henle.)

of the liver and the false ligaments of the bladder. Others, which connect certain parts of the intestine with the abdominal wall, constitute the **mesenteries**; and lastly, those which proceed from the stomach to certain viscera in its neighborhood are called **omenta**.

The **ligaments**, formed by folds of the peritoneum, include those of the liver, spleen, bladder, and uterus. They will be found described with their respective organs.

The **omenta** are the **lesser omentum**, the **greater omentum**, and the **gastrosplenic omentum**.

The **lesser or gastrohepatic omentum** (*omentum minus*) (Figs. 980 and 983) is the duplicature which extends between the transverse fissure of the liver and the right side of the abdominal portion of the œsophagus, the lesser curvature of the stomach, and the upper portion of the superior surface of the duodenum.

The portion going to the œsophagus and stomach is called the **hepatogastric ligament** (*ligamentum hepatogastricum*). The division of the ligament which goes to the œsophagus is strong and dense; the division which goes to the lesser curvature of the stomach is thin and relaxed. The portion of the lesser omentum which goes to the duodenum is continuous with the first-named portion. It is called the **hepatoduodenal ligament** (*ligamentum hepatoduodenale*). The right margin of this ligament is free and concave. The **hepatocolic ligament** (*ligamentum hepatocolicum*) is not invariably present. It is a fold of the hepatoduodenal ligament and runs from the posterior surface of the gall-bladder to the descending portion of the duodenum or possibly to the transverse colon.

The lesser omentum is thin, and is continuous with the two layers which cover respectively the anterior and posterior surfaces of the stomach. When the two layers reach the lesser curvature of the stomach, they join and ascend as the double fold to the transverse or portal fissure of the liver; to the left of this fissure the double fold is attached to the bottom of the fissure for the ductus venosus, along which it is

FIG. 984.—Structures between the layers of the lesser omentum. The liver has been raised up, and the anterior layer of the omentum removed. Semidiagrammatic. (Cunningham.)

carried to the Diaphragm, where the two layers separate to embrace the end of the œsophagus. At the right border the two layers are continuous and form a free margin which constitutes the anterior boundary of the foramen of Winslow. Between the two layers, close to this free margin, are the **hepatic artery**, the **common bile duct**, the **portal vein**, **lymphatics**, and the **hepatic plexus of nerves** (Fig. 984)—all these structures being enclosed in loose areolar tissue which is continuous with Glisson's capsule. Between the layers where they are attached to the stomach lie the **gastric artery** and the **pyloric branch of the hepatic artery**.

The **greater or gastrocolic omentum** (*omentum majus*) (Figs. 980 and 986) is the largest peritoneal fold. It consists of a double sheet of peritoneum, folded on itself so that it is made up of four layers. The two layers which descend from the stomach pass in front of the small intestines, sometimes as low down as the pelvis; they then turn upon themselves, and ascend again as far as the transverse colon, where they separate and enclose that part of the intestine. These separate layers may be easily demonstrated in the young subject, but in the adult they are more

FIG. 985.—Horizontal section through the stomach, pancreas, spleen, and the left kidney to show peritoneal reflections at the hilum of the spleen (G. S. H.)

FIG. 986.—The greater omentum as seen from the front. (Testut.)

or less inseparably blended. The left border of the greater omentum is continuous with the gastrosplenic omentum; its right border extends only as far as the duodenum. The greater omentum is usually thin, presents a cribriform appearance, and always contains some adipose tissue, which in fat persons accumulates in considerable quantity. Between its two anterior layers is the anastomosis between the right and left gastroepiploic arteries. In opening the abdomen the greater omentum is rarely found spread out evenly over the intestines. It often projects between intestinal coils, or is largely gathered in some one region, or is pushed in front of the stomach by distention of the colon.

FIG. 987.—Mesentery. Small intestine pushed upward to the right (Tillaux.)

The **gastrosplenic omentum** is the fold which connects the margins of the hilum of the spleen to the stomach, being continuous by its lower border with the greater omentum. It contains the vasa brevia.

The **mesenteries** are the **mesentery proper**, the **transverse mesocolon**, the **sigmoid mesocolon**, and the **mesentery of the vermiform appendix**. In addition to these there are sometimes present an ascending and a descending mesocolon.

The **mesentery** (*mesenterium*) (Figs. 987 and 988), is the broad, fan-shaped fold of peritoneum which connects the convolutions of the jejunum and ileum with

the posterior wall of the abdomen. Its *root* (*radix mesenterii*), the part connected with the structures in front of the vertebral column, is narrow, about six inches in length, and directed obliquely from the left side of the second lumbar vertebra to the right iliac fossa (Fig. 988). Its *intestinal border* is about twenty feet in length, and here the two layers separate so as to enclose the intestine and form its peritoneal coat. Its breadth, between its vertebral and intestinal border, is about eight inches. Its *upper border* is continuous with the under surface of the transverse mesocolon; its *lower border*, with the peritoneum covering the cecum and

FIG. 988.—Diagram devised by Dr. Delépine to show the lines along which the peritoneum leaves the wall of the abdomen to invest the viscera.

ascending colon. It serves to retain the small intestines in their position, and contains between its layers the **mesenteric vessels** and **nerves**, the **lymphatic vessels**, and **mesenteric lymph nodes**. These nodes number from 50 to 150. The mesentery is somewhat translucent, particularly at its upper part, but in stout individuals it becomes opaque on account of the fat deposited between its layers.

In most cases the peritoneum covers only the front and sides of the ascending and descending parts of the colon. Sometimes, however, these are surrounded by the serous membrane and attached to the posterior abdominal wall by an **ascending**

mesocolon (*mesocolon ascendens*) and a **descending mesocolon** (*mesocolon descendens*) respectively. At the place where the transverse colon turns downward to form the descending colon, a fold of peritoneum is continued to the under surface of the Diaphragm opposite the tenth and eleventh ribs. This is the **phrenocolic ligament** (*ligamentum phrenicocolicum*); it passes below the spleen, and serves to support this organ, and therefore it has received the name of **sustentaculum lienis**.

The **transverse mesocolon** (*mesocolon transversum*) (Fig. 988) is a broad fold, which connects the transverse colon to the posterior wall of the abdomen. It is formed by the two posterior layers of the greater omentum, which, after separating to surround the transverse colon, join behind it, and are continued backward to the vertebral column, where they diverge in front of the anterior border of the pancreas. This fold contains between its layers the vessels which supply the transverse colon.

The **sigmoid mesocolon** (*mesocolon sigmoideum*) (Fig. 988) is the fold of peritoneum which retains the sigmoid flexure in connection with the pelvic wall. Its line of attachment forms a V-shaped curve, the apex of the curve being placed about the point of division of the left common iliac artery. The curve begins on the inner side of the left Psoas, and runs upward and backward to the apex, from which it bends sharply downward and inward, and ends in the mesal plane at the level of the third sacral segment. Between the two layers of this fold run the sigmoid and superior hemorrhoidal vessels.

FIG. 989.—Superior and inferior duodenal fossæ. (Poirier and Charpy.)

The **mesoappendix** or **mesentery of the vermiform appendix** (*mesenterium processus vermiformis*) (Fig. 992) is a double fold of peritoneum derived from the left leaf of the mesentery. In the majority of cases it is triangular in shape and usually extends along the entire length of the appendix. Between its two layers lie the appendicular artery (Fig. 1037), a branch of the ileocolic artery, some connective tissue, and lymph vessels and nerves.

The **appendices epiploicæ** are small pouches of the peritoneum filled with fat and situated along the colon and upper part of the rectum. They are chiefly appended to the transverse colon.

Retroperitoneal Fossæ.—In certain parts of the abdominal cavity there are recesses of peritoneum forming *culs-de-sac* or pouches, which are of surgical interest in connection with the possibility of the occurrence of retroperitoneal hernia. One of these is the lesser sac of the peritoneum (Figs. 980 and 982), which may be regarded as a recess of peritoneum through the foramen of Winslow, in which a hernia may take place, but there are several others, of smaller size, which require mention.

These recesses or fossæ may be divided into three groups—viz.: (1) the **duodenal fossæ**; (2) **pericecal fossæ**; and (3) the **intersigmoid fossa**.

1. **Duodenal Folds and Fossæ**.—Moynihan has described no less than nine fossæ as occurring in the neighborhood of the duodenum. Three of these are fairly constant. Five of the fossæ are here considered: (a) The **inferior duodenal fossa** or **fossa of Treitz** (Fig. 989) is the most constant of all the peritoneal fossæ in this region, being present in from 70 to 75 per cent. of cases. It is situated opposite the third lumbar vertebra on the left side of the ascending portion of the duodenum. Its opening is directed upward, and is bounded by a thin, sharp fold of peritoneum with a concave free upper margin, called the **inferior duodenal fold** (*plica duodenomesocolica*). The tip of the index finger introduced into the fossa under the fold passes some little distance behind the ascending or fourth portion of the duodenum. (b) The **superior duodenal fossa** (Fig. 989) is the next most constant pouch or recess, being present in from 40 to 50 per cent. of cases.

FIG. 990.—Duodenojejunal fossa. (Poirier and Charpy.)

It often coexists with the inferior one, and its orifice looks downward, in the opposite direction to the preceding fossa. It lies to the left of the ascending portion of the duodenum. It is bounded by the free edge of the **superior duodenal fold** (*plica duodenojejunalis*), which presents a semilunar margin; to the right it is blended with the peritoneum covering the ascending duodenum, and to the left with the peritoneum covering the perirenal tissues. The fossa is bounded in front by the superior duodenal fold; behind by the second lumbar vertebra; to the right by the duodenum. (c) The **duodenojejunal fossa** or **mesocolic fossa** (*recessus duodenojejunalis*) is formed where the duodenojejunal angle enters the root of the transverse mesocolon. There are two forms: (1) a single fossa and (2) a double fossa. It can be seen by pulling the jejunum downward and to the right after the transverse colon has been pulled upward. It will appear as an almost circular opening, looking downward and to the right, and bounded by two free borders or folds of peritoneum, the **duodenomesocolic ligaments**. The opening

admits the little finger into the fossa to the depth of from four-fifths to one and one-fifth inches, or 2 to 3 cm. The fossa is bounded above by the pancreas, to the right by the aorta, and to the left by the kidney; beneath is the left renal vein. The fossa exists in from 15 to 20 per cent. of cases, and has never yet been found in conjunction with any other form of duodenal fossa. (d) **Paraduodenal fossa** or the **fossa of Landzert** (*recessus duodenojejunalis*) is most distinct in the infant, and is to the left of the ascending portion of the duodenum. The fold of peritoneum to its outer side and above is produced by the inferior mesenteric vein. Its lower limit is a fold called the **mesentericomesocolic fold**. (e) The **retro-duodenal fossa** (Fig. 980) was described in 1893 by Jonnesco. It is a peritoneal *cul-de-sac*, sometimes found behind the horizontal and ascending portions of the duodenum.

2. **Pericecal Folds and Fossæ.**—There are at least three pouches or recesses to be found in the neighborhood of the cecum, which are termed **pericecal fossæ**. (1) The **ileocolic fossa** or **superior ileocecal** (*recessus ileocecalis superior*) (Fig. 991)

FIG. 991.—The pericecal folds and fossæ.

is formed by a fold of peritoneum, the **ileocolic fold**, arching over the branch of the ileocolic artery which supplies the ileocolic junction. The fossa is a narrow chink situated between the ileocolic fold in front, and the mesentery of the small intestine, the ileum, and a small portion of the cecum behind. (2) The **ileocecal** or **ileoappendicular fossa** (*recessus ileocecalis inferior*) (Fig. 991) is situated behind the angle of junction of the ileum and cecum. It is formed by a fold of peritoneum, the **ileocecal fold** (*plica ileocecalis*), or "bloodless fold" of Treves, the upper border of which is attached to the ileum, opposite its mesenteric attachment, while the lower border, passing over the ileocecal junction, joins the mesentery of the appendix, and sometimes the appendix itself; hence this fold is sometimes called the **ileoappendicular fold**. Between this fold and the mesentery of the vermiform appendix is the **ileocecal fossa**. It is bounded *above* by the posterior surface of the ileum and the mesentery; in *front* and *below* by the ileocecal fold, and *behind* by the upper part of the mesentery of the appendix. (3) The **retrocecal** or **subcecal fossa** (*recessus retrocecalis*) (Fig. 992) is situated

behind the cecum, which has to be raised to bring the fossa into view. It varies much in size and extent. In some cases it is sufficiently large to admit the index finger and extends upward behind the ascending colon in the direction of the kidney; in others it is merely a shallow depression. It is bounded and formed by two folds: one, the **external parietocolic fold**, or the **superior cecal fold**, which is attached by one edge to the abdominal wall from the lower border of the kidney to the iliac fossa and by the other to the postero-external aspect of the colon; and the other, the **inferior cecal** or **mesentericoparietal fold**, which is in reality the insertion of the mesentery into the iliac fossa. In some instances the subcecal fossa is double.

FIG. 992.—The retrocecal fossa. The ileum and cecum are drawn backward and upward. (Souligoux.)

3. The **intersigmoid fossa** (*recessus intersigmoideus*) is constant in the fetus and common during infancy, but disappears in a large percentage of cases as age advances. Upon drawing the sigmoid flexure upward, the left surface of the sigmoid mesocolon is exposed, and on it will be seen a funnel-shaped recess of the peritoneum, lying on the external iliac vessels, in the interspace between the Psoas and Iliacus muscles. This is the orifice leading to the fossa intersigmoidea, which lies behind the sigmoid mesocolon, and in front of the parietal peritoneum. The fossa varies in size; in some instances it is a mere dimple, whereas in others it will admit the whole of the index finger.

Any of these fossæ may be the site of a **retroperitoneal hernia**. The pericecal fossæ are of especial interest, because hernia of the vermiform appendix frequently takes place into one of them, and may there become strangulated. The presence of these pouches also explains the course which pus has been known to take in cases of perforation of the appendix, where it travels upward behind the ascending colon as far as the Diaphragm.¹

Applied Anatomy.—Study of the peritoneum by Robinson and others shows that *absorption* takes place more rapidly from the region of the Diaphragm, less rapidly but still very actively from the region of the small intestine, slowly from the pelvic region. Clinically we know that pelvic

¹ On the anatomy of these fossæ, see the Arris and Gale Lectures by Moynihan, 1899.

peritonitis is not nearly so dangerous as peritonitis in the small intestine or Diaphragm areas, and that peritonitis in the region of the Diaphragm is the most fatal form of the infection. After *abdominal operations* in infected cases, it is well to elevate the head of the bed (*Fowler's position*), so as to obtain the aid of gravity in draining septic fluids away from the dangerous region and toward the safer region.¹ In areas in which absorption is rapid, protective exudation is not apt to form. In areas in which absorption is slow, inflammatory exudation is apt to circumscribe the area and prevent diffusion. After an operation in a noninfected case, if salt solution has been left in the abdominal cavity because of *shock* or *hemorrhage*, raising the foot of the bed will aid rapid absorption of the fluid by favoring the natural current toward the Diaphragm and hurrying the fluid to a region in which absorption is rapid. Dr. John B. Murphy's plan of treating general peritonitis has proved remarkably successful. He does not remove the exudation of lymph which is seen upon the peritoneum. This exudation is conservative, blocks up lymph spaces, and lessens the absorption of dangerous toxins. He inserts a drainage tube into the peritoneal cavity above the pubes, puts the patient erect or semierect in bed (*Fowler's position*), and administers salt solution continuously by low pressure proctolysis. According to Murphy, the lymph circulation is reversed and the peritoneum becomes a secreting surface. Certain it is that the salt solution absorbed from the rectum reaches the peritoneal cavity in large amounts and flows out of the drainage tube.

The *greater omentum* stores up fat, and, being movable, it is able to pass to different parts of the peritoneal cavity. Dr. Robinson, in his work on the *Peritoneum*, describes its functions as follows: "The omentum is the great protector against peritoneal infectious invasions. It builds barriers of exudates to check infection. It is like a man-of-war, ready at a moment's notice to move to invaded parts. It circumscribes abscesses, it repairs visceral wounds, and prevents adhesions of mobile viscera to the anterior abdominal wall. It resists infectious invasions by typical peritoneal exudates, and not by succumbing to absorbed sepsis. It is a director of peritoneal fluids, a peritoneal drain."

In *abdominal wounds* the greater omentum often protrudes. This structure frequently constitutes or is part of a *hernia*, and is almost invariably present in umbilical hernia. As a result of *inflammation*, it may become adherent to adjacent structures. *Adhesions* may be of service by matting together the intestines and circumscribing infections. They may be harmful by constricting the bowels and producing obstruction. A portion of the omentum may become adherent to some other part and form a *band*, and under this band the gut may be caught and *strangled*. The omentum may adhere to and plug a perforation in a hollow viscus, and the surgeon may utilize it for the same purpose, or to cover a raw surface or overlies a suture line. The omentum may be in the surgeon's way while operating. If it is, the patient is placed in the *Trendelenburg position* (pelvis elevated).

Any *tear* or opening found by the surgeon in the greater omentum must be closed with sutures, because of the danger that intestine might enter and be caught in such an opening. A tumor cut off from its proper blood supply, for instance, an ovarian cyst with a twisted pedicle, may continue to receive nourishment from adherent omentum, and gangrene may thus be prevented.

The lax character and shifting tendency of the subserous tissue explains the occurrence of *pneumosis of the abdominal viscera and kidneys*.

The vast number of nerves in the peritoneum accounts for the profound shock which follows a wound, attends an intraperitoneal calamity, or which develops from infection. An infective process of any portion of the peritoneum produces pain and reflex symptoms (vomiting, abdominal rigidity, intestinal paresis, etc.).

The parietal peritoneum is very sensitive to pain, but not to touch; hence, after injecting a local anesthetic and opening the abdomen, a fairly satisfactory exploration can be made with the finger.

The intestine, the mesentery, the stomach, the anterior margin of the liver, and the gall-bladder are insensitive, and may be cut or even burned without pain.² Viscera which obtain their innervation purely from visceral nerves are insensitive; those which receive branches from somatic nerves are sensitive (Lennander).

The oblique origin of the mesentery causes this structure to form a sort of shelf. A hemorrhage or extravasation into the abdomen, to the right of the mesentery, tends to flow into the right iliac fossa; one occurring on the left side flows into the pelvis. Monks shows how the mesentery can be utilized to determine the direction of an intestinal loop:

"Now, let us suppose that the surgeon has between his fingers a loop of bowel, and wishes to determine its direction. He knows that one side of the loop is the left side of the intestine, and that the corresponding side of the mesentery, if closely followed down to the mesenteric root, will conduct him into the left fossa; he also knows that the other side of the bowel is its right side, and that the mesentery on that side will conduct him into the right fossa. Now, if his finger goes into the great fossa on the left side of the abdomen, after having closely fol-

¹ George R. Fowler, in *Medical Record*, April 14, 1900.

² Dr. K. E. L. Lennander, in *Mittheilungen aus dem Grenzgebieten der Medizin und Chirurgie*, Band x, Heft 1, 2.

lowed the mesentery down to its root and arranged his loop to be parallel with that root, he then knows that the left and right sides of the intestine face to the left and right sides of the abdomen respectively, and that the end of the loop which points downward is the end nearest the ileocecal valve. He can determine the direction of the gut in a similar way in case his finger enters the right fossa. All this would seem very simple were it not for the twists in mesentery and intestine, which tend to mislead one. A little practice will usually enable one to recognize a twist in the mesentery. This should be untwisted by rotation of the gut, after which the direction is determined by another palpation of the mesenteric root."¹

The studies made of the arrangement and variations of the loops of the mesenteric vessels by Dr. Thomas Dwight² have been utilized and expanded by Dr. George H. Monks in laying down rules for the determination of the exact portion of small intestine which may be in the surgeon's hand.³ His views are as follows:

"General Vascularity of the Mesentery near the Bowel.—Opposite the upper part of the bowel the mesenteric vessels are distinctly larger than opposite any other part of it. These vessels grow smaller and smaller as we pass downward until the lower third of the gut is reached, where they remain about the same size as far as the ileocecal valve. The arrangement of the mesenteric vessels has some features which intimately concern the subject in hand, and which I shall describe with some detail. Diagrammatically speaking, the main branches of the superior mesenteric artery unite with each other by means of loops, which are called for convenience 'primary loops;' in some parts of the tube, 'secondary loops,' and even, occasionally, 'tertiary loops,' are superimposed upon these. From these loops little straight vessels—the vasa recta already referred to—run to the bowel, upon which they ramify, alternating, as a rule, as to the side of the intestine which they supply. The mesenteric veins are arranged in a manner somewhat similar to the arteries.

"The Loops of the Mesenteric Vessels.—Opposite the upper part of the bowel there are only primary loops. Occasionally a secondary loop appears, but it is small and insignificant as compared with the primary loops, which are large and quite regular. As we proceed down the bowel, secondary loops become more numerous, larger, and approach nearer to the bowel than the primary loops in the upper part. As a rule, secondary loops become a prominent feature at about the fourth foot. As we continue farther downward, the secondary loops (and, possibly, tertiary loops) become still more numerous and the primary loops smaller, the loops all the time getting nearer and nearer to the gut. Opposite the lower part of the gut the loops generally lose their characteristic appearance, and are represented by a complicated network.

"The Vasa Recta.—Opposite the upper part of the intestine the vasa recta are from three to five centimetres long, when the loop of small intestine to which they run is lifted up so as to put them gently on the stretch. They are straight, large, and regular, and rarely give off branches in the mesentery. In the lower third they are very short, being generally less than 1 cm. in length. Here they are less straight, smaller, less regular, and have frequent branches in the mesentery."

THE STOMACH (GASTER; VENTRICULUS) (Figs. 958, 994).

The stomach is one of the principal organs of digestion, and serves as a temporary receptacle for food. It is the most dilated part of the alimentary canal, and is situated between the termination of the œsophagus (*cardia*) and the commencement of the small intestine.

It lies more or less obliquely or horizontally in the epigastric, umbilical, and left hypochondriac regions of the abdomen, and occupies a recess or chamber called the **stomach chamber** (Fig. 983). When distended the viscus completely fills the space. When the stomach is empty it lies upon the floor of the chamber, and the portion it has vacated is occupied by the transverse colon, which ascends in front of the stomach and finally gets above it. The **anterior and left wall** of the stomach chamber is formed by the anterior abdominal wall and Diaphragm. The **roof** is formed by the under surface of the Diaphragm and the under surface of the left lobe of the liver. The **floor** is formed by the left suprarenal gland and the summit of the left kidney, the gastric surface of the spleen, the upper surface of the pancreas, the transverse mesocolon, and the colon.

¹ Intestinal Localization, by George H. Monks, *Annals of Surgery*, October, 1903.

² Reports of the Meeting of American Anatomists, 1897.

³ *Annals of Surgery*, 1903.

The shape and position of the stomach are so greatly modified by changes within itself and in the surrounding organs that no one form can be described as typical. The chief modifications are determined by (1) the amount of the stomach contents, (2) the stage which the digestive process has reached, (3) the degree of development or functional power of the gastric musculature, and (4) the condition of the adjacent intestines.

When empty and contracted, as after a period of rest,¹ the stomach is sickle- or sausage-shaped, as shown in Fig. 993. At an early stage of gastric digestion the stomach commonly consists of two segments—(a) a large, globular portion on the left, and (b) a narrow tubular portion on the right, corresponding to the fundus and pyloric portions, and forming an angle with each other, the axis of the fundus being directed downward and inward while the pyloric portion curves upward and to the right.

FIG. 993.—Form and topography of the stomach when empty and contracted, as seen immediately after death in an executed individual.

The stomach presents two openings, two borders or curvatures, and two surfaces.

Openings.—The opening by which the œsophagus communicates with the stomach is known as the **cardiac orifice**, and is situated at the level of the eleventh thoracic vertebra, corresponding to the seventh left chondrosternal junction. The short intra-abdominal portion of the œsophagus (*antrum cardiacum*) is conical in shape and curved sharply to the left, the base of the cone being continuous with the cardiac orifice of the stomach. The right margin of the œsophagus is continuous with the lesser curvature of the stomach, while the left margin joins the greater curvature at an acute angle, the **incisura cardiaca**.

The **pyloric orifice** communicates with the duodenum, and its position is indicated on the surface by a circular groove, the **duodenopyloric constriction**. This orifice lies to the right of the middle line at the level of the upper border of the first lumbar vertebra; it may be from one to two inches to the right of the middle line, depending upon the degree of distention of the stomach. Its position on the ventral surface of the body would be indicated by a point in the transpyloric plane (see p. 1243) about one inch to the right of the middle line.

FIG. 994.—Outlines of the stomach showing its anatomical landmarks.

Curvatures.—The **lesser curvature** (*curvatura ventriculi minor*), extending between the cardiac and pyloric orifices forms the right or posterior border of the stomach. It descends as a continuation of the right margin of the œsophagus

in front of the left crus of the Diaphragm, and then, turning to the right, it crosses the first lumbar vertebra and ends at the pylorus. Nearer its pyloric than its cardiac end is a well-marked notch, the **incisura angularis**, which varies somewhat in position with the state of distention of the viscus, it serves to separate the stomach

¹ An opportunity to view this condition is given by the immediate examination of the organ *in situ* in executed criminals who have not eaten for some time.

into a right and left portion. The lesser curvature gives attachment to the two layers of the gastrohepatic omentum, and between these two layers are the gastric artery and the pyloric branch of the hepatic artery.

The **greater curvature** (*curvatura ventriculi major*) is directed mainly forward and to the left, and is three or four times as long as the lesser curvature; starting from the cardiac orifice at the *incisura cardiaca* it forms an arch backward, upward, and to the left; the highest point of the convexity is on a level with the sixth left costal cartilage. From this level it may be followed downward and forward with a slight convexity to the left as low as the cartilage of the ninth rib; it then turns to the right to end at the pylorus. Directly opposite the *incisura angularis* of the lesser curvature the greater curvature presents a dilatation, the *pyloric vestibule* or *antrum*, which is limited on the right by a slight groove, the *sulcus intermedius*; this sulcus is about an inch from the duodenopyloric constriction. The portion between the *sulcus intermedius* and the duodenopyloric constriction is termed the *pyloric canal*. At its commencement the greater curvature is covered by peritoneum continuous with that covering the front of the organ. The left part of the curvature gives attachment to the gastrosplenic omentum, while to its anterior portion are attached the two anterior layers of the great omentum, separated from each other by the gastroepiploic vessels.

Surfaces.—When the stomach is in the slightly dilated condition, its surfaces are directed more upward and downward respectively, but when the viscus is distended they are directed more forward and backward. They may, therefore, be described as antero-superior and postero-inferior.

Antero-superior Surface.—The left half of this surface is in contact with the Diaphragm, which separates it from the base of the left lung, the pericardium, the seventh, eighth, and ninth ribs, and intercostal spaces of the left side. The right half is in relation with the left and quadrate lobes of the liver and with the ventral abdominal wall. When the stomach is empty the transverse colon may be found lying on the front part of this surface. The whole surface is covered by peritoneum.

The **Postero-inferior Surface** (*paries posterior*) is in relation with the Diaphragm, the gastric surface of the spleen, the left suprarenal gland, the upper part of the front of the left kidney, the anterior surface of the pancreas, the splenic flexure of the colon, and the upper layer of the transverse mesocolon. These structures form a shallow concavity ("*stomach bed*"), on which the stomach rests. The transverse mesocolon intervenes between the stomach and the duodenojejunal flexure and small intestine. The postero-inferior surface is covered with peritoneum, except over a small area close to the cardiac orifice; this area is limited by the lines of attachment of the *gastrophrenic ligament*, and lies in contact with the Diaphragm and frequently with the upper portion of the left adrenal gland.

Component Parts of the Stomach.—The stomach may be divided into a left portion or *body* and a right or *pyloric portion* or *antrum* by a plane passing through the *incisura angularis* and the left limit of the opposed dilatation (*pyloric vestibule*) on the greater curvature. The left portion of the body (*corpus ventriculi*) is known as the *fundus*, while that which is adjacent to the cardiac orifice is known as the *cardiac antrum*. The pyloric antrum is divided into a right part, the *pyloric canal*, and a left, the *pyloric vestibule*, by a plane passing through the *sulcus intermedius* at right angles to the axis of this portion (Fig. 994).

The *size* of the stomach varies considerably in different subjects. When moderately distended its greatest length, from the top of the fundus to the lowest part of the greater curvature, is from ten to twelve inches and its diameter at the widest part from four to five inches. The distance between the two orifices, when the stomach is *in situ*, is three to four inches, and the measurement from the anterior to the posterior wall three and one-half inches. Its *weight*, according

to Clendinning, is about four ounces and a half, and its *capacity* in the adult male is five to eight pints. The stomach of a newborn child holds about one ounce.

Alterations in Position.—There is no organ in the body the position and connections of which present such frequent alterations as the stomach. *When empty*, it lies at the back part of the abdomen, some distance from the ventral abdominal wall, and is in the left hypochondriac region and the left portion of the epigastric region. Its fundus is directed upward and backward toward the Diaphragm. The long axis of the viscus is quite oblique. Its pyloric end is directed toward the right, covered in front by the left lobe of the liver, and on a level with the first lumbar vertebra. When empty and contracted the stomach assumes a more or less cylindrical form, especially noticeable at its pyloric end, and resembles a piece of thick-walled intestine. *When the stomach is distended*, its surfaces become convex and the shape becomes pyriform, its long axis being downward, forward, and to the right. The greater curvature is elevated and carried forward, so that the anterior surface is turned more or less upward and the posterior surface downward, and the stomach is brought well against the anterior wall of the abdomen. Its fundus expands and rises considerably above the level of the cardiac orifice; in doing this the Diaphragm is forced upward, contracting the cavity of the thorax; hence the dyspnea complained of as inspiration is impeded. The apex of the heart is also tilted upward; hence the oppression in this region and the palpitation experienced in extreme distention of the stomach. The left lobe of the liver is pushed toward the right. When the stomach becomes distended the change in the position of the pylorus may be considerable; it is shifted to the right as much as two inches from the median line, and lies under cover of the liver, near the neck of the gall-bladder. In consequence of the distention of the stomach the pyloric antrum bulges in front of the pylorus, concealing it from view, and causing it to undergo a rotation, so that its orifice is directed backward. When the stomach is greatly distended its lower border may enter the umbilical and the left lumbar regions. *During inspiration* the stomach is displaced downward by the descent of the Diaphragm, and it is elevated by the pressure of the abdominal muscles during *expiration*. *Pressure from without*, as from tight lacing, pushes the stomach down toward the pelvis. In fact, in the female, because of tight lacing, the body of the stomach may be to the left side of the vertebral column and nearly vertical in direction, the pyloric portion being sharply angled upward toward the pylorus, which lies underneath the liver. Besides the angulation, the stomach may have a median constriction, and there may even be an *hour-glass stomach*. In disease the position and connection of the stomach may be greatly changed, from the accumulation of fluid in the thoracic cavity or abdomen, or from alteration in size of any of the surrounding viscera.

Variations According to Age.—In an early period of development the stomach is vertical, and in the newborn child it is more vertical than later on in life, as owing to the large size of the liver it is pushed over more to the left side of the abdomen, and the whole of the anterior surface is covered by the left lobe of this organ.

Interior of the Stomach.—When examined after death, the stomach is usually fixed at some temporary stage of the digestive process. A common form is that shown in Fig. 995. If the viscus be laid open by a section through the plane of its two curvatures, it is seen to consist of the two segments already described—viz., a large globular portion to the left, comprising the body and fundus, and the tubular pyloric portion to the right. The mucous membrane lining the interior is soft and velvety, red or reddish brown in the body and fundus, and of a pinkish tinge at the pyloric end. It is thrown into numerous folds or *rugæ*, chiefly longitudinal in direction and most marked toward the pyloric end and along the greater curvature. To the left of the cardiac orifice is the *incisura cardiaca*; the projection of this notch into the cavity of the stomach increases as the organ distends, and has been supposed to act as a valve preventing regurgitation into the œsophagus. In the pyloric portion are seen (*a*) the elevation corresponding to the *incisura angularis*, and (*b*) the circular projection from the duodenopyloric constriction which forms the pyloric valve. The separation of the pyloric vestibule from the pyloric canal is scarcely indicated, but the manner in which the pylorus is invaginated into the duodenum is evident.

The **pyloric valve** (*valvula pylori*) (Fig. 997) is formed by a reduplication of the mucous membrane of the stomach, containing numerous circular fibres, which are aggregated into a thick circular ring, the **Pyloric Sphincter** (*m. sphincter pylori*); some of the deeper deeper longitudinal fibres turn in and interlace with the circular fibres

of the valve. The pylorus is normally kept closed by the action of this Sphincter muscle. During the early stage of digestion it remains closed, but after a time

FIG. 995.—Interior of the stomach.

FIG. 996.—The mucous membrane of the stomach and duodenum with the bile-ducts.

opens now and then, this relaxation becoming more frequent and the period of patency more prolonged as digestion advances.

Structure.—The wall of the stomach consists of four coats—**serous, muscular, submucous, and mucous**, together with vessels and nerves.

The **serous coat** (*tunica serosa*) is derived from the peritoneum, and covers the entire surface of the organ, excepting along the greater and lesser curvatures, at the points of attachment of the greater and lesser omenta; here the two layers of peritoneum leave a small triangular space uncovered by peritoneum along which the nutrient vessels and nerves pass. On the posterior surface of the stomach, close to the cardiac orifice, there is also a small triangular area uncovered by peritoneum, where the organ is in contact with the under surface of the Diaphragm.

The **muscular coat** (*tunica muscularis*) (Figs. 998 and 999) is situated immediately beneath the serous covering, to which it is closely connected. It consists of three sets of smooth muscle tissue—**longitudinal, circular, and oblique**, from without inward, in the order named.

The **longitudinal fibres** (*stratum longitudinale*) are the most superficial, and are arranged in two sets. The first set consists of fibres continuous with the longitudinal fibres of the oesophagus; they radiate in a stellate manner from the cardiac orifice and are practically all lost before the pyloric portion is reached. The second set commences on the body of the stomach and passes to the right, its fibres becoming more closely collected as they approach the pylorus. Some of the more superficial fibres of this set pass on to the duodenum, but the deeper fibres dip in and interlace with the circular fibres of the pyloric valve Sphincter. The bundles of longitudinal

FIG. 997.—Diagrammatic view of the coats of the stomach, duodenum, and pylorus. The ridge is the pyloric valve. (Allan Thomson.)

FIG. 998.—The superficial muscular layer of the stomach, viewed from above and in front. (Spalteholz.)

muscle fibre on the upper and lower surfaces of the pylorus are particularly firm and distinct, and are called the **pyloric ligaments** (*ligamenta pylori*).

The **circular fibres** (*stratum circulare*) form a uniform layer throughout the whole extent of the stomach internal to the longitudinal fibres. They begin as tiny rings at the left extremity of

the fundus and pass over into larger and larger rings to encircle the entire organ. At the pylorus they are most abundant, and are aggregated into a **circular ring** or **Sphincter**, which projects into the cavity, and forms, with the fold of mucous membrane covering its surface, the **pyloric valve** (Fig. 997). The circular fibre stratum is continuous with the circular layer of the oesophagus, the fibres being interlaced at the transition.

The **oblique fibres** (*fibræ obliquæ*) arise at the left side of the cardia from the circular fibres of the oesophagus. The fibres pass down in the anterior and posterior walls, and almost reach the pylorus. Certain oblique muscular fibres encircle the fundus of the stomach in a series of rings.

The **submucous coat** (*tela submucosa*) consists of loose areolar tissue, connecting the mucous and muscular coats. It supports the large bloodvessels previous to their distribution to the mucous membrane; hence it is sometimes called the **vascular coat**.

The **mucous membrane** (*tunica mucosa*) (Figs. 1000, 1001, and 1002) is thick, its surface smooth, soft, and velvety. In the fresh state it is of a pinkish tinge at the pyloric end, and of a red or reddish-brown color over the rest of the surface. In infancy it is of a brighter hue, the vascular

FIG. 999.—The middle and deep muscular layer of the stomach, viewed from above and in front. (Spalteholz.)

redness being more marked. It is thin at the cardiac extremity, but thicker toward the pylorus. During the contracted state of the organ it is thrown into numerous folds or **rugæ** (*plicæ mucosæ*) (Figs. 1000 and 1002, A), which for the most part have a longitudinal direction, and are most marked toward the pyloric end of the stomach and along the greater curvature. These folds consist of mucous and submucous coats, and are entirely obliterated when the organ becomes fully distended.

Structure of the Mucous Membrane.—When examined with a lens the inner surface of the mucous membrane presents a peculiar honeycomb appearance, from being covered with small shallow depressions, the **gastric crypts** or **pits** (*foveolæ gastricae*) (Figs. 1001 and 1002, B) of a polygonal or hexagonal form, which vary from $\frac{1}{15}$ to $\frac{1}{10}$ of an inch in diameter, and are separated by slightly elevated ridges (*plicæ villosæ*). The pits in the cardiac and fundal portions of the stomach extend through about one-sixth the thickness of the mucosa, while in the pyloric end they extend through about one-half the mucous coat. In the bottom of the crypts are seen three to seven orifices of minute tubes, the **gastric glands** (Fig. 1002, B), which are placed per-

pendicularly side by side throughout the entire substance of the mucous membrane. The surface of the mucous membrane of the stomach is covered by a single layer of **columnar epithelium** and a few **goblet cells**; it lines the crypts, and also for a certain distance the mouths of the gastric glands; in the glands the character of the epithelium changes. This epithelium com-

FIG. 1000.—Mucous membrane of the stomach, from the pars pylorica, viewed from the surface. $\times 5$. (Spalteholz.)

mences very abruptly at the cardiac orifice, where the cells suddenly change in character from the **stratified epithelium** of the oesophagus.

The Gastric Glands.—The gastric glands are of three kinds—the **true gastric glands**, the **pyloric glands**, and the **cardiac glands**.

The **true gastric glands** (Fig. 1004) are called also the **oxyntic glands**, the **fundus glands**, and the **peptic glands** (*glandulae gastricae propriae*). They are distributed throughout the entire fundus and body, and may be found even at the pylorus. They are mainly of the simple tubular variety, and are lined by simple epithelial cells resting upon a delicate basement membrane supported by the tunica propria. The duct, or mouth, however, in these glands is shorter than in the other variety, sometimes not amounting to more than one-sixth of the whole length of the gland; it is lined throughout by columnar epithelium. At the point where the terminal tubes open into the mouth, and which is termed the **neck**, the epithelium alters, and consists of short columnar or polyhedral, granular cells, which almost fill the tube, so that the lumen becomes suddenly constricted, and is continued down as a very fine channel. They are known as the **chief** or the **peptic** or the **central cells of the glands**, and furnish pepsin. Between these cells and the basement membrane are found other darker granular-looking cells, studded throughout the tubes at intervals, and giving it a beaded or varicose appearance. The **fundus** is the blind extremity of the gland, and here the chief cells predominate. These are known as the **acid, parietal, or oxyntic cells**. Some of the parietal

FIG. 1001.—Mucous membrane of the stomach, from the pars pylorica, viewed from the surface. $\times 16$. (Spalteholz.)

cells empty directly into the lumen of the gland by secretory capillaries; others empty by a channel which divides into secretory capillaries. The parietal cells secrete the acid of the

FIG. 1003.—Pyloric gland.

FIG. 1004.—Peptic gastric gland.

gastric juice. Between the glands the tunica propria consists of fibroelastic connective-tissue framework with lymphoid tissue and a rich capillary plexus. In places this latter tissue, especially in early life, is collected into little masses, which to a certain extent resemble the

solitary follicles of the intestine, and are by some termed the **lenticular follicles of the stomach**. They are not, however, so distinctly circumscribed as the solitary follicles.

The **pyloric glands** (*glandulae pyloricae*) (Fig. 1003) are the branched tubular glands, and secrete mucus and pepsin.

They are placed most plentifully about the pylorus, but between the fundus and pylorus, in the region known as the **transitional or intermediate zone**, both true gastric glands and pyloric glands are found. Each pyloric gland consists of two or three short tubes opening into a common mouth or duct, the external orifice of which is situated at the bottom of a crypt. The tubes are wavy, and are of about equal length with the duct. The tubes and duct are lined throughout with simple epithelium, the duct being lined by columnar cells continuous with the epithelium lining the surface of the mucous membrane of the stomach, the tubes with tall, broad, and pale-staining cells, which are finely granular. The pyloric glands branch more frequently, are more curved in direction, and open into deeper foveolæ than the true gastric glands (Szymonowicz). They contain only chief or peptic cells and do not possess parietal cells. These glands, at times, extend into the submucous coat.

The **cardiac glands** are found about the oesophageal orifice. They resemble the glands of the oesophagus and are mucous in character.

External to the tunica propria of the mucous membrane, and between it and the submucous coat, is a thin stratum of involuntary muscle tissue (*muscularis mucosae*), which in some parts consists only of a single longitudinal layer; in others, of two layers, an inner circular, and an outer longitudinal.

Vessels and Nerves.—The arteries supplying the stomach are the **gastric**, the **pyloric**, and the **right gastroepiploic branch of the gastroduodenal**, the **left gastroepiploic** and **vasa brevia** from the splenic. The gastric artery passes to the lesser curvature just below the cardia. It gives off the **oesophageal branch**, and passes from left to right along the lesser curvature of the stomach beneath the peritoneum between the two layers of the lesser omentum and upon the wall of the stomach. It may in this course be a single vessel, or may divide into two branches,

FIG. 1005.—Terminations of the bloodvessels in the mucous membrane of the stomach. (Poirier and Charpy.)

FIG. 1006.—The arteries of the anterior surface of the stomach. (Poirier and Charpy.)

which run along each side of the lesser curvature (Fig. 1006). If there is a single artery, it gives off six or seven descending branches to the anterior wall and about the same number to the posterior wall of the stomach. It also gives branches to the lesser omentum. If two **vascular arches** form, one gives branches to the anterior wall of the stomach, the other to the posterior

wall, and both to the lesser omentum. The termination of the gastric anastomoses with the pyloric branch or two rami of the pyloric branch of the hepatic artery. From each arch six or seven **descending branches** come off to the anterior and posterior walls of the stomach. The **gastroduodenal artery** is given off by the hepatic. From the gastroduodenal comes the right gastroepiploic. The left gastroepiploic comes from the splenic. The **right gastroepiploic artery** passes from right to left in the gastrocolic omentum below the greater curvature of the stomach. The **left gastroepiploic artery** passes forward in the gastrosplenic omentum to below the greater curvature of the stomach, and passes from left to right along that curvature in the greater omentum, and joins the right gastroepiploic artery. The gastroepiploic arteries are not upon but are distinctly below the stomach wall. From them numerous gastric branches are sent to the anterior and posterior walls of the stomach, and they anastomose with branches of the gastric and pyloric. *Vasa brevia*, four or five in number, arise from the splenic, pass forward in the gastrosplenic omentum, and supply the fundus. The arteries of the stomach lie first beneath the peritoneum, but soon enter the muscular coat, supply it, pierce it, ramify in the submucous coat, and are finally distributed to the mucous membrane. The arrangement of the vessels in the mucous membrane is somewhat peculiar (Fig. 1005). The arteries break up at the base of the gastric tubules into a plexus of fine capillaries which run upward between the tubules, anastomosing with each other, and ending in a plexus of larger capillaries, which surround the mouths of the tubes and also form hexagonal meshes around the crypts.

The capillary network about the glands gives origin to the **veins**. The various small **veins unite and form a plexus in the submucous tissue** (Fig. 1005). From this plexus come branches which pass through the muscular coat and terminate in the **right gastroepiploic branch of the superior mesenteric**, the **left gastroepiploic branch of the splenic**, the veins to the splenic which correspond to the **vasa brevia arteries**, and the **gastric or coronary branch of the portal**.

The **lymphatics** (Figs. 570 and 571) arise in the mucous membrane and terminate in a network in the submucous tissue. From this network trunks arise which perforate the muscular coat in the regions of the curvatures and terminate in the seromuscular collecting trunks. The details of the lymphatic drainage of the stomach are given on page 795.

The **nerves of the stomach** come from the **right and left vagi** and from the **solar plexus of the sympathetic**. The left vagus passes to the front of the stomach, and the right nerve passes to the back, and they unite with the fibres of the sympathetic. The fibers thus formed are mostly amyelinic. They form **Auerbach's plexus** in the muscular coat between the circular and longitudinal fibres and **Meissner's plexus** in the submucous coat, the latter plexus being formed by fibres from the former. Auerbach's plexus supplies the muscular coat of the stomach, while fibres from Meissner's plexus ramify in the submucous coat and terminate in the muscularis mucosae and the mucous membrane, branches passing to the gastric glands and to just beneath the epithelium. (See nerve supply of small intestine, p. 1296.)

Relations of the Stomach.—The antero-superior surface is in relation with the left and quadrate lobes of the liver, the ventral abdominal parietes, and the costal portion of the Diaphragm. The postero-inferior surface is in relation with the lumbar portion of the Diaphragm, the pancreas, and the transverse mesocolon, while the fundus may come into contact with the left kidney and suprarenal gland, the spleen, and splenic flexure of the colon. The lesser curvature is directed toward the transverse fissure of the liver, while the greater curvature may be in contact with the transverse colon.

Movements and Innervation of the Stomach.

Movements.—It has apparently been demonstrated that the stomach "consists of two parts physiologically distinct."¹ The cardiac portion of the stomach is a food reservoir in which salivary digestion continues; the pyloric portion is the seat of active gastric digestion. Cannon affirms that there are no peristaltic waves in the cardiac portion, but that as the food passes from the pyloric portion into the intestines, tonic contraction of the muscles of the fundus squeezes the contents of the pyloric portion. Moritz, Levan, and Cannon assert that muscular activity is chiefly manifested in the pyloric portion. In this portion during digestion there is a succession of peristaltic waves, which waves in the human being pass at the rate of three per minute (Moritz). Cannon points out that the efficiency of peristalsis in mixing the food depends upon the contraction of the pyloric sphincter. So long as the sphincter holds, each constriction ring coursing from the middle to the end of the stomach presses the food into a blind pouch; the food, unable to escape through the pyloric opening, has as its only outlet the opening in the advancing ring. This is an admirable device for bringing the food under the influence of the glandular secretions of the pyloric region. For, as a constriction occurs, the secreting surface enclosed by the narrowed muscular ring is pressed close around the food within the ring. As the constriction advances it continually presses inward fresh glandular surfaces, and further-

¹ Walter B. Cannon, *Medical News*, May 20, 1905.

more, as the constriction advances, a thin stream of food is continuously forced back through the ring and thus past the mouths of the glands. The old view that the pyloric sphincter only opens after several hours' continuance of the process of digestion, and that then the stomach empties at once, is incorrect. It is emptied in small amounts, which escape at frequent intervals because of the intermittent opening of the pylorus. When the pylorus is open a wave of peristalsis forces some of the material from the stomach into the duodenum (Cannon).

Cannon is of the opinion that the pyloric sphincter is caused to relax by the presence of free hydrochloric acid in the pyloric portion of the stomach. When the pylorus is open acid chyme passes into the duodenum, and acid in the duodenum causes the pylorus to close. The acid in the duodenum causes a flow of alkaline pancreatic juice and the acid is neutralized. "As the neutralizing proceeds, the stimulus closing the pylorus is weakened until the acid in the stomach again opens the sphincter."¹

Innervation.—The stomach, as previously shown, has nerve plexuses in its walls and is connected to the cerebrospinal and sympathetic systems. It is probable that gastric peristalsis is due to a local reflex from Auerbach's plexus (Magnus), the local reflex being inaugurated by local stimulation, which stimulation, in the words of Bayliss and Starling, "produces excitation above and inhibition below the excited spot."² Reversed peristalsis cannot occur if "the reflex mechanism is intact" (Cannon). Cannon in the previously quoted article states that cutting the vagi or splanchnic nerves does not destroy the reflex mechanism of the pylorus, but, nevertheless, it is markedly affected by the central nerve system.

Surface Form (see p. 1241).—The cardiac orifice corresponds to the articulation of the seventh left costal cartilage with the sternum. The pyloric orifice of the empty stomach is about an inch to the right of the midline in the transpyloric line. According to Braune, when the stomach is distended, the pylorus moves considerably to the right, sometimes as much as three inches. The fundus of the stomach reaches, on the left side, as high as the level of the sixth costal cartilage of the left side, being a little below and behind the apex of the heart. The portion of the distended stomach which is in contact with the abdominal walls, and is therefore accessible for opening in the operations of gastrotomy and gastrostomy, is represented by a triangular space, the base of which is formed by a line drawn from the tip of the tenth costal cartilage on the left side to the tip of the ninth costal cartilage on the right, and the sides by two lines drawn from the extremity of the eighth costal cartilage on the left side to the end of the base line. What is commonly termed the **semilunar space of Traube** is that portion of the stomach which is not covered by neighboring viscera. It is bounded above by the left lobe of the liver and the inferior margin of the left lung, posteriorly and to the left by the spleen; on percussion, this area is normally tympanitic.

Applied Anatomy.—Operations on the stomach are frequently performed, ulcers are excised, malignant growths are removed with the associated lymphatic involvement, the entire stomach may be removed for cancer, etc. By "*gastrotomy*" is meant an incision into the stomach for the removal of a foreign body, or the arrest of hemorrhage, or for exploration, the opening being immediately afterward closed—in contradistinction to "*gastrostomy*," the making of a more or less permanent fistulous opening. *Gastrotomy* is probably best performed by an incision in the linea alba, especially if the foreign body is large. The cut may reach from the ensiform cartilage to the umbilicus. The incision may be made over the body itself, where this can be felt, or by one of the incisions for gastrostomy, to be mentioned shortly. The peritoneal cavity is opened, and the point at which the stomach is to be incised decided upon. This portion is then brought out of the abdominal wound and sponges carefully packed around. The stomach is now opened by a transverse incision and the foreign body extracted. The wound in the stomach is then closed by Lembert sutures—i. e., by sutures passed through the peritoneal, muscular, and submucous coats in such a way that the peritoneal surfaces on each side of the wound are brought into apposition. *Gastrostomy* was formerly done in two stages by the *direct* method. The first stage consisted in opening the abdomen, drawing up the stomach into the external wound, and fixing it there; and the second stage, performed from two to four days afterward, consisted in opening the stomach. The operation is now done by a *valvular* method. The following plan is known as the Ssabanejew-Frank operation. An incision is commenced opposite the eighth intercostal space, two inches to the left of the median line, and carried downward for three inches. By this incision the fibres of the Rectus muscle are exposed and these are separated from one another in the same line. The posterior layer of the sheath, the transversalis fascia, and the peritoneum are then divided, and the peritoneal cavity is opened. Instead of the above incision, the curved incision of Fenger can be made at the margin of the left costal cartilages. The anterior wall of the stomach is now seized and drawn out of the wound and a silk suture passed through its submucous, muscular, and serous coats at the point selected for opening the viscus. This is held by an assistant so that a long conical diverticulum of the stomach protrudes from the external wound, and the parietal peritoneum and the posterior layer of the sheath of the Rectus are sutured to the base of the cone. A second incision is made through

¹ Walter B. Cannon, Medical News, May 20, 1905.

² Ibid.

the skin, over the margin of the costal cartilage, *above and a little to the outer side* of the first incision. If Fenger's incision were used, the second incision should be above the margin of the cartilages. With a pair of dressing forceps a track is made under the skin through the subcutaneous tissue from the one opening to the other and the diverticulum of the stomach is drawn along this track by means of this suture inserted into it; so that its apex appears at the second opening. A small perforation is now made into the stomach through this protruding apex and its margin carefully and accurately sutured to the margin of the external wound. The remainder of this incision and the whole of the first incision are then closed in the ordinary way and the wound dressed.

In cases of *gastric ulcer, perforation* sometimes takes place, and this was formerly regarded as an almost fatal complication. In the present day, by opening the abdomen and closing the perforation, which is generally situated on the anterior surface of the stomach, a considerable percentage of cases are cured, provided the operation is undertaken within twelve to fifteen hours after the perforation has taken place. The opening is best closed by bringing the peritoneal surfaces on either side into apposition by means of Lembert sutures.

Pylorectomy or excision of the pylorus is performed, particularly for early cancer, but is also done for cicatricial stricture and for ulcer. The mortality after operation for cancer was, until recently, very great, but of late years it has been notably reduced, though it is still much higher than that which follows operations for any non-malignant condition.

In operating for cancer, bear in mind Cunéo's study of the lymphatics (p. 795). These observations indicate that the fundus and two-thirds of the greater curvature are free from lymphatic involvement in pyloric cancer.¹ In every operable case of cancer of the pylorus the entire lesser curvature must be removed up to the gastric artery (Mikulicz's point), and the greater curvature must be removed to the left of the involved lymph nodes (Hartmann's rule).

Gastroenterostomy is an operation which establishes a fistulous communication between the stomach and jejunum. The operation is often called *gastrojejunoanastomosis*. The opening may be made upon either the anterior or the posterior wall of the stomach, between the cardia and the seat of pyloric disease. The operation is employed for stricture of the pylorus (benign or malignant), and occasionally for ulcer of the stomach.

Hypertrophy and spasm of the circumferential muscular coat of the pylorus coming on during the first few weeks of life, and somewhat erroneously described as *congenital hypertrophic stenosis of the pylorus*, is a rare but serious disorder of infancy. It is characterized by abdominal pains and obstinate vomiting coming on after food has been given, and gastric peristalsis can be observed by inspection of the child's epigastrium after it has been fed and before vomiting has occurred. Progressive wasting for want of nourishment and death from exhaustion tend to ensue. Treatment should be by washing out the stomach, and the administration at frequent intervals of small quantities of easily digested food. Surgical interference—*pyloroplasty* or *pylorotomy*—entailing a severe operation, gives less favorable result.

Total gastrectomy is the removal of the entire stomach. It is only used for cancer. It was first performed by Conner, of Cincinnati. The first successful operation was done by Schlatter, of Zurich, in 1898. A number of successes have been reported. It is a justifiable operation only in a case in which almost the entire stomach is cancerous, in which the viscus is movable, in which there are no secondary deposits, and no irremovable diseased lymph nodes.

Gastrogastrostomy is an operation employed in hour-glass stomach. In this operation an anastomosis is made between the pyloric and cardiac ends of the stomach.

Gastroplication is the operation of suturing the stomach wall into folds or reefs, in order to lessen its size. It is employed in some cases of gastric dilatation.

Gastroptosis is a condition in which the stomach is displaced downward. In some of these cases the greater curvature almost reaches the level of the symphysis pubis, and the lesser curvature is midway between the umbilicus and ensiform cartilage. The condition is usually associated with *enteroptosis* and *movable kidney* (nephroptosis). In this condition the gastrohepatic omentum is pulled upon and lengthened. The best operation for gastroptosis was devised by Bovea. He applies sutures so as to make folds in and thus shorten the stretched omentum. Thus the stomach is elevated to its proper position, and its mobility is not lessened, as it is in other operations which suture it to the abdominal wall.

THE SMALL INTESTINE (INTESTINUM TENUE).

The **small intestine** is a convoluted tube, extending from the pylorus to the ileocecal valve, where it terminates in the large intestine. It is about twenty feet

¹ William J. Mayo, *Annals of Surgery*, March, 1904.

(6 m.) in length,¹ and gradually diminishes in size from its commencement to its termination. It is contained in the central and lower part of the abdominal cavity, and is surrounded above and at the sides by the large intestine; a portion of it extends below the brim of the pelvis and lies in front of the rectum. It is in relation, in front, with the great omentum and abdominal parietes, and the greater part of it is connected to the vertebral column by a fold of peritoneum, the *mesentery* (p. 1263). The small intestine is divisible into three portions—the *duodenum*, the *jejunum*, and the *ileum*.

The Duodenum (Figs. 1007, 1014).

The *duodenum* has received its name from being about equal in length to the breadth of twelve fingers (ten inches). It is the shortest, the widest, and the most fixed part of the small intestine, and has no mesentery, being only partially covered by peritoneum. Somewhat more than the upper half of the duodenum is placed in the epigastric region; the remainder is in the umbilical region. Its course presents a remarkable curve, somewhat of the shape of an incomplete circle, so that its termination is not far removed from its beginning.

In the adult the *course* of the duodenum is as follows: Commencing at the pylorus it passes backward, upward, and to the right, beneath the quadrate lobe of the liver to the neck of the gall-bladder, varying slightly in direction according to the degree of distention of the stomach; it then takes a sharp curve and descends along the right margin of the head of the pancreas, for a variable distance, generally to the level of the upper border of the body of the fourth lumbar vertebra. It now takes a second bend, and passes from right to left across the front of the vertebral column, having a slight inclination upward; and to the left side of the vertebral column it ascends for about an inch, and then terminates opposite the second lumbar vertebra in the jejunum. As it unites with the jejunum it turns abruptly forward, forming the *duodenojejunal flexure*. From the above description it will be seen that the duodenum may be divided into four portions—*superior*, *descending*, *transverse*, and *ascending*.

The *first or superior portion* (*pars superior*) (Figs. 1007 and 1008) is about two inches (5 cm.) in length. Beginning at the pylorus, it ends at the level of the neck of the gall-bladder. It is the most movable of the four portions. It is almost completely covered by peritoneum derived from the two layers of the lesser omentum, but a small part of its posterior surface near the neck of the gall-bladder and the inferior vena cava is uncovered (Fig. 1008). It is in such close relation with the gall-bladder that it is usually found to be stained by bile after death, especially on its anterior surface. It is in relation *above* and in *front* with the quadrate lobe of the liver, lying in a slight concavity, the *impressio duodenalis*, and the gall-bladder; *behind*, with the gastroduodenal artery, the common bile duct, and the portal vein; and *below*, with the head of the pancreas.

The *second or descending portion* (*pars descendens*) (Figs. 1007 and 1009) is between three and four inches (7.5 to 10 cm.) in length, and extends from the neck of the gall-bladder on a level with the first lumbar vertebra along the right side of the vertebral column as low as the body of the fourth lumbar vertebra. It is crossed in its middle third by the transverse colon, the posterior surface of which is uncovered by peritoneum and is connected to the duodenum by a small quantity of connective tissue. The portions of the descending part of the duodenum above and below this interspace are named the *supracolic* and *infracolic portions*, and are

¹ Treves states that in one hundred cases the average length of the small intestine in the adult male was 22 feet 6 inches, and in the adult female 23 feet 4 inches; but that it varies very much, the extremes in the male being 31 feet 10 inches in one case and 15 feet 6 inches in another, a difference of over 15 feet. He states that he has convinced himself that the length of the bowel is independent, in the adult, of age, height, and weight.

covered in front by peritoneum (Fig. 1009). The infracolic part is covered by the right leaf of the mesentery. Posteriorly the descending portion of the duodenum

FIG. 1007.—Relations of duodenum, pancreas, and spleen. (From a cast by Professor Birmingham.¹) The dotted line represents the line of attachment of the transverse mesocolon.

is not covered by peritoneum. It is in relation, in *front*, with the transverse colon, and above this with the right lobe of the liver, where it lies in the *impressio duo-*

¹ In the subject from which the cast was taken the left kidney was lower than usual.

denalis for the second part of the duodenum; *behind*, with the inner part of the right kidney, to which it is connected by loose areolar tissue, the renal vessels, and the inferior vena cava; at its *inner side* is the head of the pancreas and the common bile duct; to its *outer side* is the hepatic flexure of the colon. The common bile duct passes downward behind the first portion of the duodenum, descends to the

FIG. 1008.—Diagram of cross-section of the first part of the duodenum, to show its peritoneal relations.

FIG. 1009.—Diagram of cross-section of the second part of the duodenum, to show its peritoneal relations. (Gerrish.)

inner side of the second portion, is joined by the pancreatic duct, and the two together perforate the inner side of this portion of the intestine obliquely, and empty into the duodenum by a common opening or by two openings at the summit of a papilla, some three and a half or four inches (9 to 10 cm.) below the pylorus.

FIG. 1010.—Diagram of the third part of the duodenum, to show its peritoneal relations. (Gerrish.)

FIG. 1011.—Diagram of the fourth part of the duodenum, to show its peritoneal relations. (Gerrish.)

The relations of the second part of the duodenum to the right kidney present considerable variations.

The **third, preaortic, or transverse portion** (*pars horizontalis inferior*) (Figs. 1007 and 1010) is from two to three inches in length. It commences at the right side of the upper border of the fourth lumbar vertebra and passes from right

to left, with a slight inclination upward, in front of the great vessels and crura of the Diaphragm, and ends in the fourth portion in front of or just to the left of the abdominal aorta. It is crossed by the superior mesenteric vessels and the mesentery. Its *ventral* surface is covered by peritoneum, except near the middle line, where it is crossed by the superior mesenteric vessels (Fig. 1010). Its *posterior surface* rests upon the aorta, the inferior vena cava, and the crura of the Diaphragm. Its upper surface is in relation with the head of the pancreas. The left side of the termination of the ascending portion is also covered by peritoneum, and in this region some of the *duodenal fossæ* are found (p. 1266).

The **fourth or ascending portion of the duodenum** (*pars ascendens*) (Figs. 1007 and 1011) is about an inch (2.5 cm.) long. It ascends on the left side of the vertebral column and aorta, as far as the level of the upper border of the second lumbar vertebra, where it turns abruptly forward to become the jejunum, forming the **duodenojejunal flexure** (*flexura duodenojejunalis*) (Fig. 1012). It lies in front of the left Psoas muscle and left renal vessels, and is covered in front, and partly at the sides, by peritoneum, continuous with the left portion of the mesentery (Fig. 1011).

FIG. 1012.—Suspensory muscle of the duodenum or muscle of Treitz. (Poirier and Charpy.)

The first part of the duodenum, as stated above, is somewhat movable, but the rest is practically fixed and is bound down to neighboring viscera and the posterior abdominal wall by the peritoneum. In addition to this, the fourth part of the duodenum and the duodenojejunal flexure is further bound down and fixed by a structure called the **Suspensory muscle of the duodenum** or the **suspensory ligament of Treitz** (*m. suspensorius duodeni*) (Fig. 1012). This structure commences in the connective tissue around the coeliac axis and left crus of the Diaphragm, and passes downward to be inserted into the superior border of the duodenojejunal curve and a part of the ascending duodenum, and from this it is continued into the mesentery. It possesses, according to Treitz, some few nonstriated muscle fibres mixed with the fibrous tissue, of which it is principally made up. It is of little importance as a muscle, but acts as a suspensory ligament.

Interior of the Duodenum (Fig. 1013).—The proximal part of the duodenum is comparatively smooth. Valvulae conniventes begin to appear in the distal half

FIG. 1013.—The interior of the duodenum. (Spalteholz.)

FIG. 1014.—The duodenum, its four parts marked a, b, c, d. The liver is lifted up; the greater part of the stomach is removed, broken lines indicating its former position. (Testut.)

of the first portion, being at first trivial elevations irregularly placed. They become higher, regular, and more numerous farther on, and near the termination of the duodenum are strongly marked and closely placed transverse or spiral folds (Fig. 1013 and p. 1290). In the descending portion (Fig. 1013), to the side and rear, is a longitudinal fold (*plica longitudinalis duodeni*), which is formed by the projection of the bile duct and pancreatic duct beneath the mucous membrane.

The **caruncula major of Santorini** or the **bile papilla** is a projection in the lower part of the longitudinal fold. At the summit of this papilla the bile duct and pancreatic duct empty into the duodenum. One inch above and half an inch or more in front of the bile papilla is a much smaller papilla, the **caruncula minor of Santorini** (*papilla duodeni* [*Santorini*]), on the summit of which the accessory pancreatic duct of Santorini opens when present.

FIG. 1015.—The bloodvessels of the duodenum. (Poirier and Charpy.)

Structure of the Duodenum.—(See Structure of the Small Intestine, p. 1290.)

Vessels and Nerves.—The arteries (Fig. 1015) supplying the duodenum are the **pyloric** and **pancreaticoduodenal branches of the hepatic**, and the **inferior pancreaticoduodenal branch of the superior mesenteric**. The veins (Fig. 1015) correspond to the arteries. The **superior duodenal vein** passes into the superior mesenteric, and the **inferior duodenal vein** passes into the portal. The **lymphatics** pass along with the pancreaticoduodenal arteries, lymph nodes being present here and there, and terminate in the nodes about the coeliac axis. The **nerves** are derived from the solar plexus.

Applied Anatomy.—*Ulcer of the duodenum* is more common than used to be thought. The portion of the duodenum between the pylorus and the bile papilla is about four inches in length, and is called by the Mayo brothers the *vestibule of the duodenum*. Here the acid gastric juice enters and may produce an ulcer. The portion of the duodenum below the vestibule is not liable to ulcer, because it is protected by the alkaline bile and pancreatic juice.

A duodenal ulcer may perforate a large duodenal vessel and cause death from hemorrhage, or may perforate the intestine and produce septic peritonitis. A perforated ulcer is treated by laparotomy and closure of the perforation. Occasionally ulceration of the duodenal glands (*Curling's ulcer*) may occur in cases of extensive burns of the skin, but is not a very common complication.

The Jejunum and Ileum (Figs. 958, 987).

The remainder of the small intestine from the termination of the duodenum comprises the **jejunum** and **ileum**; the former name being given to the upper two-fifths and the latter to the remaining three-fifths. Spalteholz and others call all of the small intestine below the duodenum the **intestinum tenue mesenteriale**. There

is no morphological line of distinction between the jejunum and ileum, and the division is arbitrary; but at the same time it must be noted that the character of the intestine gradually undergoes a change from the commencement of the jejunum to the termination of the ileum, so that a portion of the bowel taken from these two situations would present characteristics and marked differences. These are briefly as follows:

	Jejunum.	Ileum.
Calibre	larger (1½ inches).	smaller (1 inch).
Wall	thicker, heavier.	thinner, lighter.
Color	red, more vascular.	pale, less vascular.
Valvulae conniventes	prominent.	smaller and fewer.
Lymphoid tissue	diffuse and few nodules.	diffuse and many Peyer's patches.
Villi	numerous, short, and broad.	fewer, slender, filiform.
Intestinal glands	more numerous.	less numerous.

The Jejunum (*intestinum jejunum*).—The jejunum is wider, its diameter being about one inch and a half (3.75 cm.), and is thicker, more vascular, and of a deeper color than the ileum, so that a given length weighs more. Its valvulae conniventes are large and thickly set and its villi are larger than in the ileum. The patches of Peyer are almost absent in the upper part of the jejunum, and in the lower part are less frequently found than in the ileum, and are smaller and tend to assume a circular form. Brunner's glands are only found in the duodenum. By grasping the jejunum between the finger and thumb the valvulae conniventes can be felt through the walls of the gut; these being absent in the lower part of the ileum, it is possible in this way to distinguish the upper from the lower part of the small intestine.

The Ileum (*intestinum ileum*).—The ileum is narrower, its diameter being one inch (2.5 cm.) or a little more, and its coats are thinner and less vascular than those of the jejunum. It possesses but few valvulae conniventes, and they are small and disappear entirely toward its lower end, but Peyer's patches are larger and more numerous. The jejunum for the most part occupies the umbilical and left iliac regions, while the ileum occupies chiefly the umbilical, hypogastric, right iliac, and pelvic regions, and terminates in the right iliac fossa by opening into the inner side of the commencement of the large intestine. The jejunum and ileum are attached to the posterior abdominal wall by an extensive fold of peritoneum, the *mesentery* (p. 1263), which allows the freest motion, so that each coil can accommodate itself to changes in form and position. The mesentery is fan-shaped; its posterior border or root, about six inches (15 cm.) in length, is attached to the posterior abdominal wall from the left side of the body of the second lumbar vertebra to the right iliac fossa, crossing successively the third part of the duodenum, the aorta, the inferior vena cava, the right ureter and the right Psoas muscle (Fig. 988). Its breadth between its vertebral and intestinal borders is about eight inches (20 cm.) from its commencement to its termination at the intestine, and it is greater in the middle than at either end of the bowel. According to Lockwood, it tends to increase in length as age advances. Between the two layers of which it is composed are contained bloodvessels, nerves, lacteals, and lymph nodes, together with a variable amount of fat.

Meckel's Diverticulum (*diverticulum ilei*).—This consists of a pouch which projects from the lower part of the ileum in about 2 per cent. of subjects. Its average position is about three feet from the ileocolic junction, and its average length about two inches. Its calibre is generally the same as that of the ileum. Sometimes only a portion of the proximal end has a lumen and the balance of the structure is impervious and shrunk to a fibrous cord. In other cases the diverticulum is actually of greater diameter than the intestine. It usually is at a right angle to the intestine, but may take almost any direction. Its blind extremity may be unattached or may be connected with the abdominal wall or with some other

portion of the intestine by a fibrous band. It represents the remains of the vitelline or omphalomesenteric duct, the duct of communication between the umbilical vesicle and the alimentary canal in early fetal life.

Structure of the Small Intestine, Including the Duodenum.—The wall of the small intestine is composed of four coats—**serous, muscular, submucous, and mucous.**

The Serous Coat (*tunica serosa*).—The relation of the peritoneum to the duodenum has been described. The remaining portion of the small intestine is surrounded by the peritoneum, excepting along its attached or mesenteric border; here a space is left for the vessels and nerves to pass to the gut.

The muscular coat (*tunica muscularis*) consists of two layers of fibres, an **external or longitudinal layer** and an **internal or circular layer.**

The **longitudinal fibres** (*stratum longitudinale*) are thinly scattered over the surface of the intestine, and are more distinct along its free border.

The **circular fibres** (*stratum circulare*) form a thick, uniform layer; they surround the cylinder of the intestine in the greater part of its circumference, and are composed of smooth muscle cells of considerable length. The muscular coat is thicker at the upper than at the lower part of the small intestine.

The **submucous coat** (*tela submucosa*) connects the mucous and muscular layers. It consists of loose, filamentous areolar tissue, which forms a bed for the subdivisions of the nutrient vessels, previous to their distribution to the mucous surface, also for the lymph channels and nerves.

The submucous coat contains **lymph nodules** (*noduli lymphatici*). Each nodule is pyramidal or pear-shaped, and the apex lies in the mucous membrane and forms a rounded elevation. These rounded elevations mark the **solitary follicles** and **Peyer's patches** (Figs. 1017 and 1024), and nowise resemble villi. In the duodenum the submucous tissue contains the **duodenal glands.** The submucous tissue is prolonged into the **valvulae conniventes.** It contains bloodvessels, Meissner's plexus of nerves, and lymph vessels.

The **mucous membrane** (*tunica mucosa*) is thick and highly vascular at the upper part of the small intestine, but somewhat paler and thinner below. It consists of the following structures: next the areolar or submucous coat is a layer of unstriped muscle tissue, the **muscularis mucosae**; internal to this is a quantity of retiform tissue, enclosing in its meshes lymph corpuscles (diffuse lymphoid tissue), and in which the bloodvessels and nerves ramify. Lastly, a basement membrane, supporting a single layer of columnar epithelial and goblet cells. They are granular in appearance, and each possesses a clear, oval nucleus. At their superficial or unattached end they present a distinct layer of highly refracting material, the **cuticular border**, marked by vertical striæ.

The mucous membrane presents for examination the following structures contained within it or belonging to it:

Valvulae conniventes.

Villi.

Intestinal glands.

Lymphatic nodules { Solitary follicles.
Peyer's or agminated follicles.

The **valvulae conniventes** or the **valves of Kerkring** (*plicae circulares* [*Kerkringi*]) (Fig. 1016) are large folds or valvular flaps projecting into the lumen of the bowel. They are composed of reduplications or folds of the mucous membrane, the two layers of the fold being bound together

FIG. 1016.—Valvulae conniventes in the upper part of the small intestine. (Poirier and Charpy.)

by submucous tissue; they contain no muscular fibres, and, unlike the folds in the stomach, they are permanent, and are not obliterated when the intestine is distended. The majority extend transversely across the cylinder of the intestine for about one-half or two-thirds of its circumference, but some form complete circles, and others have a spiral direction; the latter usually extend a little more than once around the bowel, but occasionally two or three times. The spiral arrangement is the characteristic one of the shark family of fishes. The larger folds are about one-third of an inch in depth at the broadest part; but the greater number are of smaller size. The larger and smaller folds alternate with each other. They are not found at the commencement of the duodenum, but begin to appear about one or

FIG. 1017.—Mucosa of small intestine in ideal vertical cross-section. (Testut, after Heitzmann.)

FIG. 1018.—Longitudinal section through the end of a villus from the small intestine of a cat. $\times 450$.

two inches beyond the pylorus. In the lower part of the descending portion, below the point where the bile and pancreatic ducts enter the intestine, they are very large and closely approximated. In the transverse portion of the duodenum and upper half of the jejunum they are large and numerous; and from this point, down to the middle of the ileum, they diminish considerably in size. In the lower part of the ileum they almost entirely disappear; hence the comparative thinness of this portion of the intestine as compared with the duodenum and jejunum. The valvulae conniventes retard the passage of the food along the intestine, and afford a more extensive surface for absorption.

The **villi** (*villi intestinales*) (Figs. 1018 and 1019) are minute, highly vascular processes, never larger than 1 millimeter, projecting from the mucous membrane of the small intestine throughout its whole extent, and giving to its surface a velvety appearance. They spring from the valvulae conniventes and also from the spaces between them. In shape, according to Rauber, they are short and leaf-shaped in the duodenum, tongue-shaped in the jejunum, and filiform in the ileum. They are largest and most numerous in the duodenum and jejunum, and become fewer and smaller in the ileum. Kraus estimates their number in the upper part of the small intestine at from fifty to ninety in a square line; and in the lower part from forty to seventy, the total number for the whole length of the intestine being about four millions.

FIG. 1019.—Villi of small intestine. (Cadiat.)

Structure of the Villi (Figs. 1018 and 1019).—The structure of the villi has been studied by many eminent anatomists. We shall here follow the description of Watney,¹ whose researches have a most important bearing on the physiology of that which is the peculiar function of this part of the intestine, the absorption of fat.

The essential parts of a villus are the lacteal vessel, the bloodvessels, the epithelium, the basement membrane, and muscle and lymphoid tissues of the mucosa, these structures being supported and held together by retiform tissue.

These structures are arranged in the following manner: Situated in the centre of the villus is a space, the **lacteal**, terminating near the summit in a blind extremity; running beside this vessel are unstriated muscle fibres; surrounding it is a meshwork of fibroelastic tissue supporting a plexus of capillary vessels and diffuse lymphoid tissue, the whole being enclosed by a basement membrane, and covered by simple columnar epithelium and goblet cells. Nerve fibres are contained within the villi; they form ramifications throughout the reticulum.

The **lacteals** are in some cases double, and in some animals *multiple*. Situated in the axis of a villus, each commences by a dilated cecal extremity near to, but not quite at, the summit of the villus. The walls are composed of a single layer of endothelial cells, the interstitial substance between the cells being continuous with the reticulum of the matrix. The **muscle fibres** are derived from the muscularis mucosae, and are arranged in bundles around the lacteal vessel.

¹ Phil. Trans., vol. clxv, part ii.

extending from the base to the summit of the villus, and giving off laterally individual muscle cells, which are enclosed by the reticulum, and by it are attached to the basement membrane.

The **bloodvessels** form a plexus between the lacteal and the basement membrane, and are enclosed in the reticular tissue; in the interstices of the capillary plexus, which they form, are contained the cells of the villus.

The **intestinal glands, crypts or glands of Lieberkühn** (*glandulae intestinales* [Lieberkühni]) (Figs. 1020 and 1024), are found in considerable numbers over every part of the mucous membrane of the small intestine. They consist of minute simple tubular depressions of the mucous membrane, arranged perpendicularly to the surface, upon which they open by small circular apertures. They may be seen with the aid of a lens, their orifices appearing as minute dots seen at the base of the villi. Their walls are thin, consisting of a basement membrane lined by simple columnar epithelium, and are surrounded by capillary vessels. In the glands of the ileum and also to a certain extent those of the jejunum are seen some coarsely granular cells, the **cells of Paneth**. They seem to be cells of special secretion.

The **duodenal or Brunner's glands** (*glandulae duodenales* [Brunneri]) are limited to the duodenum. They are small, branched, tubular glands in the submucous coat, and open upon the surface of the mucous membrane by minute excretory ducts. They are most numerous and largest near the pylorus. They resemble the pyloric glands in appearance, and are believed to be a direct continuation of those glands. The cells are clear and pale staining, and Stöhr states that cells resembling parietal cells are occasionally seen.

FIG. 1020.—Section of a gland of Lieberkühn in the mouse. (Paneth.)

FIG. 1021.—Transverse section of crypts of Lieberkühn. (Klein and Noble Smith.)

The **lymph nodules** (*noduli lymphatici*) are small pyriform structures. The bodies of the nodes are in the submucous coat; the apices are in the mucous membrane, which is thrown by them into rounded elevations. They are divided into **solitary follicles** and **Peyer's patches**.

The **solitary follicles** (*noduli lymphatici solitarii*) (Fig. 1017) are found scattered throughout the mucous and submucous coats of the small intestine and the large intestine. In the small intestine they are most numerous in the lower part of the ileum, upon and between the valvulae conniventes. They are small, round, whitish bodies, from one-twenty-fourth of an inch to one-quarter of an inch (1 to 6 mm.) in diameter. Their free surface is covered with villi, and each follicle is surrounded by the openings of the glands of Lieberkühn. They are now recognized as lymph nodules. They consist of a dense interlacing retiform tissue closely packed with lymph corpuscles and permeated with an abundant capillary network. The interspaces of the retiform tissue are continuous with larger lymph spaces at the base of the nodule, through which they communicate with the lacteal system. Each consists of a lighter central area, the **germinal centre**, where the leukocytes are reproducing, and a peripheral darker zone, where the cells are more numerous and closely packed.

Peyer's patches, the **agminated follicles**, or the **tonsillae intestinales** (*noduli lymphatici aggregati* [Peyeri]) (Figs. 1022, 1023, and 1024) may be regarded as aggregations of solitary follicles, forming circular or oval patches from ten to sixty in number, and varying in length from half an inch to four inches (1.25 to 10 cm.). They are largest and most numerous in the ileum. In the lower part of the jejunum they are small, of a circular form, and few in number. They are occasionally seen in the duodenum. They are placed lengthwise in the intestine, and are situated in the portion of the tube most distant from the attachment of the mesentery. Each patch is formed of a group of the above-described solitary follicles covered with mucous membrane, and in almost every respect are similar in structure to them. They do not, however, as a rule,

possess villi on their free surface nor glands. Each patch is surrounded by a circle of the crypts of Lieberkühn. They are best marked in the young subject, becoming indistinct in middle age, and sometimes altogether disappearing in advanced life. They are largely supplied with blood.

FIG. 1022.—Transverse section through the equatorial plane of three of Peyer's follicles from the rabbit.

FIG. 1023.—Free surface of a Peyer's patch. (After Quain.)

vessels, which form an abundant plexus around each follicle and give off fine branches which permeate the lymphoid tissue in the interior of the follicle. The lacteal plexuses which are found throughout the small intestine are especially abundant around these patches: here they form rich plexuses with sinuses around the glands (Fig. 1024). In typhoid fever there is ulceration of Peyer's patches.

FIG. 1024.—Vertical cell of a Peyer's patch in a man with the lymphatic vessels injected. (Frey.)

Vessels and Nerves.—The arteries (*vasa intestini tenuis*) are branches of the superior mesenteric (Fig. 471) and course within the mesentery, forming single, double, or even tertiary loops (Figs. 1025, 1026, 1027, 1028, 1029, and 1030). The terminal branches reach the intestine, and each branch divides into two, one going to each side of the intestine and passing transversely around it. At first they are directly beneath the peritoneum, but after a time they pass to the

and form a plexus, from which branches go to the mucous membrane. Some of the villi; others form plexuses about the glands of Lieberkühn (Birmingham). The arterial blood supply of the small intestines are given on page 664.

FIGS. 1025, 1026, 1027, 1028, 1029, 1030.—Diagrams showing the arrangement and variations of the loops of the mesenteric vessels for various segments of the small intestine of average length. Nearest the duodenum the mesenteric loops are primary, the vasa recta are long and regular in distribution, and the translucent spaces (lunettes) are extensive. Toward the ileocolic junction, secondary and tertiary loops are observed, the vessels are smaller and become obscured by numerous fat-tabs (After Monks.) (See p. 1270 for detailed description.)

The **veins** correspond to the arteries, and the venous blood passes to the **superior mesenteric vein**, which, it will be remembered, unites with the splenic vein to form the portal vein. The mesenteric veins are devoid of valves.

The **lacteals** are **lymphatics** (Figs. 1017 and 1024) which arise in the villi. Lymphatics also begin in sinuses at the base of the solitary follicles and in Peyer's patches. There is an extensive lymphatic plexus in the submucous coat, another in the muscular coat, another under the peritoneum. The submucous plexus is formed by lymphatics from the villi and mucous membrane. This plexus is joined by lymphatics from the bases of the solitary follicles, and the lymph passes by vessels to larger vessels at the mesenteric border of the gut. The muscular lymphatics are placed between the two muscular layers. They form a plexus and communicate freely with the lymphatics from the mucous membrane, and empty themselves in the same manner into the commencement of the lacteal vessels at the attached border of the gut. The vessels from all sources of lymphatic supply pass up between the two layers of the mesentery, being connected with the **mesenteric nodes** (Fig. 572), and unite to form a trunk, the **intestinal lymphatic trunk**, which opens into the receptaculum chyli, or the vessels unite to form several trunks, which open separately into the receptaculum chyli.

FIG. 1031.—Nerve endings in the villi of the small intestine of a rabbit. (Müller.)

FIG. 1032.—Meissner's plexus. (Ramón y Cajal.)

The **nerves of the small intestine** (Figs. 1031 and 1032) are derived from the **coeliac plexus** about the superior mesenteric artery. They pass along within the mesentery with the superior mesenteric artery and reach the intestine. They pass to the plexus of nerves and ganglia situated between the circular and longitudinal muscular fibres (**Auerbach's plexus**), from which the nerve branches are distributed to the muscular coats of the intestine. From this plexus a secondary plexus is derived (**Meissner's plexus**). It is formed by branches which have perforated the circular muscular fibres. This plexus lies in the submucous coat. It is also gangliated, and from it the ultimate fibres pass to the muscularis mucosae, to the villi, and to the mucous membrane. The nerves of the intestine are amyelinic, and some of the fibres are derived from the vagus.

Applied Anatomy.—The applied anatomy of the small intestine, especially the surgical anatomy of the **hernias**, is given on page 1316.

THE LARGE INTESTINE (INTESTINUM CRASSUM) (Figs. 959, 1033).

The large intestine extends from the termination of the ileum to the anus. It is about five feet or more in length, being one-fifth of the whole extent of the intestinal canal. It is largest at its commencement at the cecum, and gradually

diminishes as far as the rectum, where there is a dilatation of considerable size just above the anal canal. It differs from the small intestine in its greater size, its more fixed position, its sacculated wall, and in possessing certain appendages to its external coat, the **appendices epiploicae** (Fig. 1034), little peritoneal pouches containing fat.

FIG. 1033.—Large intestine. A piece of transverse colon from a child two years old. The three chief characteristics of the large intestine—sacculations, taeniae, and appendices epiploicae—are shown. (Cunningham.)

Further, the longitudinal muscle fibres of the large intestine do not form a continuous layer around the gut, but are arranged in three **longitudinal bands** or **taeniae** (*taeniae coli*) (Fig. 1033). The large intestine, in its course, describes an arch, which surrounds the convolutions of the small intestine. The segment of the intestinal tract where the small intestine joins the large is termed the **ileocecal** or **ileocolic junction**. The large intestine commences in the right inguinal region, in a dilated part, the **caecum**, together with a rudimentary structure, the **appendix**. It ascends through the right lumbar and right hypochondriac regions to the under surface of the liver; here it takes a bend to the left (**hepatic flexure**), and passes transversely across the abdomen on the confines of the epigastric and umbilical regions, to the left hypochondriac region; it then bends again (**splenic flexure**), and descends through the left lumbar region to the left iliac fossa, where it becomes convoluted, and forms the **sigmoid flexure**; finally it enters the pelvis, and descends along its posterior wall to the anus. The large intestine is divided into the **caecum**, **colon**, **rectum**, and **anal canal**.

FIG. 1034.—Segment of large intestine, showing the characteristic features of its structures. (Testut.)

The Cecum.

The **caecum** (*intestinum caecum*) (Figs. 1035 and 1036), the commencement of the large intestine, is the large blind pouch situated below the ileocecal valve. Its blind end or fundus is directed downward, and its open end upward, communicating directly with the colon, of which this blind pouch appears to be the beginning or head, and hence the old name **caput caecum coli** was applied to it. Its size is variously estimated by different authors, but on an average it may be said to be two and one-half inches (6.25 cm.) in length and three (7.5 cm.) in breadth.¹

¹ In 435 careful autopsies, Robinson found the caecum and appendix congenitally absent in one case (St. Louis Courier of Medicine, October-December, 1902). Sometimes a very large, sometimes an exceedingly small, caecum is encountered. A large caecum may be four inches in width, entirely surrounded by peritoneum, and usually is excessively mobile. An adult caecum may be only one inch in width and one-half an inch in length, and it is usually devoid of mobility.

It is situated in the right iliac fossa, above the outer half of Poupart's ligament; it rests on the Iliopsoas muscle, and lies immediately behind the abdominal wall. As a rule, it is entirely enveloped on all sides by peritoneum, but in a certain number of cases (6 per cent., according to Berry) the peritoneal covering is not complete, so that a small portion of the upper end of the posterior surface is uncovered and connected to the iliac fossa by connective tissue. The cecum lies quite free in the abdominal cavity and is capable of a considerable amount of movement, so that it may become herniated down the right inguinal canal, and has occasionally been found in an inguinal hernia on the left side.¹

The cecum varies in shape, but, according to Treves, in man it may be classified under one of four types (Fig. 1036). In early fetal life it is short, conical, and broad at the base, with its apex turned upward and inward toward the ileocecal junction. It then resembles the cecum of some of the monkey tribe, *e. g.*, Man-

FIG. 1035.—The cecum and colon laid open to show the ileocecal valve

gabey monkey. As the fetus grows the cecum increases in length more than in breadth, so that it forms a longer tube than in the primitive form and without the broad base, but with the same inclination inward of the apex toward the ileocecal junction. This form is seen in others of the monkey tribe, *e. g.*, the spider monkey. As development goes on, the lower part of the tube ceases to grow and the upper part becomes greatly increased, so that at birth there is a narrow tube, the **vermiform appendix**, hanging from a conical projection, the **cecum**. This is the **infantile form**, and as it persists throughout life, in about 2 per cent. of cases it is regarded by Treves as the **first** of his four types of human ceca. The cecum is conical and the appendix rises from its apex. The three longitudinal bands start from the appendix and are equidistant from each other. In the **second** type, the conical cecum has become quadrate by the growing out of a saccule on either side of the anterior longitudinal band. These saccules

are of equal size, and the appendix arises from between them instead of from the apex of a cone. This type is found in about 3 per cent. of cases. The **third** type is the normal type of man. Here the two saccules, which in the second type were uniform, have grown at unequal rates, the right with greater rapidity than the left. In consequence of this an apparently new apex has been formed by the growing downward of the right saccule, and the original apex, with the appendix attached, is pushed over to the left toward the ileocecal junction. The three longitudinal bands still start from the base of the appendix, but they are now no longer equidistant from one another, because the right saccule has grown between the anterior and postero-external bands, pushing them over to the left. This type occurs in about 90 per cent. of cases. The **fourth** type is merely an exaggerated condition of the third; the right saccule is still larger, and at the same time the left saccule has been atrophied, so that the original apex of the cecum, with the appendix, is close to the ileocecal junction, and the anterior band courses inward to the same situation. This type is present in about 4 per cent. of cases.

¹ In 310 adult males, Robinson found 8 per cent. with undescended cecum and appendix. Nondescent was found in less than 4 per cent. of females. A partly descended cecum usually lies upon the right kidney.

rior of the Cecum.—Corresponding to the surface sacculations are seen *sa-like depressions* (*haustra*) bounded by the *semilunar folds* (*plicae semilunari*) (Fig. 1035), corresponding to the surface constrictions which mark *sacculi*. The interior of the cecum is continued into the colon above, *orifice of the ileum* and of the appendix open into it. These orifices, respectively by the *ileocecal valve* and by the valve of Gerlach, are described s 1300 and 1302.

FIG. 1036.—The four types of cecum.

The Vermiform Appendix (*processus vermiformis*) (Figs. 1038 and 1044).—The vermiform appendix is found only in man, the higher apes, and the wombat, although in certain rodents a somewhat similar arrangement exists. In carnivorous animals the cecum is very slightly developed; in herbivorous animals (with a simple stomach) it is, as a rule, extremely large. It has been suggested that the vermiform process in man is the degenerated remains of the herbivorous cecum, which has been replaced by the carnivorous form. The vermiform appendix is a long, narrow, worm-shaped, musculomembranous tube, which starts from what was originally the apex of the cecum. After development has advanced the vermiform appendix comes off, as a rule, from the inner side of the posterior wall of the cecum, below and behind the termination of the ileum. This origin usually corresponds to *McBurney's point* on the abdominal wall, midway between the umbilicus and the anterior superior iliac spine, and which is the usual seat of the greatest

tenderness in appendicitis. The origin of the appendix varies with the type of cecum present. These variations are shown in Fig. 1036. The movable portion of the appendix may be met with in different situations. It may pass upward and in front of the cecum and colon, upward and behind the cecum, and even behind the colon between the two layers of the mesocolon; upward and to the inner side or upward and to the outer side of the cecum and colon. It may pass to the left under the ileum and mesentery, upward and to the left or downward and to the left into the true pelvis. It may pass directly downward under the cecum. It may pass to the right in front of or back of the cecum. It may occupy any one of the cecal fossæ (p. 1267), but most often enters the ileocecal fossa. When the cecum is mobile the appendix may be found almost anywhere within the abdomen. When the cecum is undescended, the appendix of course shares in the failure to descend, and may be below the gall-bladder or in front of the right kidney, and may pass in several directions—upward behind the cecum, to the left behind the ileum and mesentery; or downward and inward into the true pelvis. It varies from one-

FIG. 1037.—Arteries of the cecum and of the appendix vermiformis and of the terminal portion of the ileum. (Poirier and Charpy.)

half an inch to nine inches in length (1.25 to 22.5 cm.) its average being about three inches (7.5 cm.). Its diameter is from one-eighth inch to one-quarter inch (3 to 6 mm.). The operating surgeon may occasionally fail to find an appendix buried in one of the cecal fossæ, and may conclude that the diverticulum is absent. In rare instances the appendix has been found absent. It is retained in position by a fold of peritoneum derived from the left leaf of the mesentery, which forms a mesentery for it, and is called the **mesoappendix** (p. 1265 and Figs. 991 and 992). This fold, in the majority of cases, is more or less triangular in shape, and, as a rule, extends along the entire length of the tube. In color the healthy appendix is yellowish-pink and is soft and smooth to the touch. The **canal of the appendix** is small and extends throughout the whole length of the organ. The walls of the healthy diverticulum are thick, and the diameter of the lumen is usually trivial as compared with the diameter of the appendix itself. The lumen of the appendix communicates with the cecum by an orifice which is placed below and behind the ileocecal opening (Fig. 1042). It is sometimes guarded above and to the left side by a semilunar fold of mucous membrane, the **valve of Gerlach** (*valvula processus vermiformis*). The valve is inconstant, and is never perfect. It is stated that the lumen of the appendix tends to undergo obliteration as an involution change in a functionless organ. The lumen rarely contains foreign bodies after death, but often contains fecal concretions. Certain it is that in 25 per cent. of necropsies upon adults or elderly people the lumen is found to be partially or completely occluded.

Structure of the Appendix (Fig. 1040).—The coats of the appendix correspond to the coats of the bowel—**serous**, **muscular** (the outer layer of longitudinal, the inner of circular fibres), **submucous**, and **mucous**.

The **outer or serous coat** forms a complete investment for the appendix except along the narrow line of attachment of its mesentery in its proximal two-thirds or more.

The **longitudinal muscle layer** is thin and irregularly distributed, and in certain regions may be exceedingly thin or actually absent, so that the peritoneal and submucous coats are contiguous over small areas.

The **circular muscle layer** is a much thicker layer than the preceding, and at the blind extremity forms a dome-like collection of interlacing fibres. Both layers have openings at intervals for the passage of bloodvessels.

The **submucous coat** varies greatly in thickness. It contains bloodvessels, nerves, and lymphatics, and a large number of lymphoid follicles (300 to 400) and, at times, adipose tissue.

The **mucous membrane** (Fig. 1038) is lined by columnar epithelium and contains numerous solitary lymph follicles, glands of Lieberkühn (about 25,000), surrounded by diffuse lymphoid tissue, bloodvessels, lymphatics, and nerves.

The **muscularis mucosae** may be absent, may be scanty, or may be distinct. The **lymphoid follicles** are visible to the naked eye (Fig. 1038). Some of them are in the submucosa, some of them chiefly in the mucosa, the bases of the latter, however, being in the submucosa.

The **arteries of the cecum and appendix** are derived from the ileocolic branch of the superior mesenteric artery. Close to the ileocecal junction the ileocolic artery gives off *anterior* and *posterior ileocecal* branches to the terminal part of the ileum and beginning of the large intestine. The terminal branches to the cecum are called *anterior* and *posterior cecal* arteries. The appendix is supplied by the *appendicular artery*, a branch of the posterior ileocecal artery (see p. 665).

The **veins** of the appendix are numerous, thin walled, and large. Veins from the submucous plexus pass through the muscular gaps and enter the subperitoneal plexus. Veins from the subperitoneal plexus pass into the veins in the mesoappendix which correspond to but do not really

FIG. 1038.—The internal surface of the vermiform appendix. (Bonamy and Broca.)

FIG. 1039.—Arteries and veins of the cecum and vermiform appendix seen from behind. (Poirier and Charpy.)

accompany the arteries (Lockwood). Most of the veins of the mesoappendix pass to the **posterior ileocecal vein**, though some pass directly to the **cecal vein**. These veins are radicles of the portal system.

The **lymphatics** of the cecum and appendix are described on page 797.

The Ileocecal Valve (*valvuli coli*) (Figs. 1042 and 1043).—The lower end of the ileum terminates by opening into the inner and back part of the large intestine, at the point of junction of the cecum with the colon. The opening is guarded by a valve, consisting of two semilunar segments, an **upper or colic segment** (*labium superius*) and a **lower or cecal segment** (*labium inferius*), which project into the

FIG. 1040.—Transverse section of the vermiform appendix of man. (Kölliker.)

lumen of the large intestine. The upper one, nearly horizontal in direction, is attached by its convex border to the point of junction of the ileum with the colon; the lower segment, which is more concave and longer, is attached to the point of junction of the ileum with the cecum. At each end of the aperture the two segments

FIG. 1041.—Lymphatics of the cecum and appendix, anterior view. (Poirier and Charpy.)

of the valve coalesce, and are continued as a narrow membranous ridge around the canal for a short distance. Each ridge is known as the **frenulum of the valve** (*frenulum valvulae coli*). The left or anterior part of the aperture is rounded; the right or posterior is narrow and pointed. In the formation of the valve the termination of the small intestine invaginates for a short distance into the lumen

of the large intestine (Fig. 1043), the invaginated portion of the wall of the small intestine uniting with a corresponding portion of the wall of the large intestine. Each segment of the valve is formed by a reduplication of the mucous membrane and of the circular muscle fibres of the intestine, the longitudinal fibres and peritoneum being continued uninterruptedly across the one portion of the intestine to the other.

The surface of each segment of the valve directed toward the ileum possesses villi, and presents the characteristic structure of the mucous membrane of the

FIG. 1042.—Ileocecal valve of the circular type. (Poirier.)

FIG. 1043.—Vertical section through the cecum and ileocecal valve. (Gegenbaur.)

small intestine; while that turned toward the large intestine is destitute of villi, and marked with the orifices of the numerous tubular glands peculiar to the mucous membrane of the large intestine. These differences in structure continue as far as the free margins of the valve. When the cecum is distended it is supposed that the margins of the opening are approximated so as to prevent reflux into the ileum. It is known, however, that a very large enema which distends the cecum and colon may in part enter the ileum, being driven there by waves of reversed peristalsis. The valve resists, but a certain amount of pressure overcomes it. Some believe that the so-called ileocecal valve is not a valve, but a distinct sphincter. This has been demonstrated to be true in cats and dogs, but lacks demonstration in man (p. 1314).

FIG. 1044.—Cecum and vermiform appendix; ileum cut through. (Sappey.)

Applied Anatomy.—The vermiform appendix is very liable to become inflamed, the condition being known as *appendicitis*. The condition may be set up by a catarrhal inflammation arising in the appendix or derived from the colon. It may remain catarrhal and then subside. It may become purulent or may be purulent from the beginning. Anything which lessens vital

resistance makes the appendix a ready prey to bacteria. Among causes which lessen resistance are fecal concretions, twists of the mesoappendix cutting off the blood supply, bruises inflicted by the Psoas muscle (Byron Robinson), blocking of the outlet of the appendix by catarrhal exudate, concretions, proliferated lymphoid tissue, or adhesions. Appendicitis may arise by the

FIG. 1045.—Ileocecal valve. (Sappey.)

appendix becoming twisted, owing to the shortness of its mesentery, in consequence of distention of the cecum. As the result of inflammation, its blood supply, which is mainly through one large artery running in the meso-appendix, becomes interfered with. Again, in rarer cases, the inflammation is set up by the impaction of a solid mass of feces or a foreign body in the appendix. The inflammation may result in ulceration and perforation, or in gangrene of the appendix the appendix may be blocked and full of pus, or abscess may form outside of it (*appendicular abscess*). These conditions require prompt operative interference, and in cases of recurrent attacks of appendicitis it is advisable to remove this diverticulum between the attacks.

The cecum and appendix may be implicated in cases of strangulated hernia, giving rise to serious symptoms of obstruction. An obstruction in the

distal part of the large bowel causes distention, particularly of the cecum, which sometimes assumes enormous dimensions, and has been known to rupture, causing fatal peritonitis.

The Colon.

The colon is divided into four parts—the **ascending**, **transverse**, and **descending colon** and the **sigmoid flexure**.

The **ascending colon** (*colon ascendens*) is smaller than the cecum, with which it is continuous. It passes upward, from its commencement at the cecum, opposite the ileocecal valve, to the under surface of the right lobe of the liver, on the right of the gall-bladder, where it is lodged in a shallow depression on the liver, the **impressio colica**; here it bends abruptly forward and inward to the left, forming the **hepatic flexure** (*flexura coli dextra*). It is retained in contact with the posterior wall of the abdomen by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by loose areolar tissue with the Quadratus lumborum muscle, and with the front of the lower and outer part of the right kidney (Fig. 1046). Sometimes the peritoneum almost completely invests it, and forms a distinct but short mesocolon¹ (p. 1251). It is in relation, in front, with the convolutions of the ileum and the abdominal parietes.

The **transverse colon** (*colon transversum*) (Fig. 983), the longest and most movable part of the large intestine, passes transversely from the right hypochondriac region across the abdomen, opposite the confines of the epigastric and umbilical zones, into the left hypochondriac region, where it curves downward beneath the lower end of the spleen, forming the **splenic flexure** (*flexura coli sinistra*). In its course the transverse colon describes an arch, the concavity of

¹ Treves states that after a careful examination of one hundred subjects, he found that in fifty-two there was neither an ascending nor a descending mesocolon. In twenty-two there was a descending mesocolon, but no trace of a corresponding fold on the other side. In fourteen subjects there was a mesocolon to both the ascending and the descending segments of the bowel; while in the remaining twelve there was an ascending mesocolon, but no corresponding fold on the left side. It follows, therefore, that in performing lumbar colostomy a mesocolon may be expected on the left side in 36 per cent. of all cases, and on the right in 26 per cent. (The Anatomy of the Intestinal Canal and Peritoneum in Man, 1885, p. 55.)

which is directed backward toward the vertebral column and a little upward. It is almost completely invested by peritoneum, and connected to the posterior

FIG. 1046.—Diagram of the relations of the large intestine and kidneys, from behind.

abdominal wall by a large and wide duplication of that membrane, the **transverse mesocolon** (Fig. 998). The transverse colon is in relation, by its upper surface, with the liver and gall-bladder, the greater curvature of the stomach, and the lower

end of the spleen; by its under surface, with the small intestines; by its anterior surface, with the anterior layers of the greater omentum and the abdominal parietes; its posterior surface on the right side is in relation with the second portion of the duodenum, and on the left side is in contact with some of the convolutions of the jejunum and ileum.

FIG. 1047.—Sigmoid colon, front view. Semidiagrammatic. (Testut.)

The *splenic flexure* is in relation with the lower end of the spleen and the tail of the pancreas. It lies at a higher level than, and on a plane posterior to, the hepatic flexure, and is attached to the Diaphragm opposite the tenth and eleventh ribs, by a peritoneal fold, the *phrenocolic ligament* (see p. 1265).

The **descending colon** (*colon descendens*) passes downward through the left hypochondriac and lumbar regions along the outer border of the left kidney. At the lower end of the kidney it turns

FIG. 1048.—Sigmoid colon and rectum, front view. The broken lines indicate the situation of the concealed part of the sigmoid colon. The small intestine is drawn away, and the anus is turned forward. (Testut.)

inward toward the outer border of the Psoas muscle, along which it descends to the crest of the ilium, where it terminates in the sigmoid flexure. It is retained

in position by the peritoneum, which covers its anterior surface and sides, its posterior surface being connected by areolar tissue with the outer border of the left kidney, and the *Quadratus lumborum* muscle (Fig. 988). It is smaller in calibre and more deeply placed than the ascending colon, and is more frequently covered with peritoneum on its posterior surface than the ascending colon (Treves).

The **sigmoid flexure, pelvic colon, or sigmoid colon** (*colon sigmoideum*) (Figs. 1047 and 1048) is the narrowest part of the colon; it is situated in the left iliac fossa, commencing from the termination of the descending colon, at the margin of the crest of the ilium, and then forming a loop, which varies in length and position, and which terminates in the rectum at the level of the attachment of the mesentery upon the front of the third sacral vertebra. It passes downward about two inches (5 cm.) parallel to the outer border of the *Psoas* muscle, then taking a transverse direction enters the cavity of the pelvis, crosses this cavity from left to right and a little upward to the lower margin of the right iliac fossa; thence it passes downward, backward, and inward along the anterior surface of the sacrum to its junction with the rectum. It is surrounded by the peritoneum and is attached to the posterior abdominal wall by the **mesosigmoid**. When the sigmoid is lifted upward and to the right and the mesosigmoid is put slightly on the stretch the intersigmoid fossa (p. 1268) is brought into view. When the sigmoid flexure is empty most of it falls into the rectovesical or rectovaginal space (Fig. 1048). When distended it mounts up into the abdomen, reaching to or even above the umbilicus. The sigmoid flexure is in relation in front with the small intestine and abdominal parietes. The sigmoid mesocolon is attached to a line running downward and inward from the crest of the ilium, across the *Psoas* muscle (Fig. 988).

Applied Anatomy.—The diameter of the large intestine gradually diminishes from the cecum, which has the greatest diameter of any part of the bowel, to the point of junction of the sigmoid flexure with the rectum, at or a little below which point stricture most commonly occurs and diminishes in frequency as one proceeds upward to the cecum. When distended by some obstruction low down, the outline of the large intestine can be defined throughout nearly the whole of its course—all, in fact, except the hepatic and splenic flexures, which are more deeply placed; the distention is most obvious in the two flanks and on the front of the abdomen just above the umbilicus. The cecum, however, is that portion of the bowel which is, of all, most distended (see p. 1297). The hepatic flexure and the right extremity of the transverse colon are in close relationship with the liver, and abscess of this viscus sometimes bursts into the gut in this situation. The gall-bladder may become adherent to the colon, and gallstones may find their way through into the gut, where they may become impacted or may be discharged per anum. The mobility of the sigmoid flexure renders it more liable to become the seat of a *volvulus* or twist than any other part of the intestine. It generally occurs in patients who have been the subjects of habitual constipation, and in whom, therefore, the mesosigmoid is elongated. The gut at this part being loaded with feces, from its weight falls over the gut below, and so gives rise to the twist.

The Rectum (*Intestinum Rectum*) (Figs. 1049, 1050).

The rectum is continuous with the sigmoid flexure, while below it ends in the anal canal. From its origin at the level of the third sacral vertebra it passes downward, lying in the sacrococcygeal curve, and extends for about an inch (2.5 cm.) in front of, and a little below, the tip of the coccyx, as far as the apex of the prostate gland. It then bends sharply backward to continue as the anal canal.

It therefore presents two antero-posterior curves. An upper, with its convexity backward, is due to the conformation of the sacrococcygeal column. The lower one has its convexity forward, and is angular. Two lateral curves are also described—the one to the right, opposite the junction of the third and fourth sacral

FIG. 1049.—Sagittal section in the median line of the male pelvis. Rectum distended. (Poirier and Charpy.)

FIG. 1050.—Median sagittal section of the female pelvis. Rectum distended. (Luschka.)

vertebræ; the other to the left, opposite the sacrococcygeal articulation. They are, however, of little importance.

The adult rectum measures about five inches (12.5 cm.) in length, and at its commencement its calibre is similar to that of the sigmoid flexure, but near its termination it is dilated to form the **rectal ampulla**. The rectum has no sacculations comparable to those of the colon, but a sacculated condition, due to the presence in its interior of valves (shortly to be described), is sometimes seen.

The peritoneum is related to the upper two-thirds of the rectum, covering at first its front and sides, but lower down its front only; from the latter it is reflected on to the seminal vesicles in the male and the posterior vaginal wall in the female.

The level at which the peritoneum leaves the anterior wall of the rectum to be reflected on to the viscus in front of it is of considerable importance from a surgical point of view, in connection with removal of the lower part of the rectum. It is higher in the male than in the female. In the former the height of the rectovesical pouch is about three inches (7.5 cm.); that is to say, the height to which an ordinary index finger can reach from the anus. In the female the height of the rectovaginal pouch is about two and a quarter inches (5.2 cm.) from the anal orifice. The rectum is surrounded by a dense tube of fascia derived from the *fascia endopelvina*, but fused behind with the fascia covering the sacrum and coccyx. The fascial tube is loosely attached to the rectal wall by areolar tissue in order to allow the viscus to distend.

FIG. 1051.—Diagram of rectum, showing Houston's valves in the interior. (Cunningham.)

Relations of the Rectum.—The upper part of the rectum is in relation, *behind*, with the superior hemorrhoidal vessels, the left Piriformis muscle, and left sacral plexus of nerves, which separate it from the anterior surfaces of the sacral vertebræ; in its lower part it lies directly on the sacrum, coccyx, and Levatores ani, a dense fascia alone intervening; *in front*, it is separated above, in the male, from the posterior surface of the bladder; in the female, from the posterior surface of the uterus and its appendages by some convolutions of the small intestine (Fig. 1050). To the sides below the peritoneal reflections, the rectum is surrounded by cellular tissue in which on each side lie the lateral sacral artery and the bifurcated hypogastric plexus.

FIG. 1052.—The anal canal and lower part of the rectum in the fetus. A. Aged four to five months. B. Six months. C. Nine months. In each the anal canal is distinctly marked off from the rectum proper; the columns of Morgagni and the rectal valves are distinct. (Cunningham.)

This portion of the rectum is separated from the sacrum and coccyx by an interval, the **retro-rectal space**, which is filled with cellular tissue. The lower or prostatic portion in the male is in relation anteriorly with the triangular portion of the base of the bladder, the seminal vesicles, vasa deferentia, and, more anteriorly, with the prostate gland; in the female, with the posterior wall of the vagina.

The Anal Canal (*pars analis recti*) (Figs. 1052 and 1053).—The anal canal is the terminal portion of the large intestine. It begins at the level of the apex of the prostate, is directed downward and backward, and ends at the anus. It forms an angle with the lower part of the rectum and measures an inch to an inch and a half (2.5 to 3.75 cm.) in length. It has no peritoneal covering, but is invested by the Internal sphincter, supported by the Levatores ani muscles, and surrounded at its termination by the External sphincter; in the empty condition it presents the appearance of a longitudinal slit. Behind is a mass of muscle and fibrous tissue, the *anococcygeal body*; in front of it, in the male, are the membranous portion and bulb of the urethra, and the base of the triangular ligament, and in the female it is separated from the lower end of the vagina by a mass of muscle and fibrous tissue, named the *perineal body*.

FIG. 1053.—The interior of the anal canal and lower part of the rectum, showing the columns of Morgagni and the anal valves between their lower ends. The columns were more numerous in the specimen than usual. (Cunningham.)

The **Anal Orifice** or **Anus** is the external opening of the anal canal, formed by pigmented skin containing numerous sebaceous and sudoriparous glands (*glandulae circumanales*) and furnished with hairs. While the anus is closed, the skin around it is thrown into radial folds by the contraction of the External sphincter.

Structure of Large Intestine.—The large intestine has four coats—**serous**, **muscular**, **sub-mucous**, and **mucous**. The **serous coat** is derived from the peritoneum, and invests the different portions of the large intestine to a variable extent. The cecum is completely covered by the serous membrane, except in a small percentage of cases (5 or 6 per cent.), where a small portion of the upper end of the posterior surface is uncovered. The ascending and descending colon are usually covered only in front and at the sides; a variable amount of the posterior surface is uncovered.¹ The transverse colon is almost completely invested, the parts corresponding to the attachment of the great omentum and transverse mesocolon being alone excepted. The sigmoid flexure is completely surrounded, except along the line to which the sigmoid mesocolon is attached. The upper two-thirds of the rectum is covered in front and laterally by the peritoneum, but not posteriorly, between the two posterior folds of peritoneum, the so-called mesorectum; later it is covered only on its anterior surface; and the lower portion is entirely devoid of any serous covering. In the course of the colon the peritoneal coat is thrown into a number of small pouches filled with fat, called **appendices epiploicae**. They are chiefly appended to the transverse colon, and are particularly numerous along the anterior band.

The **muscular coat** consists of an **external longitudinal** and an **internal circular layer** of smooth muscle tissue.

The **longitudinal fibres** do not form a uniform layer over the whole surface of the large intestine. In the cecum and colon they are especially collected into three flat **longitudinal bands**

¹ See footnote, page 1304.

or *taeniae* (*taenia coli*) (Figs. 1034 and 1035), each being about half an inch (12 mm.) in width, and named, respectively, the mesocolic, omental, and free longitudinal bands or *taeniae*. These bands commence at the base of the vermiform appendix, which structure is surrounded by a uniform layer of longitudinal muscular fibres. The bands pass from the base of the appendix to the rectum. At this point they broaden, fuse, and surround the rectum. On the ascending, descending, and sigmoid colon the **mesocolic band** (*taenia mesocolica*) is posterior and internal; the **omental band** (*taenia omentalis*) is posterior and external; the **free band** (*taenia libera*) is anterior. On the transverse colon the *taenia libera* is inferior; the *taenia mesocolica* is posterior; the *taenia omentalis* is anterior and superior. These bands are one-sixth shorter than the other coats of the intestine to which they are applied, and serve to produce the **sacculi** (Fig. 1034), which are characteristic of the cecum and colon; accordingly, when they are dissected off, the tube can be lengthened, and its sacculated character becomes lost. There are three rows of the **sacculations** separated from each other by the longitudinal bands. These pouches are also subdivided by transverse furrows which correspond to concave folds of mucous membrane, called **semilunar folds** (*pliae semilunares coli*). In the sigmoid flexure the longitudinal fibres become more scattered, and around the rectum they spread out and form a layer which completely encircles this portion of the gut, but is thicker on the anterior and posterior surfaces than on the lateral surfaces. In addition to the muscular fibres of the bowels, two bands of smooth muscle fibres arise from the second and third coccygeal vertebrae, and pass downward and forward to blend with the longitudinal muscle tissue on the posterior wall of the anal canal. They are known as the **rectococcygeal muscles** (*m. rectococcygeus*).

The **circular fibres** form a thin layer over the cecum and colon, being especially accumulated in the intervals between the sacculi. In the rectum the circular fibres constitute a thick layer, and in the anal canal they become numerous and constitute the **Internal sphincter**.

The **submucous coat** (*tela submucosa*) connects the muscular and mucous layers closely together. Solitary follicles are quite numerous here.

The **mucous membrane**, in the cecum and colon, is pale, smooth, destitute of villi, and raised into numerous crescentic folds which correspond to the intervals between the sacculi. In the rectum it is thicker, of a darker color, more vascular, and connected loosely to the muscular coat, as in the oesophagus. It consists of simple columnar and goblet cells resting upon a basement membrane, beneath which is seen the tunica propria, which contains the capillaries and a considerable amount of diffuse lymphoid tissue. Externally, is seen the *muscularis mucosae*. Simple tubular glands, lined chiefly by goblet cells, are present. They are much broader than those of the small intestine.

When the lower part of the rectum is contracted, its mucous membrane is thrown into a number of folds, which are longitudinal in direction and are effaced by the distention of the gut. Besides these, are certain permanent horizontal folds, of a semilunar shape, known as the **rectal** or **Houston's valves** (Fig. 1052). They are usually three in number; sometimes a fourth is found, and occasionally only two are present.¹ One is situated near the commencement of the rectum, on the right side; a second extends inward from the left side opposite the middle of the sacrum; a third, the largest and most constant, projects backward from the forepart of the rectum, opposite the base of the bladder. When a fourth is present, it is situated nearly an inch (2.5 cm.) above the anus on the left and posterior wall of the tube. These folds are about half an inch (12 mm.) in width and contain some of the circular fibres of the gut. In the empty state of the intestine they overlap each other so effectually that they render the introduction of a bougie or the finger somewhat difficult, and their use seems to be "to support the weight of fecal matter, and prevent its urging toward the anus, where its presence always excites a sensation demanding its discharge."

The lumen of the anal canal presents, in its upper half, a number of vertical folds, produced by an infolding of the mucous membrane and some of the muscle tissue. They are known as the **columns of Morgagni** or **anal columns** (*columnae rectales* [Morgagni]) (Figs. 1053 and 1054). There are from five to ten of these folds, each of which is about half an inch long. They are most prominent when the Sphincter contracts. The outer angle of each column below passes into a semilunar valve. The grooves between the columns are shallow above and deeper below, and end in the anal valves. The **valves of Morgagni** or **anal valves** (Figs. 1053 and 1054) are folds which stretch from the base of one column to another, and form the **anal pockets** or **crypts of Morgagni** (*sinus rectales*). Just below the anal valves is the junction of the mucous membrane of the anal canal with the skin; this is indicated by the so-called *white line of Hilton* or *anocutaneous line of Hermann* (Fig. 1054).

Vessels and Nerves of the Large Intestine.—The **arteries** (see also p. 665) supplying the large intestine give off large branches, which ramify between the muscular coats supplying them, and, after dividing into small vessels in the submucous tissue, pass to the mucous membrane. The cecum, the appendix, and the ileocecal valve are supplied by the branches from the anastomotic loops between the **right colic** and **ileocolic branches of the superior mesenteric artery**

¹ Dublin Hospital Reports, vol. v, p. 163.

(Fig. 1055). The ascending colon is supplied by the **right colic**, and the transverse colon by the **middle colic branch of the superior mesenteric**. The descending colon is supplied by the

left colic branch of the inferior mesenteric, and the sigmoid flexure by the sigmoid branches of the inferior mesenteric. The rectum (Fig. 1056) is supplied mainly by the superior hemorrhoidal branch of the inferior mesenteric, but also at its lower end by the middle hemorrhoidal from the internal iliac, and the inferior hemorrhoidal from the internal pudic artery. The superior hemorrhoidal, the continuation of the inferior mesenteric, divides into two branches, which run down either side of the rectum to within about five inches (12.5 cm.) of the anus; they here split up into about six branches, which pierce the muscular coat and descend between it and the mucous membrane in a longitudinal direction, parallel with each other as far as the Internal sphincter, where they anastomose with the other hemorrhoidal arteries and form a series of loops around the anus. The veins of the large intestine correspond to the arteries and join the superior and inferior mesenteric veins which join the portal vein. The veins of the rectum (Fig. 1056) commence in a plexus of vessels which surrounds the lower extremity of the intestinal canal. In the vessels forming this plexus are small saccular dilations just within the margin of the anus (Figs. 1054 and 1056); from it about six vessels of considerable size are given off. These ascend between the muscular and mucous coat for about five inches (12.5 cm.), running parallel to each other; they then pierce the muscular coat, and, by their union, form a single trunk, the superior hemorrhoidal vein, which empties into the inferior mesenteric tributary of the portal vein. This arrangement is termed the **hemorrhoidal plexus** (Fig. 524); it communicates with the tributaries of the middle and inferior hemorrhoidal veins at its commencement, and thus a communication is established between the systemic and portal circulations. The inferior hemorrhoidal veins empty into the internal pudic veins, and the middle hemorrhoidal veins empty into the internal iliac veins.

FIG. 1056.—The bloodvessels of the rectum and anus, showing the distribution and anastomosis on the posterior surface near the termination of the gut. (Poirier and Charpy.)

The lymphatics of the large intestine are described on page 797.

The nerves are derived from the sympathetic plexuses around the branches of the superior and inferior mesenteric arteries. They are distributed in a similar way to those found in the small intestine. The spinal centre for the nerves of the anus and rectum is situated in the first and second sacral segments of the spinal cord.

Movements and Innervation of the Intestines.

Movements.—As the *small intestine* is devoid of any sphincter arrangement, peristalsis cannot mix the food as it does in the pyloric portion of the stomach. The process by which the food is mixed with the secretions and is brought against the intestinal wall for absorption is called by Cannon "rhythmic segmentation." Rhythmic motions "mix the food and expose it to the

mucosa without advancing it *appreciatively* along the canal."¹ In this process constrictions occur in the circular fibres, with the result that a collection of stationary food is divided into a number of segments. In the middle of each segment constrictions appear and the earlier constrictions relax. Then the latter constrictions relax and the earlier reappear, and so on until the food is thoroughly mixed with digestive secretions. Finally, the food is driven on by peristalsis, coming again to rest, and being again subjected to "rhythmic segmentation." Cannon says that in the duodenum "rhythmic segmentation" lasts for several minutes, but in other parts of the intestine it may continue for half an hour or more, the food which is being subjected to it scarcely moving along the canal. It is probable that in man there are from seven to eight segmentations per minute in a given area. It is also probable that there is a sphincter action at the ileocecal opening.

Cannon divides the large intestine into two parts—a distal part, in which the material is hard and lumpy and is "advanced by rings of tonic contraction," and a proximal part, in which the material is soft. In this part "the common movements are waves of constriction running back-

ward toward the cecum." The resistance of the valve or sphincter enables reversed peristalsis or antiperistalsis to mix the food. When more food enters from the small intestine, antiperistalsis ceases, tonic contraction of the cecum and proximal portion of the colon occurs, some of the food is merged into the transverse colon, and antiperistalsis again begins to act on what remains. The above facts have been observed in animals and are probably true in man.

Innervation.—The vagus fibres of the small intestine seem to excite contraction of the circular fibres after a brief preliminary period of inhibition.² Some observers maintain that the splanchnic fibres are inhibitory, but others claim that they are also motor. The local reflex of the small intestine is in Auerbach's plexus. Cannon quotes Bayliss and Starling to the effect that the pelvic visceral nerves to the large intestine, "arising like the vagus from the central nerve system, are augmentary nerves, whereas the supply from the sympathetic system is purely inhibitory in its action." It is further contended that the pelvic visceral nerves are distributed to the distal colon only. "The region of antiperistalsis does not, therefore, receive motor impulses from the pelvic nerves."

FIG. 1057.—Transverse section of wall of large intestine.

Surface Form.—The coils of the small intestine occupy the front of the abdomen below the transverse colon, and are covered more or less completely by the great omentum. For the most part the coils of the jejunum occupy the left side of the abdominal cavity—i. e., the left lumbar and inguinal regions and the left half of the umbilical region—while the coils of the ileum are situated to the right, in the right lumbar and inguinal regions, in the right half of the umbilical region, and also in the hypogastric region. The cecum is situated in the right inguinal region. Its position varies slightly, but the mid-point of a line drawn from the anterior superior spinous process of the ilium to the symphysis pubis will about mark the middle of its lower border. It is comparatively superficial. From it the ascending colon passes upward through the right lumbar and hypochondriac regions, and becomes more deeply situated as it ascends to the hepatic flexure, which is deeply placed under cover of the liver. The transverse colon crosses the belly transversely on the confines of the umbilical and epigastric regions, its lower border being on a level slightly above the umbilicus, its upper border just below the greater curvature of the stomach. The splenic flexure of the colon is situated behind the stomach in the left hypochondrium, and is on a higher level than the hepatic flexure. The descending colon is deeply seated, passing down through the left hypochondriac and lumbar regions to the sigmoid flexure, which is situated in the left inguinal region, and which can be felt in thin persons, with relaxed abdominal walls, rolling under the fingers when empty, and when distended forming a distinct bulge. The usual position of the base of the vermiform appendix is indicated by a point on the cutaneous surface two inches (5 cm.) from the anterior superior spinous process of the ilium, on a line drawn from this process to the umbilicus. This is known as **McBurney's point**. Another mode of defining the position of the base of the appendix is to draw a line between the anterior superior spines of the ilia and marking the point where this line intersects the right semilunar line.

¹ Medical News, May 20, 1905.

² Bayliss and Starling, Journal of Physiology, 1899.

Upon introducing the finger into the rectum, the membranous portion of the urethra can be felt, if an instrument has been introduced into the bladder, exactly in the middle line; behind and above this the prostate gland can be recognized by its shape and hardness and any enlargement detected; above the prostate the fluctuating wall of the bladder when full can be felt, and if thought desirable it can be tapped in this situation; on either side and behind the prostate the seminal vesicles can be readily felt, especially if enlarged by tuberculous disease. Behind, the coccyx is to be felt, and on the mucous membrane one or two of Houston's folds. The ischio-rectal fossæ can be explored on either side, with a view to ascertaining the presence of deep-seated collections of pus. Finally, it will be noted that the finger is firmly gripped by the sphincter for about an inch (2.5 cm.) up the bowel.

Applied Anatomy.—The small intestine is much exposed to injury, but, in consequence of its elasticity and the ease with which one fold glides over another, it is not so frequently ruptured as would otherwise be the case. Any part of the small intestine may be *ruptured*, but probably the most common situation is the transverse duodenum, on account of its being more fixed than other portions of the bowel, and because it is situated in front of the bodies of the vertebrae, so that if this portion of the intestine is struck a sharp blow, as from the kick of a horse, it is unable to glide out of the way, but is compressed against the bone and lacerated. Wounds of the intestine sometimes occur. If the wound is a small puncture, under, it is said, one-quarter of an inch (6 mm.) in length, there may be no extravasation of the contents of the bowel. The mucous membrane becomes everted and perhaps plugs the little opening. The bowels, therefore, may be punctured with a fine capillary trocar, in cases of excessive distention of the intestine with gas, without much danger of extravasation. A longitudinal wound gapes more than a transverse wound, owing to the greater thickness of the circular muscular coat. In closing a wound of the intestine, use Lembert's inversion sutures, which bring the peritoneal surfaces in contact. Halsted showed that these sutures must include the tough submucous coat. The portions of intestine which lie in the pelvis are inflamed in *pelvic peritonitis* and become embedded in adhesions. The portions of intestine which may be present are the termination of the ileum, the portion of small intestine with the largest mesentery (Treves), the rectum, and the pelvic colon. The small intestine, and most frequently the ileum, may become *strangulated* by internal bands, or through apertures, normal or abnormal. The bands may be formed in several different ways: they may be old peritoneal adhesions from previous attacks of peritonitis; or adherent omentum from the same cause; or the band may be formed by *Meckel's diverticulum*, which has contracted adhesions at its distal extremity; or the band may be the result of the abnormal attachment of some normal structure, as the adhesion of two appendices epiploicae, or an adherent vermiform appendix or Fallopian tube. *Intussusception* or invagination of the small intestine may take place in any part of the jejunum and ileum, but the most frequent situation is at the ileocecal valve, the valve forming the apex of the entering tube. This form may attain great size, and it is not uncommon in these cases to find the valve projecting from the anus. *Stricture, the impaction of foreign bodies, and twisting of the gut (volvulus)* may lead to intestinal obstruction. Volvulus is most common in the sigmoid flexure. Meckel's diverticulum may itself become twisted and strangulated.

Resection of a portion of the intestine may be required in cases of gangrene of the bowel; in cases of intussusception; for the removal of a newgrowth in the bowel; in dealing with artificial anus; and in cases of rupture. The operation is termed *enterectomy*, and is performed as follows: The abdomen having been opened and the amount of bowel requiring removal having been determined upon, the gut must be clamped on either side of this portion in order to prevent the escape of any of the contents of the bowel during the operation. The portion of bowel is then separated above and below by means of scissors. If the portion removed is small, it may be simply removed from the mesentery at its attachment and the bleeding vessels tied; but if it is large, it will be necessary to remove also a triangular piece of the mesentery, and having secured the vessels, suture the cut edges of this structure together. The surgeon then proceeds to unite the cut ends of the bowel. He may do it by the operation termed *end-to-end anastomosis*. There are many ways of doing this, which may be divided into two classes—one, where the anastomosis is made by means of some mechanical appliance, such as Murphy's button, or one of the forms of decalcified bone bobbins; and the other, where the operation is performed by simply suturing the ends of the bowel in such a manner that the peritoneum covering the free divided ends of the bowel is brought into contact, so that speedy union may ensue.

In some cases after resection each open end of the gut is closed, the side of the terminal portion is sutured to the side of the initial portion, a fistula is made in each, and the suturing is completed so as to cause the two fistulae to correspond. A permanent side-to-side opening is thus made. *Lateral anastomosis* without resection may be practised between two pieces of intestine, in order to side-track an intervening portion, which is the seat of malignant disease or of an artificial anus. *Complete exclusion* of a portion of intestine is performed for irremovable tumors or persistent fecal fistulae of the large intestine. The intestine is cut through above and below the diseased area and the ends of the healthy gut are united to each other, or the larger end is closed, an opening is made into the side of the larger end and the smaller end is implanted in it

(*lateral implantation*). The two ends of the excluded portion are fastened to the skin and are left open.

In ascites resulting from cirrhosis of the liver, benefit occasionally follows the performance of *Talma's operation* (*epiploexy*). The abdomen is opened and the omentum is sutured to the anterior abdominal wall or in the abdominal wound, in the hope of establishing a more free communication between the portal and systemic circulations, thus lowering portal pressure.

Hernia.—The two chief sites at which external hernia may take place are the *inguinal region* and the *crural canal*. The description of the inguinal canal and its relations will be found on pages 438 to 440, and that of the crural canal on pages 504 and 686. Some points in regard to the disposition of the peritoneum in these regions may, however, be recapitulated here.

Between the upper margin of the front of the pelvis and the umbilicus, the peritoneum, when viewed from behind, will be seen to be raised into fine folds with intervening depressions, by more or less prominent bands which converge to the umbilicus. The urachus, situated in the middle line, is covered by a fold of peritoneum known as the *plica urachi*. On either side of this a fold of peritoneum around the impervious hypogastric artery forms the *plica hypogastrica*. To either side of these three cords is the deep epigastric artery covered by the *plica epigastrica*. Between these raised folds are depressions constituting the so-called *fossæ*. The most internal, between the *plica urachi* and *plica hypogastrica*, is known as the *internal inguinal fossa* (*fovea supraventricularis*). The middle one is situated between the *plica hypogastrica* and *plica epigastrica*, and is termed the *middle inguinal fossa* (*fovea inguinalis medialis*). The external one is external to the *plica epigastrica* and is known as the *external inguinal fossa* (*fovea inguinalis lateralis*). Occasionally the deep epigastric artery corresponds in position to the impervious hypogastric artery, and then there is but one fold on each side of the middle line. In the usual position of the parts the floor of the external inguinal fossa corresponds to the internal abdominal ring, and into this fossa an oblique inguinal hernia descends. To the inner side of the *plica epigastrica* are the two internal fossæ, and through either of these a direct hernia may descend. The whole of the space between the deep epigastric artery, the margin of the Rectus and Poupart's ligament, is known as **Hesselbach's triangle**. Below the level of Poupart's ligament is a small depression corresponding to the position of the crural ring. It is known as the *femoral fossa*, and into it a femoral hernia descends.

Inguinal Hernia.—Inguinal hernia is that form of protrusion which makes its way through the abdomen in the inguinal region. There are two principal varieties of it—external or oblique, and internal or direct.

In **oblique inguinal hernia** the intestine escapes from the abdominal cavity at the internal ring, pushing before it a pouch of peritoneum which forms the hernial sac. As it enters the inguinal canal it receives an investment from the extraperitoneal tissue and is enclosed in the infundibuliform fascia. In passing along the inguinal canal it displaces upward the arched fibres of the Transversalis and Internal oblique, and receives a covering of Cremaster muscle and cremasteric fascia. It then passes along the front of the spermatic cord and escapes from the inguinal canal at the external ring, becoming invested by intercolumnar fascia. Lastly, it descends into the scrotum, receiving coverings from the superficial fascia and the integument.

The seat of stricture in oblique inguinal hernia is at either the external or internal abdominal ring; most frequently in the latter situation. If it is situated at the external ring, the division of a few fibres at one point of the circumference is all that is necessary for the replacement of the hernia. If at the internal ring, it is necessary to divide the aponeurosis of the External oblique so as to lay open the inguinal canal; in dividing the aponeurosis the incision should be directed parallel to Poupart's ligament, and the constriction at the internal ring should then be divided directly upward.

When the intestine passes along the inguinal canal and escapes from the external ring into the scrotum, it is called complete oblique inguinal or scrotal hernia. If the intestine does not escape from the external ring, but is retained in the inguinal canal, it is called incomplete inguinal hernia or bubonocoele. In each of these cases the coverings which invest it will depend upon the extent to which it descends in the inguinal canal.

There are some other varieties of oblique inguinal hernia (Figs. 1058 to 1062) depending upon congenital defects in the processus vaginalis, the pouch of peritoneum which precedes the descent of the testis. Normally this pouch is closed before birth, closure commencing at two points—viz., at the internal abdominal ring and at the top of the epididymis, and gradually extending until the whole of the intervening portion is converted into a fibrous cord. From failure in the completion of this process, variations in the relation of the hernial protrusion to the testis and tunica vaginalis are produced; these constitute distinct varieties of inguinal hernia—viz., congenital, infantile, encysted, and hernia of the funicular process.

Where the processus vaginalis remains patent throughout, the cavity of the tunica vaginalis communicates directly with that of the peritoneum. The intestine descends along this pouch into the cavity of the tunica vaginalis which constitutes the sac of the hernia, and the gut lies in contact with the testis. Though this form of hernia is termed *congenital*, the term does not imply that the hernia existed at birth, but merely that a condition is present which may allow of the

descent of the hernia at any moment. As a matter of fact, congenital herniæ frequently do not appear until adult life.

Where the processus vaginalis is occluded at the internal ring only and remains patent throughout the rest of its extent, two varieties of oblique inguinal hernia may be produced—viz., infantile

FIG. 1058.—Common scrotal hernia.

FIG. 1059.—Congenital hernia.

FIG. 1060.—Infantile hernia.

FIG. 1061.—Encysted hernia.

FIG. 1062.—Hernia into the funicular process.

FIGS. 1058 TO 1062.—Varieties of oblique inguinal hernia.

and encysted herniæ. In the *infantile* form (Fig. 1060) the bowel pressing upon the septum and the peritoneum in its immediate neighborhood causes it to yield and form a sac which descends behind the tunica vaginalis; so that in front of the bowel there are three layers of peritoneum,

the two layers of the tunica vaginalis and its own sac. In the *encysted* form (Fig. 1061) pressure at the occluded spot causes the septum to yield and form a sac which projects into the tunica vaginalis, forming thus a sac within a sac, so that in front of the bowel there are two layers of peritoneum, one from the tunica vaginalis and one from its own sac.

Where the processus vaginalis is occluded at the lower point only, *i. e.*, just above the testis, the intestine descends into the pouch of peritoneum as far as the testis, but is prevented from entering the sac of the tunica vaginalis by the septum which has formed between it and the pouch. This is known as *hernia into the funicular process*; it resembles the congenital form except that instead of enveloping the testis it lies above it.

In *direct inguinal hernia* the protrusion makes its way through some part of Hesselbach's triangle, either through (a) the outer part, where only extraperitoneal tissue and transversalis fascia intervene between the peritoneum and the aponeurosis of the External oblique; or through (b) the conjoined tendon which stretches across the inner two-thirds of the triangle between the artery and the middle line. In the former the hernial protrusion escapes from the abdomen on the outer side of the conjoined tendon, pushes before it the peritoneum, extraperitoneal tissue, and transversalis fascia, and enters the inguinal canal. It passes along nearly the whole length of the canal and finally emerges from the external ring, receiving an investment from the inter-columnar fascia. The coverings of this form of hernia are similar to those of the oblique form, except that a portion derived from the general layer of transversalis fascia replaces the infundibuliform fascia.

In the second form, which is the more frequent, the hernia is either forced through the fibres of the conjoined tendon, or the tendon is gradually distended in front of it so as to form a complete investment for it. The intestine then enters the lower end of the inguinal canal, escapes at the external ring lying on the inner side of the cord, and receives additional coverings from the external spermatic fascia, the superficial fascia, and the integument. The coverings of this form, therefore, differ from those of the oblique form in that the conjoined tendon is substituted for the cremaster, and the infundibuliform fascia is replaced by a portion of the general layer of the transversalis fascia.

The seat of stricture in both varieties of direct hernia is usually found either at the neck of the sac or at the external ring. In that form which perforates the conjoined tendon it not infrequently occurs at the edges of the fissure through which the gut passes. In all cases of inguinal hernia, whether direct or oblique, it is proper to divide the stricture directly upward; by cutting in this direction the incision is made parallel to the deep epigastric artery—external to it in the oblique variety, internal to it in the direct form of hernia; all chance of wounding the vessel is thus avoided. Direct inguinal hernia is of much less frequent occurrence than the oblique, and is found more often in men than in women. The main differences in position between it and the oblique form are: (a) it is placed over the pubis and not in the course of the inguinal canal; (b) the deep epigastric artery runs on the outer or iliac side of the neck of the sac; and (c) the spermatic cord lies along its external and posterior sides, not directly behind it, as in oblique inguinal hernia.

Femoral Hernia.—In femoral hernia the protrusion of the intestine takes place through the crural ring. As already described (p. 504), this ring is closed by the septum crurale, a partition of modified extraperitoneal tissue; it is, therefore, a weak spot in the abdominal wall, and especially in the female, where the ring is larger and where profound changes are produced in the tissues of the abdomen by pregnancy. Femoral hernia is, therefore, more common in women than in men.

When a portion of intestine is forced through the femoral ring it carries before it a pouch of peritoneum which forms the hernial sac. It receives an investment from the extraperitoneal tissue or septum crurale and descends along the femoral canal, or inner compartment of the sheath of the femoral vessels, as far as the saphenous opening; at this point it changes its course, being prevented from extending farther down the sheath on account of the narrowing of the latter, and its close contact with the vessels, and also from the close attachment of the superficial fascia and femoral sheath to the lower part of the circumference of the saphenous opening. The tumor is consequently directed forward, pushing before it the cribriform fascia, and then curves upward over Poupart's ligament and the lower part of the External oblique, being covered by the superficial fascia and integument. While the hernia is contained in the femoral canal it is usually of small size owing to the resisting nature of the surrounding parts, but when it escapes from the saphenous opening into the loose areolar tissue of the groin it becomes considerably enlarged. The direction taken by a femoral hernia in its descent is at first downward, then forward and upward; in the application of taxis for the reduction of a femoral hernia, therefore, pressure should be directed in the reverse order.

The coverings of a femoral hernia, from within outward, are peritoneum, septum crurale, femoral sheath, cribriform fascia, superficial fascia, and integument. Sir Astley Cooper has described an investment for femoral hernia under the name of *fascia propria*, lying immediately external to the peritoneal sac but frequently separated from it by some adipose tissue. Surgically it is important to remember the frequent existence of this layer on account of the ease with

which an inexperienced operator may mistake the fascia for the peritoneal sac and the contained fat for omentum, as there is often a great excess of subperitoneal fatty tissue enclosed in the "fascia propria." In many cases it resembles a fatty tumor, but on further dissection the true hernial sac will be found in the centre of the mass of fat. The fascia propria is merely modified extraperitoneal tissue which has been thickened to form a membranous sheet by the pressure of the hernia.

When the intestine descends along the femoral canal only as far as the saphenous opening the condition is known as incomplete femoral hernia. The small size of the protrusion in this form of hernia, on account of the firm and resisting nature of the canal in which it is contained, renders it an exceedingly dangerous variety of the disease from the extreme difficulty of detecting the existence of the swelling, especially in corpulent subjects. The coverings of an incomplete femoral hernia would be, from without inward, integument, superficial fascia, superior falciform process of fascia lata, femoral sheath, septum crurale, and peritoneum.

The seat of stricture of a femoral hernia varies; it may be in the peritoneum at the neck of the hernial sac; in the greater number of cases it is at the point of junction of the superior falciform process with the free edge of Gimbernat's ligament; or it may be at the margin of the saphenous opening. The stricture should in every case be divided in a direction upward and inward for a distance of about one-sixth to one-quarter of an inch. All vessels or other structures of importance in relation to the neck of the sac will thus be avoided.

The spine of the pubis forms an important landmark in serving to differentiate the inguinal from the femoral variety of hernia. The inguinal protrusion is above and to the inner side of the spine, while the femoral is below and to its outer side.

By the term *internal hernia*, we mean hernia into the foramen of Winslow, into the retro-duodenal fossa, into the retrocecal fossa, or into the intersigmoid fossa. Such a hernia produces the symptoms of acute strangulation of the intestine.

In *typhoid fever* there is ulceration of Peyer's patches. One of these ulcers may *perforate*. The only chance for life is immediate laparotomy and closure of the perforation. This saves one-fifth, or possibly one-third, of the cases. The incision is made to expose the lower ileum, as in the vast majority of cases the perforation is in this portion of the gut.

The surgical anatomy of the rectum is of considerable importance. There may be congenital malformation due to arrested or imperfect development. Thus, there may be no invagination of the ectoderm, and consequently a complete absence of the anus; or the hind gut may be imperfectly developed, and there may be an absence of the rectum, though the anus is developed; or the invagination of the ectoderm may not communicate with the termination of the hind gut from want of solution of continuity in the septum which in early fetal life exists between the two. The mucous membrane is thick and but loosely connected to the muscular coat beneath and thus favors *prolapse*, especially in children. The vessels of the rectum are arranged as mentioned above, longitudinally, and are contained in the loose cellular tissue between the mucous and muscular coats, and receive no support from surrounding tissues, and this favors varicosity. Moreover, the veins, after running upward in a longitudinal direction for about five inches in the submucous tissue, pierce the muscular coats, and are liable to become constricted at this point by the contraction of the muscular wall of the gut. In addition to this there are no valves in the superior hemorrhoidal veins, and the vessels of the rectum are placed in a dependent position, and are liable to be pressed upon and obstructed by hardened feces. The anatomical arrangement, therefore, of the hemorrhoidal vessels explains the great tendency to the occurrence of piles. The presence of the Sphincter ani is of surgical importance, since it is the constant contraction of this muscle which prevents an *ischio-rectal abscess* from healing and tends to cause a fistula. Also, the reflex contraction of this muscle is the cause of the severe pain complained of in *fissure of the anus*. The relations of the peritoneum to the rectum are of importance in connection with the operation of removal of the lower end of the rectum for malignant disease. The membrane gradually leaves the rectum as it descends into the pelvis; first leaving its posterior surface, then the sides, and then the anterior surface, to become reflected in the male on to the posterior wall of the bladder, forming the rectovesical pouch, and in the female on to the posterior wall of the vagina, forming Douglas' pouch. The rectovesical pouch of peritoneum extends to within three inches (7.5 cm.) from the anus, so that it is not desirable to remove more than two and a half inches (6.25 cm.) of the entire circumference of the bowel, for fear of the risk of opening the peritoneum. When, however, the disease is confined to the posterior surface of the rectum, or extends farther in this direction, a greater amount of the posterior wall of the gut may be removed, as the peritoneum does not extend on this surface to a lower level than five inches from the margin of the anus. The rectovaginal or Douglas' pouch in the female extends somewhat lower than the rectovesical pouch of the male, and therefore it is advisable to remove a less length of the tube in this sex. Of recent years, however, much more extensive operations have been done for the removal of cancer of the rectum, and in these the peritoneal cavity has necessarily been opened. If, in these cases, the opening is plugged with iodoform gauze until the operation is completed, and then the edges of the wound in the peritoneum are accurately brought together with sutures, no evil result appears to follow. For cases

of cancer of the rectum which are too low to be reached by abdominal section, and too high to be removed by the ordinary operation from below, Kraske has devised an operation which goes by his name. The patient is placed on his right side and an incision is made from the second sacral spine to the anus. The soft parts are now separated from the back of the left side of the sacrum as far as its left margin, and the greater and lesser sacrosacral ligaments are divided. A portion of the lateral mass of the sacrum, commencing on the left border at the level of the third posterior sacral foramen, and running downward and inward through the fourth foramen to the cornu, is now cut away with a chisel. The left side of the wound being now forcibly drawn outward, the whole of the rectum is brought into view, and the diseased portion can be removed, leaving the anal portions of the gut, if healthy. The two divided ends of the gut can perhaps then be approximated and sutured together. Kraske's operation is in many cases preceded by the performance of iliac colostomy. In cancer high up in the rectum removal of the growth through the abdomen is sometimes practised, the divided lower end of the rectum being sutured to the divided upper end (Weir's operation).

The colon frequently requires opening in cases of intestinal obstruction, and by some surgeons this operation is performed in cases of cancer of the rectum, as soon as the disease is recognized, in the hope that the rate of growth may be retarded by removing the irritation produced by the passage of fecal matter over the diseased surface. The operation of *colostomy* may be performed either in the inguinal or lumbar region; but *inguinal colostomy* (Maydl's operation) has at the present day superseded the lumbar operation. The main reason for preferring this operation is that a spur-shaped process of the mesocolon can be formed, which prevents any fecal matter finding its way past the artificial anus and becoming lodged on the diseased structures below. The sigmoid flexure being surrounded by peritoneum, a coil can be drawn out of the wound, and when it is opened transversely a spur is formed, and this prevents any fecal matter finding its way from the gut above the opening into that below. The operation is performed by making an incision two or three inches in length from a point one inch internal to the anterior superior spinous process of the ilium, parallel to Poupart's ligament. The various layers of abdominal muscles are cut through, and the peritoneum opened and sewed to the external skin. The sigmoid flexure is now sought for, and pulled out of the wound and fixed by pushing a glass bar through a slit in the mesocolon. The two parts of the loop are sutured together. The intestine is now sutured to the parietal peritoneum. The wound is dressed, and either immediately or between the second to the fourth day, according to the requirements of the case, the protruded coil of intestine is opened. It is opened transversely with the Paquelin cautery.

The loose connective tissue around the rectum is occasionally the site of an abscess, the active focus of which, however, may be located elsewhere. This form of abscess may be described as the *superior pelvic rectal*; it is placed above the pelvic diaphragm, but beneath the peritoneum. The acute variety is generally due to ulceration or perforation of the bowel (possibly produced by a foreign body) above the level of the attachment of the Levator ani. The abscess may also occur above a stricture (simple or malignant) of the rectum; occasionally it arises from suppuration around the prostate, and more rarely follows abscess of the seminal vesicles. Chronic abscesses also appear in the same region either from caries of the anterior surface of the sacrum or from caseation of the presacral lymph nodes, while in other cases an abscess finds its way down into the pelvis from disease of the anterior surfaces of the bodies of the lumbar vertebral.

THE LIVER (HEPAR) (Figs. 1063, 1064).

The liver is the largest gland in the body and is situated in the upper and right part of the abdominal cavity, occupying almost the whole of the right hypochondrium, the greater part of the epigastrium, and not uncommonly extending into the left hypochondrium as far as the midclavicular line. In the male it weighs from fifty to sixty ounces; in the female, from forty to fifty. It is relatively much larger in the fetus than in the adult, constituting, in the former, about one-eighteenth, and in the latter, about one-thirty-sixth of the entire body weight. Its greatest transverse measurement is from eight to nine inches (20 to 22 cm.). Vertically, near its lateral or right surface, it measures about six or seven inches (15 to 18 cm.), while its greatest antero-posterior diameter is on a level with the upper end of the right kidney and is from four to five inches (10 to 12 cm.). Opposite the vertebral column its measurement from before backward is reduced to about three inches (7.5 cm.). Its consistence is that of a soft solid; it is, however, friable and easily lacerated; its color is a dark reddish brown, and its specific gravity is 1.05.

To obtain a correct idea of its shape, it must be hardened *in situ*, and it will then be seen to present the appearance of a wedge, the base of which is directed to the right and the thin edge toward the left. Symington describes its shape as that "of a right-angled triangular prism with the right angles rounded off."

Surfaces.—The liver possesses five surfaces—viz., a **superior**, **inferior**, **anterior**, **posterior**, and a **right, lateral surface**. A sharp, well-defined margin divides the inferior from the anterior and lateral surfaces, but the other surfaces are separated from one another by thick, rounded borders. The superior and anterior surfaces are separated from each other by a thick rounded border, and are attached to the Diaphragm and anterior abdominal wall by a triangular or falciform fold of peritoneum, the **suspensory or falciform ligament**, in the free margin of which is a rounded cord, the **ligamentum teres** or impervious umbilical vein. The line of attachment of the falciform ligament divides the liver into two unequal parts, termed the **right and left lobes**, the right being much the larger. The inferior and posterior surfaces are divided into five lobes by five fissures, which are arranged in the form

FIG. 1063.—The liver. Upper surface. (Drawn from His' model.)

of the letter H. The left limb of the H marks on these surfaces the division of the liver into right and left lobes; it is known as the **longitudinal fissure**, and consists of two parts—viz., the **umbilical fissure** in front and the **fissure for the ductus venosus** behind. The right limb of the H is formed in front by the **fissure or fossa for the gall-bladder**, and behind by the **fissure for the inferior vena cava**; these two fissures are separated from one another by a band of liver substance, termed the **caudate lobe**. The bar connecting the two limbs of the H is the **transverse or portal fissure**; in front of it is the **quadrate lobe**, behind it is the **Spigelian lobe**.

The **superior surface** (*facies superior*) (Fig. 1063) comprises a part of both lobes, and, as a whole, is convex, and fits under the vault of the Diaphragm; its central part, however, presents a shallow depression, the **cardiac depression** (*impressio cardiaca*), which corresponds with the position of the heart on the upper surfaces of the Diaphragm. It is separated from the anterior, posterior, and lateral surfaces by thick, rounded borders. Its left extremity is continued into the under surface by a prominent sharp margin. Except along the lines of attachment of the falciform ligament this surface is completely covered by peritoneum.

The **anterior surface** is large, triangular in shape, and comprises also a part of both right and left lobes. It is directed forward, and the greater part of it is in

contact with the Diaphragm, which separates it on the right from the sixth to the tenth ribs and their cartilages, and on the left from the seventh and eighth costal cartilages. In the middle line it lies behind the ensiform cartilage, and in the angle between the diverging rib cartilages of opposite sides the anterior surface is in contact with the abdominal wall. It is separated from the inferior surface by a sharp margin, and from the superior and lateral surfaces by thick rounded borders. It is completely covered by peritoneum except along the line of attachment of the falciform ligament.

The **lateral or right surface** (Figs. 1063 and 1064) is convex from before backward and slightly so from above downward. It is directed toward the right side, forming the base of the wedge, and lies against the lateral portion of the Diaphragm, which separates it from the lower part of the left pleura and lung, outside which are the right costal arches from the seventh to the eleventh inclusive.

The **inferior or visceral surface** (*facies inferior*) (Figs. 1064 and 1065) is uneven, concave, directed downward, backward, and to the left, and is in relation with the stomach and duodenum, the hepatic flexure of the colon, and the right kidney and suprarenal glands. The surface is divided by a longitudinal fissure into a right and a left lobe, and is almost completely invested by peritoneum; the only parts where this covering is absent are where the gall-bladder is attached to the liver and at the transverse fissure, where the two layers of the lesser omentum are separated from each other by the bloodvessels and duct of the viscus. The under surface of the left lobe presents to the right and near the centre a rounded eminence, the **omental tuberosity** (*tuber omentale*) (Fig. 1064), which is in contact with the lesser omentum. It is surrounded by a broad depression, the **gastric surface** or **impression** (*impressio gastrica*), with which the stomach is in contact. Between the gall-bladder and the left lobe is the **quadrate lobe**. The quadrate lobe is bounded to the left by the **umbilical fissure** or the **fissure for the umbilical vein** (*fossa venae umbilicalis*), which is the anterior portion of the longitudinal fissure and lodges the **round ligament**. The under surface of the right lobe is divided into two unequal portions by a fossa, which lodges the gall-bladder and is called the **fossa vesicalis** (*fossa vesicae felleae*). The portion to the left, the smaller of the two, is the **quadrate lobe**, and is in relation with the pyloric end of the stomach (*impressio pylorica*) and the first portion of the duodenum. The portion of the under surface of the right lobe to the right of the fossa vesicalis presents two shallow concave impressions, one situated behind the other, the two being separated by a ridge. The anterior of these two impressions, the **colic impression** (*impressio colica*), is produced by the hepatic flexure of the colon; the posterior, the **renal impression** (*impressio renalis*), is occupied by the upper end of the right kidney and lower part of the suprarenal gland (Fig. 1064). To the inner side of the renal impression is a third and slightly marked impression, lying between it and the neck of the gall-bladder. This is caused by the second portion of the duodenum, and is known as the **duodenal impression** (*impressio duodenalis*). Just in front of the inferior vena cava is a narrow strip of liver tissue, the **caudate lobe**, which connects the right inferior angle of the Spigelian lobe to the under surface of the right lobe. It forms the upper boundary of the foramen of Winslow.

The **posterior surface** (*facies posterior*) (Fig. 1065) is rounded and broad behind the right lobe, but narrow on the left. Over a large part of its extent it is not covered by peritoneum; this **uncovered area** (Fig. 1064) is about three inches (7.5 cm.) broad, and is in direct contact with the Diaphragm, being united to it by areolar tissue. It is marked off from the upper surface by the line of reflection of the upper or anterior layer of the coronary ligament and from the under surface of the liver by the line of reflection of the lower layer of the coronary ligament (Fig. 1066). The central part of the posterior surface presents a deep concavity which is moulded on the vertebral column and crura of the Diaphragm. To the

right of this the inferior vena cava is lodged in an indentation in the liver substance, lying between the uncovered area and the Spigelian lobe. Close to the right of this indentation and immediately above the renal impression is a small triangular depressed area, the **suprarenal impression** (*impressio suprarenalis*) (Fig. 1064), the greater part of which is devoid of peritoneum; it lodges the right suprarenal gland, which is inserted between the liver and Diaphragm. To the left of the fossa for the inferior vena cava is the **Spigelian lobe**, which lies between the fissure for the inferior vena cava and the fissure for the ductus venosus. Below and in front it projects and forms part of the posterior boundary of the transverse fissure. Here, to the right, it is connected with the under surface of the right lobe of the liver by the caudate lobe, and to the left it presents a tubercle, the **tuberculum papillare** (Fig. 1064). It is opposite the tenth and eleventh thoracic vertebræ, and rests upon the aorta and crura of the Diaphragm, being covered by the peritoneum of the lesser sac. On the posterior surface to the left of the Spigelian lobe is a groove, the **oesophageal groove** (*impressio oesophagea*), indicating the position of the abdominal portion of the oesophagus (Fig. 1064).

FIG. 1064.—The liver. Posterior and inferior surfaces. (Drawn from His' model.)

The **inferior border or margin** (*margo inferioris*) is thin and sharp, and marked opposite the attachment of the falciform ligament by a deep notch, the **umbilical notch** (*incisura umbilicalis*), and opposite the cartilage of the ninth rib by a second notch for the fundus of the gall-bladder (*incisura vesicae felleae*). In adult males this border generally corresponds with the lower margin of the thorax in the right midclavicular line; but in women and children it usually projects below the ribs.

The **left extremity of the inferior margin of the liver** is thin and flattened from above downward.

Fissures.—Five fissures are seen upon the under and posterior surfaces of the liver, which serve to divide it into its five lobes. They are: the **umbilical fissure**, the **fissure for the ductus venosus** (forming together the longitudinal fissure), the **transverse fissure**, the **fissure for the gall-bladder**, and the **fissure for the inferior vena cava**.

The **longitudinal fissure** (*fossa longitudinalis sinistra*) is a deep groove, which extends from the notch on the anterior margin of the liver to the upper border of the posterior surface of the organ. It separates the right and left lobes, the transverse fissure (Fig. 1064) joins it, at right angles, and divides it into two parts. The anterior part, or **umbilical fissure** (*fossa venae umbilicalis*), lodges the umbilical

vein in the fetus, and its remains (*ligamentum teres*) in the adult; it lies between the quadrate lobe and the left lobe of the liver, and is often partially bridged over by a prolongation of the hepatic substance, the *pons hepatis*. The posterior part or fissure for the ductus venosus (*fossa ductus venosi*) lies between the left lobe and the Spigelian lobe; it lodges in the fetus the ductus venosus, and in the adult a slender fibrous cord (*lig. venosum*) the impervious remains of that vessel.

The transverse or portal fissure (*porta hepatis*) (Fig. 1064) is a short but deep fissure, about two inches (5 cm.) in length, extending transversely across the under surface of the left portion of the right lobe, nearer to its posterior surface than its anterior border. It joins, nearly at right angles, with the longitudinal fissure, and separates the quadrate lobe in front from the caudate and Spigelian lobes behind. By the older anatomists this fissure was considered the gateway (*porta*) of the liver; hence the large vein which enters at this fissure was called the **portal vein** (Fig. 1065). Besides this vein, the fissure transmits the hepatic artery and nerves, and the hepatic duct and lymphatics. At their entrance into the fissure, the hepatic duct lies in front and to the right, the hepatic artery to the left, and the portal vein behind and between the duct and artery.

FIG. 1065.—Posterior and under surfaces of the liver. (Drawn from His' model.)

The *fossa* or fissure for the gall-bladder (*fossa vesicae felleae*) is a shallow, oblong fossa, placed on the under surface of the right lobe, parallel with the longitudinal fissure. It extends from the anterior free margin of the liver, which is notched for its reception, to the right extremity of the transverse fissure.

The fissure for the inferior vena cava (*fossa venae cavae*) (Fig. 1064) is a short, deep fissure, in some cases a complete canal, in consequence of the substance of the liver occasionally surrounding this vessel. It extends obliquely upward from the lobus caudatus, which separates it from the transverse fissure on the posterior surface of the liver, and is situated between the Spigelian lobe and the bare area of the liver. On slitting open the inferior vena cava the orifices of the hepatic veins will be seen opening into this vessel at its upper part, after perforating the floor of this fissure.

Lobes.—The lobes of the liver, like the ligaments and fissures, are five in number—the right lobe, the left lobe, the lobus quadratus, the lobus Spigelii, and the lobus caudatus, the last three being merely parts of the right lobe.

The **right lobe** (*lobus hepatis dexter*) (Figs. 1063 and 1064) is much larger than the left, the proportion between them being as six to one. It occupies the right hypochondrium, and is separated from the left lobe, on its upper and anterior surfaces, by the falciform ligament; on its under and posterior surfaces by the longitudinal fissure; and in front by the umbilical notch. It is of a somewhat quadrilateral form, its under and posterior surfaces being marked by three fissures—the transverse fissure, the fissure for the gall-bladder, and the fissure for the inferior vena cava, which separate its left part into three smaller lobes—the lobus Spigelii, lobus quadratus, and lobus caudatus. On it are seen four shallow impressions—one in front, for the hepatic flexure of the colon; a second behind, for the right kidney; a third internal, between the last-named and the gall-bladder, for the second part of the duodenum; and a fourth on its posterior surface, for the suprarenal gland.

The **lobus quadratus** (Figs. 1064 and 1065) is situated on the under surface of the right lobe, is bounded in front by the inferior margin of the liver; behind, by the transverse fissure; on the right, by the fissure of the gall-bladder; on the left, by the umbilical fissure. It is oblong in shape, its antero-posterior diameter being greater than its transverse.

The **lobus Spigelii** (*lobus caudatus* [*Spigelii*]) (Figs. 1064 and 1065) is situated upon the posterior surface of the right lobe of the liver. It looks directly backward, and is nearly vertical in direction. It is bounded below by the transverse fissure, on the right by the fissure for the inferior vena cava, and on the left by the fissure for the ductus venosus. It is longer from above downward, and is somewhat concave in the transverse direction. Its lower end usually projects in the form of a rounded process, the **tuber papillare** (*processus papillaris*).

The **lobus caudatus** (*processus caudatus*) (Fig. 1064), or tailed lobe, is a small elevation of the hepatic substance extending obliquely outward, from the lower extremity of the Spigelian lobe to the under surface of the right lobe. It is situated behind the transverse fissure, and separates the fissure for the gall-bladder from the commencement of the fissure for the inferior vena cava.

The **left lobe** (*lobus hepatis sinister*) (Figs. 1063 and 1064) is smaller and more flattened than the right. It is situated in the epigastric and left hypochondriac regions. Its upper surface is slightly convex; its under surface is concave, and presents a shallow depression for the stomach, the **gastric impression**. This is situated in front of the groove for the œsophagus, and is separated from the longitudinal fissure by the **omental tuberosity**, which lies against the small omentum and lesser curvature of the stomach. The posterior end of the left lobe frequently exhibits a flat projection, composed of connective tissue, and called the **appendix fibrosus hepatis**. In the adult, portions only of bile ducts are present in it. In the newborn it is a definite portion of secreting liver substance, which later undergoes connective-tissue transformation.

Ligaments.—The liver is connected to the under surface of the Diaphragm and the anterior walls of the abdomen by five ligaments, four of which are peritoneal folds; the fifth is a round, fibrous cord, resulting from the occlusion of the umbilical vein. These ligaments are the **falciform**, two **lateral**, **coronary**, and **round**. It is also attached to the lesser curvature of the stomach by the gastro-hepatic or small omentum (p. 1260).

The **falciform ligament** (*ligamentum falciforme hepatis*) (Figs. 1066 and 1067) is a broad and thin antero-posterior peritoneal fold, falciform in shape, its base being directed downward and backward, its apex upward and backward. It is attached by one margin to the under surface of the Diaphragm, and the posterior surface of the sheath of the right Rectus muscle as low down as the umbilicus; by its hepatic margin it extends from the notch on the anterior margin of the liver, as far back as its posterior surface. It is composed of two layers of peritoneum closely united. Its free edge contains the round ligament of the liver.

The **coronary ligament** (*ligamentum coronarium hepatis*) (Figs. 1063 and 1066) connects the posterior surface of the liver to the Diaphragm. It consists of two layers. The *upper layer* is formed by the reflection of the peritoneum from the upper margin of the bare area of the liver to the under surface of the Diaphragm, and is continuous with the right layer of the falciform ligament. The *lower layer* is reflected from the lower margin of the bare area on to the right kidney and suprarenal gland.

FIG. 1066.—The peritoneal ligaments of the liver. (Schematic.) (Poirier and Charpy.)

The **lateral ligaments** (Figs. 1063 and 1066) are two in number, and are called the **right and left lateral ligaments**.

The **right lateral ligament** (*ligamentum triangulare dextrum*) (Figs. 1063 and 1066) is in reality the right extremity of the coronary ligament. This ligament is triangular in form, runs from the liver to the Diaphragm, and is formed by the apposition of the upper and lower layers of the coronary ligament.

The **left lateral ligament** (*ligamentum triangulare sinistrum*) (Figs. 1063 and 1066) is a fold of some considerable size, which connects the posterior part of the upper surface of the left lobe to the Diaphragm; its anterior layer is continuous with the left layer of the falciform ligament.

The **round ligament** (*ligamentum teres hepatis*) (Figs. 1065 and 1067) is a fibrous cord resulting from the occlusion of the fetal umbilical vein. It ascends from the umbilicus, in the free margin of the falciform ligament, to the notch in the anterior border of the liver, from which it may be traced along the umbilical fissure on the inferior surface of the

FIG. 1067.—Diagram to show the relations of the falciform or suspensory and round ligaments to the liver and the abdominal wall. (Gerrish.)

liver; on the posterior surface it is continued upward as the impervious ductus venosus (*lig. venosum*) as far as the inferior vena cava.

Support and Movability of the Liver.—The liver is movable within certain narrow limits. It moves with respiration. On inspiration it moves down with the Diaphragm to distinctly below the costal arch in the right midclavicular line. Its fixation to the under surface of the Diaphragm by means of connective tissue gives it its strongest support.

Abnormalities of the Liver.—The liver may be divided into many lobules, and such lobulation is most evident on the parietal surface of the right lobe. Lobulation is probably a pathological change. Occasionally the right lobe is small and the left large.

Accessory Livers are fragments of hepatic tissue or rests, which are entirely separated from the liver. They are seldom met with. When they do exist their most common situation is in the suspensory ligament, but they have been found in the great omentum, in the peritoneum, wall of the gall-bladder, and in other situations. They may be congenital or may be due to atrophy of the pedicle of an accessory lobe or of a pedunculated lobe. **Tight lacing** alters the shape and position of the liver (Fig. 1068). It may flatten the dome and increase the length of the anterior surface, this change being especially obvious in the right lobe, and a costal groove may be formed by the pressure of a rib. "When the elongated right lobe passes over the right kidney, there is atrophy of the hepatic substance and thickening of the capsule, which is opaque and forms a hinge-like ligament between the main part of the right lobe above the constricted lower portion. This lobe is variously termed **partial hepatoptosis**, **constriction lobe**, or the **sustentacular formation of the right lobe** (Hertz). The constriction furrow is produced by the pressure of the corset in front and the resistance of the kidney behind. The constriction lobe tapers to a point, so that the shape of the liver, as seen from the front, is that of a right-angled triangle, with the apex downward."¹ Such a constriction lobe is known as **Riedel's lobe**. The left lobe may also project down, but not so markedly. Tight lacing may cause the entire organ

FIG. 1068.—Deformed female liver. (Poirier and Charpy.)

to occupy a level higher than normal. Such a liver is thick and excessively convex above and thin below, and reaches to or laps over the spleen. In severe cases the superior surface is thrown into antero-posterior creases or folds. Riedel's lobe (Fig. 1068) may be congenital, may be due to tight lacing, or may arise in cholelithiasis or cholecystitis from the traction of adhesions. Such a lobe comes off from the right lobe. It may be a tapering mass of liver tissue, it may have a thin pedicle of liver tissue, or its pedicle may be merely a double fold of peritoneum. The gall-bladder may lie upon its under surface, or may be placed to the left of it.

Vessels.—The bloodvessels connected with the liver are the **hepatic artery**, the **portal vein**, and the **hepatic veins**.

The **hepatic artery** and **portal vein** (Figs. 468, 469, 557, and 1069), accompanied by numerous lymphatics and nerves, ascend to the transverse fissure between the layers of the gastrohepatic omentum, and in front of the foramen of Winslow. The **hepatic duct**, lying in company with them, descends from the transverse fissure between the layers of the same omentum. The relative position of the three structures in the lesser omentum (Fig. 984) is as follows: The hepatic

¹ Rolleston, on Diseases of the Liver.

duct lies to the right, the hepatic artery to the left, and the portal vein behind and between the other two. They enter the transverse fissure in the above-described order, but in that fissure undergo rearrangement, the duct being in front, the artery in the middle, and the vein behind. The artery, the vein, and the duct divide into a right and left branch and several smaller branches, and within the organ the vessels from the three sources accompany each other and divide at the

FIG. 1069.—Schematic section of the liver. The fibrous tunic is shown in black and the capsule of Glisson in red.

same points; so each branch of the portal vein is accompanied by a branch of the hepatic artery and of the duct. They are enveloped in a loose areolar tissue, the **capsule of Glisson** (Fig. 1069), which accompanies the vessels in their course through the *portal canals* in the interior of the organ.

The **hepatic veins** (Fig. 472) convey the blood from the liver. They commence in the substance of the liver, in the capillary terminations of the portal vein and hepatic artery; these tributaries, gradually uniting, usually form three veins, which converge toward the posterior surface of the liver and open into the portion of the inferior vena cava situated in the groove at the back part of this organ. Of these three veins, one from the right and another from the left lobe open obliquely into the inferior vena cava, that from the middle of the organ and lobus Spigelii having a straight course.

FIG. 1070.—The relations of the vessels as they pass into the transverse fissure of the liver. (Poirier and Charpy.)

The hepatic veins have very little cellular investment; what there is binds their parietes closely to the walls of the canals through which they run; so that, on section of the organ, these veins remain widely open and solitary (Fig. 1072), and may be easily distinguished from the branches of the portal vein (Fig. 1073), which are more or less collapsed, and always accompanied by an artery and duct; the hepatic veins are destitute of valves.

Structure.—The substance of the liver is composed of **lobules** held together by extremely fine areolar tissue, and of the ramifications of the portal vein, hepatic duct, hepatic artery, hepatic veins, lymphatics, and nerves, the whole being invested by a serous and fibrous coat.

The **serous coat** (*tunica serosa*) is derived from the peritoneum, and invests the greater part of the surface of the organ. It is intimately adherent to the fibrous coat.

The **areolar or fibrous coat** (*capsula fibrosa* [Glissoni]) lies beneath the serous investment and covers the entire surface of the organ; it is called the **capsule of Glisson**; the latter term has also been retained for the heavy fibrous tissue, at the portal fissure, that envelops and accompanies the vessels into the liver. It is difficult of demonstration, excepting where the serous coat is deficient. The areolar tissue which surrounds and binds together the liver lobules is continuous with the areolar coat.

The Lobules (*lobuli hepatis*) (Fig. 1076).—The lobules form the chief mass of the hepatic substance; they may be seen either on the surface of the organ or by making a section through the gland. They are small granular bodies about the size of a millet seed, measuring from one-twentieth to one-tenth of an inch in diameter. In the human subject their outline is very irregular, but in some of the lower animals (for example, the pig) they are well defined, and when divided transversely have a polygonal outline. If divided longitudinally they are more or less foliated or oblong. The bases of the lobules are clustered around the smallest radicles of the hepatic veins (*sublobular veins*), to which each is connected by means of a small branch which issues from the centre of the lobule (*intralobular vein*). The remaining part of the surface of each lobule is imperfectly isolated from the surrounding lobules by a thin stratum of areolar tissue in which are **ducts** and a plexus of vessels, the **interlobular plexus** (Figs. 1074 and 1075). In some animals, as the pig, the lobules are completely isolated from one another by this interlobular areolar tissue.

If one of the sublobular veins be laid open, the bases of the lobules may be seen through the thin wall of the vein on which they rest, arranged in the form of a tessellated pavement, the centre of each polygonal space presenting a minute aperture, the mouth of an intralobular vein (Fig. 1072).

FIG. 1071.—The hepatic cells at different stages of digestion. (Heidenhain.)

Microscopic Appearance.—Each lobule is composed of irregular, anastomosing chains of cells, **hepatic cells** (Fig. 1071), surrounded by a dense capillary plexus, composed of vessels which penetrate from the circumference to the centre of the lobule, and terminate in a single straight central vein, which runs through its centre, to open at its base into one of the radicles of the hepatic vein. These structures are supported by a delicate meshwork of retiform connective tissue. Within the chains of the cells are the minute commencements of the bile ducts. Therefore, in the lobule we have all the essentials of a secreting gland; that is to say, (1) **cells**, by which the secretion is formed; (2) **bloodvessels**, in close relation with the cells, containing the blood from which the secretion is derived; and (3) **ducts**, by which the secretion, when formed, is carried away. Each of these structures will have to be further considered.

1. The **hepatic cells** are epithelial in nature and of more or less cuboidal or polygonal form. They vary in size from the $\frac{1}{1000}$ to the $\frac{1}{100}$ of an inch in diameter; they consist of a granular protoplasm without any cell wall, and contain one or sometimes two distinct nuclei. In the nucleus is a highly refracting nucleolus with granules. Embedded in the protoplasm are numerous brownish particles, the coloring matter of the bile, oil globules, and glycogen granules in varying quantities. Secretory capillaries are to be found in the cells. The cells adhere together by their surfaces so as to form rows, which radiate from the centre to the circumference of the lobules. As stated above, they are the chief agents in the secretion of the bile.

2. **The Bloodvessels.**—The blood in the capillary plexus around the liver cells is brought to the liver principally by the portal vein, but also to a certain extent by the hepatic artery. For the sake of clearness the distribution of the blood derived from the hepatic artery may be considered first.

The **hepatic artery**, entering the liver at the transverse fissure with the portal vein and hepatic duct, ramifies with these vessels through the portal canals. It gives off **vaginal branches** which

¹ According to Mall (Jour. of Anat., vol. v, No. 3), the lobule as here described is not his *structural unit*, which refers to all the tissue surrounding each terminal branch of the portal vein.

ramify in the interlobular tissue, and appear to be destined chiefly for the nutrition of the coats of the large vessels, the ducts, and the investing membrane of the liver. It also gives off **capsular branches** which reach the surface of the organ, terminating in the fibrous coat in stellate plexuses. Finally, it gives off **interlobular branches** (*rami arteriosi interlobulares*) which form a plexus of capillaries (*interlobular capillaries*) on the outer side of each lobule, to supply its wall and the accompanying bile ducts. From this plexus some lobular branches enter the lobule and end in the capillary network between the cells.

FIG. 1072.—Longitudinal section of an hepatic vein. (After Kiernan.)

FIG. 1073.—Longitudinal section of a small portal vein and canal. (After Kiernan.)

The **portal vein** also enters at the transverse fissure and runs through the portal canals, dividing into branches in its course, which finally break up into a plexus, the **interlobular plexus**, in the interlobular connective tissue. In their course these branches receive the vaginal and capsular veins, corresponding to the vaginal and capsular branches of the hepatic artery (Fig. 1073). Thus it will be seen that all the blood carried to the liver by the portal vein and hepatic

FIG. 1074.—Horizontal section of injected liver (dog).

artery, except perhaps that derived from the interlobular branches of the hepatic artery, directly or indirectly finds its way into the interlobular plexus. From this plexus the blood is carried into the lobule by fine branches which pierce its wall and then converge from the circumference to the centre of the lobule, forming a number of converging vessels, **intralobular capillaries**, which are connected by transverse branches (Figs 1074 and 1076). In the interstices of the network

of vessels thus formed are situated, as before said, the liver cells; and here it is that the blood is brought into intimate connection with the liver cells and the bile is secreted. The endothelium of

FIG. 1075.—Magnified section of a human liver, placed in preservative a few minutes after death (electrocution). The sinusoidal endothelium is seen closely applied to the hepatic epithelial cells. The cell elements of the blood in the sinusoids have been omitted, but in this as in other similarly obtained preparations numerous bell-shaped forms of red blood cells were seen.

FIG. 1076.—A lobule of human liver. (After Rauber-Kopsch.)

the capillaries and the epithelial cells are closely adherent to each other, forming *sinusoids*. Arrived at the centre of a lobule, all these minute vessels empty themselves into one vein, of

considerable size, which runs down the centre of the lobule from apex to base and is called the **intralobular or central vein** (*vena intralobularis*) (Fig. 1076). At the base of the lobule this vein opens directly into the **sublobular vein**, with which the lobule is connected, and which, as before mentioned, is a radicle of the hepatic vein. The sublobular veins, uniting into larger and larger trunks, end at last in the hepatic veins, which do not receive any intralobular veins directly. Finally, the hepatic veins, as mentioned on page 754, converge to form three large trunks which open into the inferior vena cava, while that vessel is situated in the fissure appropriated to it at the back of the liver. The portal vein is the nutrient vessel of the parenchyma of the liver, while the hepatic artery nourishes the vessels, ducts, and interlobular connective tissue.

3. **The Ducts.**—Having shown how the blood is brought into intimate relation with the hepatic cells in order that the bile may be secreted, it remains now only to consider the way in which the secretion, having been formed, is carried away. Several views have prevailed as to the mode of origin of the hepatic ducts; it seems, however, to be clear that they commence by little passages, which are formed between the cells and which have been termed **intercellular biliary passages**, **bile capillaries**, or **bile canaliculi** (*ductus biliferi*). These passages are merely little channels or spaces left between the contiguous surfaces of two cells or in the angle where three or more liver cells meet, and it seems doubtful whether there is any delicate membrane forming the wall of the channel. Heidenhain, however, thinks they have coats. The channels

FIG. 1077.—X-ray picture of the bile ducts and the pancreatic ducts. (Robinson.)

thus formed radiate to the circumference of the lobule, and empty into small interlobular ducts between the lobules. These are lined by low epithelial cells supported by a basement membrane and a little fibrous tissue. The **interlobular ducts** pass into the portal canals, become enclosed in Glisson's capsule, and, accompanying the portal vein and hepatic artery (Fig. 1076), join with other ducts to form two main trunks, the right and left branches of the hepatic duct, which leave the liver at the transverse or portal fissure, and by their union form the hepatic duct. The larger interlobular ducts possess some circularly arranged smooth muscle tissue, while the main ducts possess three coats—**mucous**, **muscular**, and **fibrous**. The **mucous coat** consists of tall columnar epithelial cells, basement membrane, and tunica propria. The **muscular coat** consists of smooth muscle tissue circularly arranged. The **fibrous coat** consists of loose white fibrous tissue supporting the other coats.

The **lymphatics**, in the substance of the liver (Fig. 569), commence in lymphatic spaces around the capillaries of the lobules; they accompany the vessels of the interlobular plexus, often enclosing and surrounding them. These unite and form larger vessels, which run in the portal canals, enclosed in Glisson's capsule, and emerge at the portal fissure to be distributed in the manner described. Other superficial lymphatics arise from the superficial lobules, pass under the peritoneum, and form a close plexus, where this membrane covers the liver. The first-named group of lymphatics gives origin to the deep collecting trunks, the second to the superficial

collecting trunks. One group of deep collecting trunks accompanies the portal vein, there being fifteen to eighteen of them emerging from the transverse fissure. They empty into the lymph nodes of the hilum. Another group accompanies the hepatic veins. There are five or six trunks which pass through the Diaphragm and terminate in the lymph nodes about the inferior vena cava (*intrathoracic nodes*). The superficial trunks of the superior surface are divided into posterior, anterior, and superior trunks. Some of the posterior trunks terminate in the nodes about the coeliac axis, others in the nodes about the lower portion of the inferior vena cava in the thorax; others in the nodes about the abdominal portion of the oesophagus. The anterior trunks which are limited to the right lobe pass to the nodes of the hilum. The superior trunks ascend in the suspensory ligament. Some pass to the nodes about the inferior vena cava, just above the Diaphragm; others to the hepatic nodes. The balance unite to form a very large trunk, which passes through the Diaphragm and divides into branches which enter the nodes back of the base of the ensiform cartilage.

The **nerves** of the liver are derived from the **left vagus** and **sympathetic**. The branches of the left vagus ascend from in front of the stomach within the lesser omentum. The sympathetic nerves pass along the hepatic artery, enter the liver at the transverse fissure, and accompany the vessels and ducts to the interlobular spaces. Here, according to Korolkow, the myelinic fibres are distributed almost exclusively to the coats of the bloodvessels, while the amyelinic fibres enter the lobules and ramify between the cells.

The Excretory Apparatus of the Liver.

The excretory apparatus of the liver consists of (1) the **hepatic duct**, formed, as we have seen, by the junction of the two main ducts, which pass out of the liver at the transverse fissure; (2) the **gall-bladder**, which serves as a reservoir for the bile; (3) the **cystic duct**, or the duct of the gall-bladder; and (4) the **common bile duct**, formed by the junction of the hepatic and cystic ducts.

The Hepatic Duct (*ductus hepaticus*) (Figs. 1078 and 1079).—Two main trunks of nearly equal size issue from the liver at the transverse fissure, one from the **right**, the other from the **left lobe**; these unite to form the hepatic duct, which then passes downward and to the right for about an inch and a half or two inches (3.75 to 5 cm.), between the layers of the lesser omentum, where it is joined at an acute angle by the cystic duct, and so forms the common bile duct (*ductus communis chole-dochus*). The hepatic duct is accompanied by the hepatic artery and portal vein (Fig. 1070).

The Gall-bladder (*vesica fellea*) (Figs. 1064 and 1078).—The gall-bladder is the reservoir for the bile; it is a conical or pear-shaped musculomembranous sac, lodged in a fossa on the under surface of the right lobe of the liver, and fixed in it by connective tissue, and extending from near the right extremity of the transverse fissure to the anterior border of the organ. It is from three to four inches (7.5 to 10 cm.) in length, one inch (2.5 cm.) in breadth at its widest part, and holds from eight to ten drams (30 to 40 c.c.). It is divided into a fundus, body, and neck. The **fundus** (*fundus vesicae felleae*), or broad extremity, is directed downward, forward, and to the right, and projects

FIG. 1078.—The gall-bladder and bile ducts, opened up. (Spalteholz.)

beyond the anterior border of the liver; the **body** (*corpus vesicae felleae*) and **neck** (*collum vesicae felleae*) are directed upward and backward to the left. The neck of the gall-bladder is on a slightly higher level than the lowest point of the gall-bladder; thus the weight of the bile is away from rather than toward the outlet. The upper surface of the gall-bladder is attached to the liver by connective tissue and vessels. The under surface is covered by peritoneum, which is reflected on to it from the surface of the liver. Occasionally the whole of the organ is invested by the serous membrane, and is then connected to the liver by a kind of mesentery.

Relations.—The body of the gall-bladder is in relation, by its upper surface, with the liver, to which it is connected by areolar tissue and vessels; by its under surface, with the commencement of the transverse colon; and farther back, with the upper end of the descending portion of the duodenum or sometimes with the pyloric end of the stomach or the first portion of the duodenum. The **fundus** is completely invested by peritoneum; it is in relation, in front, with the abdominal parietes, immediately below the ninth costal cartilage; behind, with the transverse arch of the colon. The **neck** is narrow, and curves upon itself like the letter S; at its point of connection with the cystic duct it presents a well-marked constriction.

When the gall-bladder is distended with bile or filled with calculi, the fundus may be felt through the abdominal parietes, especially in an emaciated subject; the relations of this sac will also serve to explain the occasional occurrence of abdominal biliary fistulae, through which biliary calculi may pass out, and of the passage of calculi from the gall-bladder into the stomach, duodenum, or colon, which occasionally happens.

Structure.—The gall-bladder consists of three coats—**serofibrous**, **muscular**, and **mucous**.

The **external or serofibrous coat** (*tunica serosa vesicae felleae*) consists of white fibrous tissue that surrounds the muscle coat; the fundus is completely covered by peritoneum, while the body and neck are covered on their under surfaces only.

The **muscular coat** (*tunica muscularis vesicae felleae*) is a thin but strong layer which forms the framework of the sac, consisting of dense fibrous tissue which interlaces in all directions and is mixed with plain muscle fibres which are disposed chiefly in a longitudinal direction, a few running transversely.

The **internal or mucous coat** (*tunica mucosa vesicae felleae*) is loosely connected with the fibrous portion of the preceding coat. It is generally tinged with a yellowish-brown color, and is everywhere elevated into minute **rugae**, by the union of which numerous meshes are formed, the depressed intervening spaces having a polygonal outline. The meshes are smaller at the fundus and neck, being most developed about the centre of the sac. Opposite the neck of the gall-bladder the mucous membrane projects inward in the form of oblique ridges or folds, forming a spiral valve (Fig. 1078).

The mucous membrane is covered with columnar epithelium, and secretes an abundance of thick viscid mucus; it is continuous through the hepatic duct with the mucous membrane lining the ducts of the liver, and through the ductus communis choledochus with the mucous membrane of the duodenum. Mucous glands may be found in this coat, as well as diffuse lymphoid tissue and solitary follicles.

The Cystic Duct (*ductus cysticus*).—The cystic duct, the smallest of the three biliary ducts, is about an inch and a half (3.75 cm.) in length. It passes obliquely downward and to the left from the neck of the gall-bladder, and joins the hepatic duct to form the common bile duct. It lies in the gastrohepatic omentum in front of the portal vein, the hepatic artery lying to its left side. The mucous membrane lining its interior is thrown into a series of crescentic folds, from five to twelve in number, similar to those found in the neck of the gall-bladder. They project into the duct in regular succession, and are directed obliquely around the tube, presenting much the appearance of a continuous spiral valve (*valvula spiralis* [Heisteri]) (Fig. 1078). When the duct is distended, the spaces between the folds are dilated, so as to give to its exterior a twisted appearance.

The **common bile duct** (*ductus choledochus*) (Figs. 1078 and 1079), the largest of the three, is the common excretory duct of the liver and gall-bladder. It is about three inches in length, is of the diameter of a goose-quill, and is formed by the junction of the cystic and hepatic ducts.

It descends along the right border of the lesser omentum behind the first portion of the duodenum, in front of the portal vein, and to the right of the hepatic

artery (Fig. 984); it then passes between the head of the pancreas and descending portion of the duodenum, and, running for a short distance along the right side of the terminal part of the pancreatic duct, passes with it obliquely through the wall of the descending portion of the duodenum between the mucous and muscular coats in the submucous tissue for one-half to three-quarters of an inch (1.25 to 2 cm.). The two ducts usually unite just before opening into the duodenum

(Figs. 1079 and 1080), but may remain independent throughout (in about 10 per cent. of individuals). The **ampulla of Vater** (Fig. 1079) is the conical cavity formed by the fusion of the two ducts, and is much larger than the opening on the bile papilla. It averages 3.9 mm. in length. The average diameter of the orifice is 2.5 mm. (Opie). The two ducts open by a common orifice if there is an ampulla, or by two separate orifices if there is no ampulla, upon the summit of a papilla, situated at the inner side of the descending portion of the duodenum, a little below its middle and about three or four inches (7.5 to 10 cm.) below the pylorus. Circular muscle fibres, contin-

FIG. 1079.—The biliary ducts. (Schematic.) (Poirier and Charpy.)

FIG. 1080.—The sphincter of the common bile duct. (Poirier and Charpy.)

uous with the longitudinal fibres of the ducts, surround the termination of the two ducts in the ampulla. These fibres constitute the so-called sphincter of Oddi (Fig. 1080).

Structure.—The coats of the large biliary ducts are an **external** or **fibrous**, a **middle** or **muscular**, and an **internal** or **mucous**. The **fibrous coat** is composed of strong fibroareolar tissue. The **muscular coat** consists chiefly of circularly arranged smooth muscle tissue. The **mucous coat** is continuous with the lining membrane of the hepatic ducts and gall-bladder, and also with that of the duodenum; and, like the mucous membrane of these structures, its epithelium is of the simple columnar variety. It is provided with numerous mucous glands, which are lobulated and open by minute orifices scattered irregularly in the larger ducts. It is questionable if the smallest biliary ducts, which lie in the interlobular spaces, have any coats. Heidenhain thinks they have a connective-tissue coat, in which are muscle cells arranged both circularly and longitudinally, and an epithelial layer, consisting of short columnar cells.

Dimensions of the Bile Ducts.—The hepatic duct is about two inches (5 cm.) in length, and its lumen is one-sixth of an inch (4 mm.) in diameter. The cystic duct is about one and one-half inches (3.75 cm.) in length, and its lumen is one-twelfth of an inch (2 mm.) in diameter. The common duct is about three inches (7.5 cm.) in length, and its lumen is one-quarter of an inch (6 mm.) in diameter. The duodenal opening is smaller than the common duct. The ducts are capable of considerable distention, but the duodenal opening cannot be dilated (Hyrtl).

Bloodvessels, Lymphatics, and Nerves of the Gall-bladder and Bile Ducts.—The **cystic artery** (Fig. 468), a branch from the right division of the hepatic, supplies the gall-bladder and

cystic duct with blood. It passes along the cystic duct, and on reaching the gall-bladder divides into an upper branch and a lower branch. The upper branch lies between the gall-bladder and the liver and sends branches to each. The lower branch is between the peritoneum and the wall of the gall-bladder. The **cystic veins** empty into the portal vein. The common duct receives branches from the **superior pancreaticoduodenal artery**. There is a **submucous lymphatic network** and a **muscular lymphatic network**. The lymphatics are much less numerous at the fundus of the gall-bladder than at the neck or in the extrahepatic ducts. The collecting trunks end in lymph nodes along the cystic and common ducts, and these glands are in communication with the duodenal lymphatics and the lymphatics from the head of the pancreas. The **nerves** of the gall-bladder and bile ducts come from the **coeliac plexus** of the sympathetic.

The Bile (*fel*).—The bile is a reddish-brown or greenish fluid. It contains pigments (bilirubin and biliverdin), fats and soaps, cholesterin, sodium salts of glycocholic and taurocholic acid, lecithin, and nuclealbumin furnished by the mucous membrane. There are also present CO₂; chlorides, carbonates, phosphates, and sulphates of the alkalies and of calcium, and iron. The amount normally secreted is from one pint to one and one-half pints in the twenty-four hours.

Surface Relations.—The liver is situated in the right hypochondriac and the epigastric regions, and is moulded to the arch of the Diaphragm. In the greater part of its extent it lies under cover of the lower ribs and their cartilages, but in the epigastric region it comes in contact with the abdominal wall, in the subcostal angle. The *upper limit of the right lobe of the liver* may be defined in the middle line by the junction of the mesosternum with the ensiform cartilage; on the right side the line must be carried upward as far as the fifth rib cartilage in the midclavicular line and then downward to reach the seventh rib at the side of the thorax. The *upper limit of the left lobe* may be defined by continuing this line to the left with an inclination downward to a point about 7 cm. to the left of the mesal plane on a level with the sixth left costal cartilage. The *lower limit of the liver* may be indicated by a line drawn half an inch below the lower border of the thorax on the right side as far as the ninth right costal cartilage, and thence obliquely upward across the subcostal angle to the eighth left costal cartilage. A slight curved line with its convexity to the left from this point—i. e., the eighth left costal cartilage—to the termination of the line indicating the upper limit will denote the left margin of the liver. The fundus of the gall-bladder approaches the surface behind the anterior extremity of the ninth costal cartilage, close to the outer margin of the right Rectus muscle.

It must be remembered that the liver is subject to considerable alterations in position, and the student should make himself acquainted with the different circumstances under which this occurs, as they are of importance in determining the existence of enlargement or other diseases of the organ.

Its position varies according to the posture of the body. In the erect position in the adult male the edge of the liver projects about half an inch below the lower edge of the right costal cartilages, and its anterior border can be often felt in this situation if the abdominal wall is thin. In the supine position the liver gravitates backward and recedes above the lower margin of the ribs, and cannot then be detected by the finger. In the prone position it falls forward, and can then generally be felt in a patient with loose and lax abdominal walls. Its position varies also with the ascent or descent of the Diaphragm. In a deep inspiration the liver descends below the ribs; in expiration it is raised behind them. Again, in emphysema, where the lungs are distended and the Diaphragm descends very low, the liver is pushed down; in some other diseases, as phthisis, where the Diaphragm is much arched, the liver rises very high up. Pressure from without, as in tight lacing, by compressing the lower part of the thorax, displaces the liver considerably, its anterior edge often extending as low as the crest of the ilium; and its convex surface is often at the same time deeply indented from the pressure of the ribs. Again, its position varies greatly according to the greater or less distention of the stomach and intestines. When the intestines are empty the liver descends in the abdomen, but when they are distended it is pushed upward. Its relations to surrounding organs may also be changed by the growth of tumors or by collections of fluid in the thoracic or abdominal cavities.

Applied Anatomy.—*Movable liver* or *hepatoptosis* is a rare condition, in which the liver moves or can be moved from its normal position. It is due to lessened tone of the abdominal muscles and relaxation of the liver supports. In movable liver the organ may be rotated on its vertical axis or on its transverse axis. Tongue-like lobes have been referred to. On account of its large size, its fixed position, and its friability, the liver is more frequently *ruptured* than any of the abdominal viscera. The rupture may vary considerably in extent, from a slight scratch to an extensive laceration completely through its substance, dividing it into two parts. Sometimes an *internal rupture* without laceration of the peritoneal covering takes place, and such injuries are most susceptible of repair; but small tears of the surface may also heal; when, however, the laceration is extensive, death usually takes place from hemorrhage, on account of the fact that the hepatic veins are contained in rigid canals in the liver substance and are unable to contract, and are, moreover, unprovided with valves. The liver may also be torn by the end of a broken rib perforating the Diaphragm. The liver may be injured by *stabs* or other *punctured wounds*, and when these are inflicted through the chest wall both pleural and peritoneal

cavities may be opened up and both lung and liver be wounded. In cases of *wound of the liver* from the front, protrusion of a part of this viscus may take place, but can generally easily be replaced. In cases of laceration of the liver, when there is evidence that bleeding is going on, the abdomen must be opened, the laceration sought for, and the bleeding arrested. This may be done temporarily by introducing the forefinger into the foramen of Winslow and placing the thumb on the gastrohepatic omentum and compressing the hepatic artery and portal vein between the two. Any bleeding points can then be seen. Bleeding is, if possible, arrested by suture ligatures. The edges of a small laceration are simply brought together and sutured by means of a blunt, curved, round needle passed from one side of the wound to the other. All sutures must be passed before any are tied, and this must be done with the greatest gentleness, as the liver substance is very friable. If suture fails the actual cautery may succeed. When the laceration is extensive, the liver is sutured to the abdominal wall to hold it firm when pressure is applied, and then the laceration is packed with a piece of iodoform gauze, the end of which is allowed to hang out of the external wound. *Abscess of the liver* is of not infrequent occurrence, and may open in many different ways on account of the relations of this viscus to other organs. Thus, it may burst into the lung, the pus being coughed up, or into the stomach, the pus perhaps being vomited; it may burst into the colon or into the duodenum, or, by perforating the Diaphragm, it may empty itself into the pleural cavity. Frequently it makes its way forward, and points on the anterior abdominal wall, and finally it may burst into the peritoneal or pericardiac cavity. Abscesses of the liver require opening, and this must be done by an incision in the abdominal wall, in the thoracic wall, or in the lumbar region, according to the direction in which the abscess is tracking. The incision through the abdominal wall is to be preferred when possible. The abdominal wall is incised over the swelling, and unless the peritoneum is adherent, gauze is packed all around the exposed liver surface and the abscess opened, if deeply seated, preferably by the thermo-cautery. *Hydatid cysts* are more often found in the liver than in any other of the viscera. The reason of this is not far to seek. The embryo of the egg of the tenia echinococcus being liberated in the stomach by the disintegration of its shell, bores its way through the gastric walls and usually enters a bloodvessel, and is carried by the blood stream to the hepatic capillaries, where its onward course is arrested, and where it undergoes development into the fully formed hydatid. *Tumors of the liver* have recently been subjected to surgical treatment by removal of a portion of the organ. The abdomen is opened and the diseased portion of liver exposed; the circulation is controlled by compressing the portal vein and the hepatic artery in the gastrohepatic omentum and a wedge-shaped portion of liver containing the tumor removed; the divided vessels are ligated, and the cut surfaces brought together and sutured in the manner directed above.

When the *gall-bladder* or one of its main ducts is *ruptured*, which may occur independently of laceration of the liver, death usually occurs from peritonitis. If the symptoms have led to the performance of a laparotomy and a small rent is found, it should be sutured; if an extensive opening is found the gall-bladder should be removed. If the cystic duct is torn, its intestinal end must be closed and the gall-bladder removed. In rupture of either of the other ducts, simply provide for free drainage.

The gall-bladder may become distended with bile in cases of *obstruction of its duct* or of the *common bile duct*, or it may become distended from a collection of *gallstones* within its interior, thus forming a large tumor. The swelling due to distention with bile is pear-shaped, and projects downward and forward to the umbilicus. It moves with respiration, since it is attached to the liver. To relieve a patient of *gallstones*, the gall-bladder must be opened and the gallstones removed. The operation is performed by an incision two or three inches long in the right semi-lunar line, commencing at the costal margin. The peritoneal cavity is opened, and, the tumor having been found, gauze pads are packed around it to protect the peritoneal cavity, and it is aspirated. When the contained fluid has been evacuated the flaccid bladder is drawn out of the abdominal wound and its wall incised to the extent of an inch; any gallstones in the bladder are now removed and the interior of the sac sponged dry. If the case is one of obstruction of the duct, an attempt must be made to dislodge the stone by manipulation through the wall of the duct; or it may be crushed from without by the fingers or carefully padded forceps. If this does not succeed, the safest plan is to incise the duct, extract the stone, close the incision in the duct by fine sutures in two layers, and employ drainage. After all obstruction has been removed, four courses are open to the surgeon: (1) The wound in the gall-bladder may be at once sewed up, the organ returned into the abdominal cavity, and the external incision closed. (2) The edges of the incision in the gall-bladder may be sutured to the fascia of the external wound, and a fistulous communication established between the gall-bladder and the exterior; this fistulous opening usually closes in the course of a few weeks. (3) The gall-bladder may be connected with the intestinal canal, preferably the duodenum, by means of a lateral anastomosis; this is known as *cholecystenterostomy*. (4) The gall-bladder may be completely removed (*cholecystectomy*).

If a stone blocks the ampulla of Vater and if the common bile duct and the pancreatic duct empty into the diverticulum, it is evident that both ducts will be blocked. It has been

demonstrated that in such a case the pressure urging the bile onward is sufficient to overcome the pressure in the pancreatic duct and drive bile into the ducts of the pancreas, the result, perhaps, being disastrous inflammation of the pancreas.

Septic trouble arises more rapidly when a stone is blocked in the duct than when stones merely block the gall-bladder, because the first-named part is richer in lymphatics (Murphy).

THE PANCREAS (Figs. 1081, 1083).

Dissection.—The pancreas may be exposed for dissection in three different ways: (1) By raising the liver, drawing down the stomach, and tearing through the gastrohepatic omentum and the ascending layer of the transverse mesocolon. (2) By raising the stomach, the arch of the colon, and greater omentum, and then dividing the inferior layer of the transverse mesocolon and raising its ascending layer. (3) By dividing the two layers of peritoneum, which descend from the greater curvature of the stomach to form the greater omentum; turning the stomach upward, and then cutting through the ascending layer of the transverse mesocolon (see Fig. 980).

FIG. 1081.—Position and relations of pancreas.

The **pancreas** is a compound racemose gland, analogous in its structure to the salivary glands, though softer and less compactly arranged than those organs. It is long and irregularly prismatic in shape, and of a reddish-white color. Its right extremity, being broad, is called the **head**, and is connected to the main portion of the organ, the **body**, by a slight constriction, the **neck**; while its left extremity gradually tapers to form the **tail**. It is situated transversely across the posterior wall of the abdomen, at the back of the epigastric and left hypochondriac regions. Its length varies from five to six inches (12.5 to 15 cm.), its breadth is an inch and a half (3.75 cm.), and its thickness from half an inch to an inch (1.25 to 2.5 cm.), being greater at its right extremity and along its upper border. Its weight varies from two to three and one-half ounces (60 to 100 grams).

The **head** (*caput pancreatis*) (Fig. 1081) is flattened from before backward, and is lodged within the curve of the duodenum. The upper border is in contact with the first part of the duodenum, and its lower overlaps the third part; its right and left borders overlap in front, and insinuate themselves behind, the second and fourth parts of the duodenum respectively. The angle of junction of the lower

and left lateral borders forms a prolongation, termed the **processus uncinatus**. In the groove between the duodenum and the right lateral and lower borders in front are the anastomosing superior and inferior pancreaticoduodenal arteries; the common bile duct descends behind, along the right border, to its termination in the second part of the duodenum.

FIG. 1082.—The pancreas and duodenum from behind. (Drawn from His' model.)

The greater part of the right half of the **anterior surface** is in contact with the transverse colon, only areolar tissue intervening. From its upper part the neck originates, its right limit being marked by a groove for the gastroduodenal artery. The lower part of the right half, below the transverse colon, is covered by peritoneum continuous with the inferior layer of the transverse mesocolon, and is in contact with the coils of the small intestine. The superior mesenteric artery passes down in front of the left half across the uncinate process; the superior mesenteric vein runs upward along the right side of the artery, and, behind the neck of the pancreas, joins with the splenic vein to form the portal vein.

The **posterior surface** is in relation with the inferior vena cava, the renal veins, the right crus of the Diaphragm, and the aorta.

The **neck** springs from the right upper portion of the front of the head. It is about an inch (2.5 cm.) long, and is directed, at first, upward and forward, and then upward and to the left to join the body; it is somewhat flattened from above downward and backward. Its antero-superior surface supports the pylorus; its postero-inferior surface is in relation with the commencement of the portal vein; on the right it is grooved by the gastroduodenal artery.

FIG. 1083.—Duodenal orifice of the pancreatic duct and of the duct of Santorini.

The **body** (*corpus pancreatis*) is somewhat prismatic in shape, and has three surfaces—**anterior**, **posterior**, and **inferior**.

The **anterior surface** (*facies anterior*) is somewhat concave, and is directed forward and upward; it is covered by the postero-inferior surface of the stomach which rests upon it, the two organs being separated by the lesser sac of the peritoneum. Where it joins the neck extremity there is a well-marked prominence, called the **omental tuberosity** (*tuber omentale*), which abuts against the posterior surface of the small omentum.

The **posterior surface** (*facies posterior*) is devoid of peritoneum, and is in contact with the aorta, the splenic vein, the left kidney and its vessels, the left suprarenal gland, the crura of the Diaphragm, and the origin of the superior mesenteric artery.

The **inferior surface** (*facies inferior*) (Fig. 1082) is narrow on the right, but broader on the left, and is covered by peritoneum; it lies upon the duodenojejunal flexure and on some coils of the jejunum; its left extremity rests on the splenic flexure of the colon.

The **superior border** (*margo superior*) (Fig. 1082) of the body is blunt and flat to the right; narrow and sharp to the left, near the tail. It commences to the right in the omental tuberosity, and is in relation with the coeliac axis, from which the hepatic artery courses to the right just above the gland, while the splenic branch runs toward the left in a groove along this border.

The **anterior border** (*margo anterior*) separates the anterior from the inferior surface, and along this border the two layers of the transverse mesocolon diverge from each other; one passing upward over the anterior surface, the other backward over the inferior surface.

The **inferior border** (*margo inferior*) separates the posterior from the inferior surface; the superior mesenteric vessels emerge under its right extremity.

The **tail** (*cauda pancreatis*) is narrow; it extends to the left as far as the lower part of the gastric surface of the spleen, and it is in contact with the splenic flexure of the colon.

Birmingham describes the body of the pancreas as projecting forward as a prominent ridge into the abdominal cavity and forming a sort of shelf on which the stomach lies. He says: "The portion of the pancreas to the left of the middle line has a very considerable antero-posterior thickness; as a result the anterior surface is of considerable extent, it looks strongly upward, and forms a large and important part of the shelf. As the pancreas extends to the left toward the spleen it crosses the upper part of the kidney, and is so moulded on to it that the top of the kidney forms an extension inward and backward of the upper surface of the pancreas and extends the bed in this direction. On the other hand, the extremity of the pancreas comes in contact with the spleen in such a way that the plane of its upper surface runs with little interruption upward and backward into the concave gastric surface of the spleen, which completes the bed behind and to the left, and, running upward, forms a partial cap for the wide end of the stomach."

The principal excretory duct of the pancreas, called the **pancreatic duct** or **canal of Wirsung** (*ductus pancreaticus* [*Wirsungi*]) (Figs. 1081 and 1083), extends transversely from left to right through the substance of the pancreas. In order to expose it, the superficial portion of the gland must be removed. It commences by the junction of the small ducts of the lobules situated in the tail of the pancreas, and, running from left to right through the body, it constantly receives the ducts of the various lobules composing the gland. Considerably augmented in size, it reaches the neck, and, turning obliquely downward, backward, and to the right, it comes into relation with the common bile duct, lying to its left side; leaving the head of the gland, it passes very obliquely through the mucous and muscular coats

of the duodenum, and usually terminates by an orifice common to it and the common bile duct upon the summit of an elevated papilla, situated at the inner side of the descending portion of the duodenum, three or four inches (7.5 to 10 cm.) below the pylorus (Figs. 1079 and 1080).

Sometimes the pancreatic duct and common bile duct open separately into the duodenum (Fig. 1013). Frequently there is an accessory duct, which is given off from the canal of Wirsung in the neck of the pancreas and passes horizontally to the right to open into the duodenum about an inch above the orifice of the main duct. This is known as the **duct of Santorini** (*ductus pancreaticus accessorius* [*Santorini*]) (Fig. 1083).

FIG. 1084.—Transverse section through the middle of the first lumbar vertebra, showing the relations of the pancreas. (Braune.)

The **pancreatic duct**, near the duodenum, is about the size of an ordinary quill; its walls are thin, consisting of three coats, an **external fibrous**, a **middle muscular**, and an **internal mucous**; the latter is smooth, and furnished near its termination with a few scattered follicles.

Structure.—In structure, the pancreas resembles the salivary glands. It differs from them, however, in certain particulars, and is looser and softer in its texture. It is not enclosed in a distinct capsule, but is surrounded by areolar tissue, which dips into its interior, and connects the various lobules of which it is composed. Each lobule, like the lobules of the salivary glands, consists of one of the ultimate ramifications of the main duct, terminating in a number of cecal pouches or alveoli, which are mainly grape-like. The minute ducts connected with the alveoli are narrow and lined with flattened cells. The alveoli are almost completely filled with secreting cells, so that scarcely any lumen is visible. In the centre of the end-tubules flat cells are frequently found. They are continuations into the tubules of the duct epithelium. These cells are known as the **centro-acinar cells of Langerhans**. The true secreting cells which line the wall of the alveolus are very characteristic. They are pyramidal or rounded in shape and present two zones—an outer one clear and finely striated next the basement membrane, and an inner granular one next the lumen. The highly refracting granules are known as **zymogen granules**. During digestion the granules gradually disappear and the cells become clear. During fasting the granular zone occupies more than one-half of the cell (Szymonowicz). In some secreting cells of the pancreas is a spherical mass, staining more easily than the rest of the cells;

this is termed the **paranucleus**, and it is believed to be an extension from the nucleus. The connective tissue among the gland tubules and alveoli presents in certain parts collections of cells, which are termed **interalveolar cell islets**, or **islands of Langerhans**. Opie points out that they are most common in the splenic end of the pancreas. The cells of the islands are smaller and paler than the secreting cells of the alveoli, and are arranged in layers with intervening spaces. The islands are sharply demarcated from the alveoli, are much larger than the latter, and are very vascular. There are no ducts in the islands of Langerhans. Their function is to furnish the internal secretion of the pancreas.

Bloodvessels, Lymphatics, and Nerves.—The arteries of the pancreas come from the superior pancreaticoduodenal branch of the gastroduodenal; the inferior pancreaticoduodenal branch of the superior mesenteric; the inferior pancreatic branch of the superior mesenteric; pancreatic branches of the hepatic and pancreatic branches of the splenic. In a few cases a large artery, the **pancreatica magna**, accompanies the pancreatic duct. In most cases there is no such vessel. The veins are the anterior pancreaticoduodenal branch of the superior mesenteric; the posterior pancreaticoduodenal branch and other pancreatic branches of the

FIG. 1085.—Section of human pancreas, showing pancreatic islands. (Radasch.)

portal; and pancreatic branches of the splenic. The lymphatics arise in a network about the lobules. Numerous collecting trunks pass to the surface of the pancreas, anastomose with each other, and enter into nodes about the pancreas. The **splenic nodes** receive most of the trunks. Others are received by nodes along the aorta (Sappey), nodes at the origin of the superior mesenteric artery, and nodes along the pancreaticoduodenal vessels. The **nerves** come from the **cœliac**, **superior mesenteric**, and **splenic plexuses**.

The Pancreatic Juice.—The pancreatic juice is a clear, somewhat viscid alkaline liquid. Its specific gravity is about 1.030. The solid matter consists chiefly of proteids, and amounts to about 10 per cent. of a sample of the juice. The juice contains a ferment which breaks up fat, a ferment which converts starch into sugar, and a ferment which digests proteid material.

Surface Form.—The pancreas lies in front of the second lumbar vertebra, and can sometimes be felt, in emaciated subjects, when the stomach and colon are empty, by making deep pressure in the middle line about three inches above the umbilicus.

Applied Anatomy.—Of late years our knowledge of the structure, functions, and diseases of the pancreas has been notably increased, and surgeons have begun to operate for certain pancreatic diseases. It is occasionally the seat of **cancer**, which usually affects the head or duodenal end, and therefore often speedily involves the common bile duct, leading to persistent jaundice. Cancer of the pancreas may be primary or secondary. **Primary sarcoma** is very unusual; secondary sarcoma is more common, but cancer is far commoner than either form of sarcoma. **Adenoma** may also occur. Cases are on record of the successful removal of tumors of the pancreas, but the operations are very dangerous, are extremely difficult, and are seldom attempted. The pancreas may be the seat of **syphilitic** or **tuberculous disease**. As a result of pancreatic injury, there may be *effusion into the lesser peritoneal cavity*. The lesser cavity becomes distended,

and the fluid of this *pseudocyst* may contain pancreatic juice (Jordan Lloyd). True *cysts* of the pancreas are occasionally found. Pancreatic cysts may result from blocking of the duct, from epithelial proliferation, from traumatism and hemorrhage, or from hydatid disease. *Con-genital cysts* may occur, and *cystic carcinoma* is sometimes encountered. Cysts of the pancreas may present in the epigastric region above and to the right of the umbilicus. The fluid in these cysts contains some of the pancreatic secretion. A pancreatic cyst is best treated by opening the abdomen, suturing the cyst to the skin, opening the cyst, and providing for drainage. Complete extirpation of the cyst is invariably difficult and is usually impossible. It has been said that the pancreas is the only abdominal viscus which has never been found in a hernial protrusion; but even this organ has been found, in company with other viscera, in rare cases of *diaphragmatic hernia*. The pancreas has been known to become invaginated into the intestines and portions of the organ have sloughed off. In cases of *excision of the pylorus* great care must be exercised to avoid wounding the pancreas, as the escape of the pancreatic fluid may be attended with serious and even with fatal results, peritonitis and *fat necrosis*, and gangrene being caused.

Rupture of the pancreas as a solitary result of traumatism is very unusual, but is more common in violent injuries which rupture the liver and spleen as well. An injury which lacerates the pancreas and permits blood and pancreatic juice to flow into the lesser peritoneal cavity is usually rapidly fatal, but may not be. The foramen of Winslow may be occluded by inflammation, and a *pseudocyst* may form. In severe laceration of the pancreas alone it would be proper to open the abdomen, ligate bleeding vessels, suture the pancreas, and drain the lesser peritoneal cavity posteriorly. A *gunshot wound of the pancreas* requires posterior drainage. Every effort must be made in a pancreatic wound to rapidly get rid of pancreatic fluid by drainage from the wound area, as this fluid is extremely irritant and may cause gangrene.

Inflammation of the pancreas is due to infection. Occasionally it seems to follow the entrance of bile into the pancreatic duct, because of plugging of the ampulla with a calculus (Halsted, Opie). Hemorrhage into the pancreas is frequent in acute pancreatitis, and fat necrosis is common in the fat of the mesentery, subperitoneal tissue, omentum, and other parts. Acute pancreatitis may be recovered from if the abdomen is opened, the pancreas incised, and drainage employed.

In *chronic interstitial pancreatitis* of the head of the pancreas the bile duct is apt to become blocked, and the disease is frequently mistaken for cancer. Cure may follow opening and drainage of the gall-bladder.

Extensive fibrosis of the islands of Langerhans is one of the commonest lesions found post mortem in cases of *diabetes mellitus*.

THE URINOGENITAL ORGANS.¹

THE urinogenital organs (*apparatus urogenitalis*) consist of (a) the urinary organs for the excretion of the urine, and (b) the genital organs which are concerned with the process of reproduction.

THE URINARY ORGANS.

The urinary organs comprise the **kidneys**, which secrete the urine; the **ureters** or ducts which convey it to the **bladder**, where it is for a time retained; and the **urethra**, through which it is discharged from the body.

THE KIDNEYS (RENES) (Figs. 1086, 1088).

The **kidneys** are situated in the posterior part of the abdomen, one on each side of the vertebral column, *behind* the peritoneum, and are surrounded by a mass of fat and loose areolar tissue. Their upper extremities are on a level with the upper border of the twelfth thoracic vertebra, the lower extremity on a level with the third lumbar vertebra. The right kidney is usually on a slightly lower level than the left, probably on account of the vicinity of the liver. In the female the kidneys are a little lower than in the male. The long axis of each kidney is directed from above downward and outward, the transverse axis from within backward and outward.

Each kidney is about four and one-half inches (11.5 cm.) in length, two to two and one-half inches (5.5 cm.) in breadth, and about one and one-half inches (3.7 cm.) in thickness. The left is somewhat longer and narrower than the right. The weight of the kidney in the adult male varies from four and one-half ounces to six ounces (130 to 170 grams); in the adult female, from four ounces to five and one-half ounces (115 to 155 grams). The specific gravity is about 1052. The kidney has a characteristic form, resembling that of a lima bean, and presents for examination two surfaces, two borders, and an upper and a lower extremity. The combined weight of the two kidneys in proportion to the body is about 1 to 240.

Relations.—The **anterior surface** (*facies anterior*) of each kidney is convex, and looks forward and outward. Its relations to adjacent viscera differ so completely on the two sides that separate descriptions are necessary.

(a) **Anterior Surface of Right Kidney.**—A narrow portion at the upper extremity is in relation with the suprarenal gland. Immediately below this a large area, involving about three-fourths of the surface, lies in the renal impression on the inferior surface of the liver, and a narrow but somewhat variable area near the inner border is in contact with the second part of the duodenum. The lower part of the anterior surface is in contact externally with the hepatic flexure of the

¹ Usage has sanctioned the employment of *urogenital* as the equivalent of *urinogenital*, although the latter form only is philologically correct.

colon, and internally with the small intestine. The areas in relation with the liver and intestine are covered by peritoneum; the suprarenal, duodenal, and colic areas are devoid of peritoneum.

FIG. 1086.—The relations of the viscera and large vessels of the abdomen. (Seen from behind, the last thoracic vertebra being well raised.)

(b) **Anterior Surface of Left Kidney.**—A small area along the upper part of the inner border is in relation with the suprarenal gland, and close to the outer border is a narrow strip in contact with the renal impression on the spleen. A broad,

somewhat quadrilateral field, about the middle of the anterior surface, marks the site of contact with the body of the pancreas, on the deep surface of which are the splenic vessels. Above this is a small triangular portion, between the suprarenal and splenic areas, in contact with the postero-inferior surface of the stomach. Below the pancreatic area the outer part is in relation with the splenic flexure of the colon, the inner with the small intestine. The area in contact with the stomach is covered by the peritoneum of the lesser sac, while that in relation to the small intestine is covered by the peritoneum of the greater sac; behind the latter are some branches of the left colic vessels.

FIG. 1087.—Posterior abdominal wall, after removal of the peritoneum, showing kidneys, suprarenal capsules, and great vessels. (Corning.)

The Posterior Surface (*facies posterior*) (Fig. 1089).—The posterior surface of the kidney is flatter than the anterior and is directed backward and inward. It is entirely devoid of peritoneal covering, being embedded in areolar and fatty tissues. It lies upon the Diaphragm, the anterior layer of the lumbar aponeurosis, the external and internal arcuate ligaments, the Psoas and Transversalis muscles, one or two of the upper lumbar arteries, the last thoracic, iliohypogastric, and ilioinguinal nerves. The **lumbocostal ligaments** overlie the posterior surface of the kidney (Fig. 977). The right kidney rests upon the twelfth rib (Fig. 977), the left usually on the eleventh and twelfth ribs. The Diaphragm separates the

kidney from the pleura as the pleura dips down to form the **phrenicocostal sinus** (Fig. 900), but frequently the muscle fibres of the Diaphragm are defective or

FIG. 1088.—Right kidney. Anterior view.

FIG. 1089.—Left kidney. Posterior view.

absent over a triangular area immediately above the external arcuate ligament, and when this is the case the perirenal areolar tissue is in immediate apposition

FIG. 1090.—The anterior surfaces of the kidneys, showing areas of contact of neighboring viscera.

with the diaphragmatic pleura. In the lower part of the posterior surface of the kidney is an impression produced by the *Quadratus lumborum* muscle and called

the **impressio muscularis**. A little internal to this a flattening, caused by the Psoas muscle, is often recognizable.

FIG. 1091.—The posterior surfaces of the kidneys, showing areas of relation to the parietes.

FIG. 1092.—Longitudinal section, showing the arrangement of the capsule of the kidney. (After Gerota.)

FIG. 1093.—Transverse section, showing the relations of the capsule of the kidney and the two layers of fat. (After Gerota.)

Borders.—The **external border** (*margo lateralis*) (Figs. 1088 and 1089) is convex, and is directed outward and backward, toward the postero-lateral wall of the

abdomen. On the left side it is in contact, at its upper part, with the spleen (Fig. 1087).

The **internal border** (*margo medialis*) (Figs. 1088 and 1089) is concave, and is directed forward, inward, and a little downward. It presents a deep longitudinal fissure, bounded by a prominent overhanging anterior and posterior lip. This fissure is named the **hilum** (*hilus renalis*) (Fig. 1089), and allows of the passage of the vessels, nerves, and ureter into and out of the kidney.

At the hilum of the kidney the relative position of the main structures passing into and out of the kidney is as follows: The vein is in front, the artery in the middle, and the duct or ureter behind and toward the lower part (Fig. 1088). By a knowledge of these relations the student may distinguish between the right and left kidney. The kidney is to be laid on the table before the student on its posterior surface, with its lower extremity toward the observer—that is to say, with the ureter *behind* and *below* the other vessels; the hilum will then be directed to the side to which the kidney belongs. Frequently, however, the branches of both artery and vein are placed behind the ureter.

Extremities.—The **superior extremity** (*extremitas superior*) (Figs. 1088 and 1089) is directed slightly inward as well as upward, being situated about 4 cm. from the mesal plane. It is thick, broad, bulky, and rounded, and is surmounted by the suprarenal gland (Fig. 1094), which covers also a small portion of the anterior surface.

The **inferior extremity** (*extremitas inferior*) (Figs. 1088 and 1089), directed a little outward as well as downward, is smaller and thinner and usually more pointed than the superior. It is situated about 6 cm. from the mesal plane, and extends to within two inches (5 cm.) of the crest of the ilium.

Fixation of the Kidney (Figs. 1092 and 1093).—The kidney and its vessels are embedded in a mass of fatty tissue termed the **capsula adiposa** (*perirenal fat*), which is thickest at the margins of the kidney and is prolonged through the hilum into the renal sinus. The kidney and the capsula adiposa are enclosed in a sheath of fibrous tissue continuous with the subperitoneal fascia, and named the **fascia renalis**. At the outer border of the kidney the fascia renalis splits into an anterior and a posterior layer. The anterior layer is carried inward in front of the kidney and its vessels, and is continuous over the aorta with the corresponding layer of the opposite side. The posterior layer extends inward behind the kidney and

FIG. 1094.—Vertical section of kidney.

blends with the fascia on the Quadratus lumborum and Psoas muscles and through this fascia is attached to the vertebral column. At the upper margin of the suprarenal gland the two layers of the fascia renalis fuse, and unite with the fascia of the Diaphragm; below they remain separate, and are gradually lost in the subperitoneal fascia of the iliac fossa (Fig. 1092). The fascia renalis is connected to the fibrous capsule of the kidney by numerous trabeculae, which traverse the adipose capsule and are strongest near the lower end of the organ. The perirenal fat does not look like the fat in other regions, but is soft, delicate, and of a canary-yellow color. Behind the fascia renalis is a considerable quantity of fat which

constitutes the **pararenal fat or body**. The kidney is held in position through the attachments of the fascia renalis and by the apposition of the neighboring viscera.

General Structure of the Kidney.—

The kidney is invested by a capsule of interlacing bundles of fibrous connective tissue (*tunica fibrosa*), which forms a firm, smooth covering for the organ. The capsule can be easily stripped off, but in doing so, numerous fine processes of connective tissue and small bloodvessels are torn through. Beneath this coat, a thin wide-meshed network of unstriated muscle fibres forms an incomplete covering. When the capsule is removed, the surface of the kidney is found to be smooth and even, and of a very deep red color. In infants, fissures extending for some depth may be seen on the surface of the organ, a remnant of the lobular construction of the gland (Fig. 1105). The kidney is dense in texture, but is easily lacerable by mechanical force. If a vertical section of the kidney be made from its convex to its concave border, and the loose tissue and fat removed from around the vessels and the excretory duct, it will be seen that the organ consists of a central cavity surrounded, except at the hilum, by the proper kidney substance (Fig. 1094).

FIG. 1095.—Area cribrosa of renal papilla. (Toldt.)

This central cavity is called the **renal sinus** (*sinus renalis*) and is lined by a prolongation of the capsule, which is continued around the lips of the hilum. Through the hilum the bloodvessels of the kidney and its excretory duct pass, and therefore these structures, upon entering the kidney, are contained within the sinus.

The **excretory duct** or **ureter** begins as a funnel-shaped sac, the **pelvis of the ureter** (*pelvis uretericus s. renalis*). The pelvis begins at the renal papillæ in the form of a number of truncated cup-shaped infundibular divisions, the **calices minores**, into each of which usually one papilla projects. These minor calices vary from ten to twenty in number. Several minor calices unite to form larger divisions, the **calices majores** (Fig. 1096), which are usually two in number, though more may be present. These major calices unite to form the main compartment of the pelvis, which becomes narrowed below at the level of the second lumbar vertebra to be continued as the ureter proper (Fig. 1096).

The **kidney substance** or **parenchyma** consists of very irregular tubules, the **uriniferous tubules**, which are supported by a framework of retiform connective tissue

FIG. 1096.—The right kidney with its pelvis exposed, viewed from behind. (Spalteholz.)

and surrounded by blood- and lymph vessels and nerves. It is readily divisible into an outer third, the **cortex**, about one-third to one-half of an inch (8 to 12 mm.) in thickness, and an inner two-thirds, the **medulla**, two-thirds to three-quarters of an inch (16 to 20 mm.) in thickness.

The **cortex** is reddish brown in color and soft and granular in consistence. It lies immediately beneath the capsule, arches over the bases of the pyramids, and dips in between adjacent pyramids toward the renal sinus in the form of **renal columns** (*columnae renales* [Bertini]). If a section of the cortex be examined with a lens, it will be seen to consist of a series of lighter colored, ray-like prolongations of straight tubules from the medulla, called the **medullary rays** (*pars radiata*). The darker colored intervening substance composing the remainder of the cortex, from the complexity of its structure, is called the **labyrinth** (*pars convoluta*), and contains the convoluted portions of the uriniferous tubules and the Malpighian corpuscles. The medullary rays gradually taper toward the circumference of the kidney, but do not reach the capsule.

The **medulla** consists of reddish, striated, conical masses, the **medullary pyramids** (*pyramides renales* [Malpighii]), the number of which, varying from ten to twenty, corresponds to the number of lobes of which the organ is composed in the fetal state. The pyramids are composed of straight tubes which pass from the base to the apex. The sides of the pyramids are contiguous with the renal columns, while the apices, known as the **renal papillae**, project into the minor calices of the ureteral pelvis, each calix receiving one, two, or three papillae. Each papilla shows

FIG. 1097.—A section through the cortex of an ape's kidney. A Malpighian corpuscle, together with the beginning of the tubule, is shown. $\times 350$. (Szymonowicz.)

upon its apex a number (16 to 20) of minute orifices of the excretory ducts of the pyramid; this perforated area of the apex is called the **area cribrosa** (Fig. 1095).

The **renal columns** (of Bertin) separate the pyramids from one another and consist of cortical masses extending toward the renal sinus. At the sinus ends they contain a considerable amount of white fibrous and adipose tissue. They serve as a passageway for the main bloodvessels, lymphatics, and nerves to and from the parenchyma of the organ.

Minute Anatomy.—The **uriniferous tubules** (*tubuli renales*) are in part very convoluted and in part straight and regular. They arise in the cortex, pass into the medulla, return to the cortex, and end at the area cribrosa of the renal papilla. Each tubule starts at the **glomerulus** or **renal corpuscle** (*Malpighian body*), a small, round, reddish mass, which measures 120 to 200 μ . Each of these little bodies is composed of two parts, a central glomerulus of vessels, called a **Malpighian tuft** and a membranous envelope, the **Malpighian capsule**, or **capsule of Bowman**, which is the small pouch-like commencement of a uriniferous tubule.

The **Malpighian tuft**, or vascular glomerulus, is a network of convoluted capillary bloodvessels, held together by scanty connective tissue. This capillary network is derived from a small arterial twig, the **afferent vessel**, which pierces the wall of the capsule, generally at a point opposite to that at which the latter is connected with the tube; and the resulting vein, the **efferent vessel**,

merges from the capsule at the same point. The afferent vessel is usually the larger of the two (Fig. 1097). The *Malpighian* or *Bowman's capsule*, which surrounds the glomerulus, is formed of a hyaline membrane, supported by a small amount of connective tissue, which is continuous with the connective tissue of the tube. It is lined on its inner surface by a layer of squamous epithelial cells, which are reflected from the lining membrane to the glomerulus, at the point of entrance or exit of the afferent and efferent vessels. The whole surface of the glomerulus is covered with a continuous layer of the same cells, which rests on a delicate supporting membrane (Fig. 1097). Thus, between the glomerulus and the capsule a space is left, forming a cavity lined by a continuous layer of squamous cells; this cavity varies in size according to the state of secretion and the amount of fluid present in it. In the fetus and young subject the cells are polyhedral or even columnar.

At the junction of a tubule with the Malpighian capsule there is a somewhat constricted portion, which is termed the *neck* (Fig. 1099). Beyond this the tubule becomes convoluted, and pursues a considerable course in the cortical structure, constituting the *proximal* or *first convoluted tubule* (Figs. 1099 and 1102). After a time the convolutions disappear, and the tubule approaches the medullary portion of the kidney in a more or less spiral manner. This section of the tubule has been called the *spiral tube of Schachowa*. Throughout this portion of their course the tubuli uriniferi are contained entirely in the cortical structure, and present a fairly uniform calibre. They now enter the medullary portion, suddenly become much smaller,

FIG. 1098.—Part of a section through the cortex of the kidney in the direction of the straight tubules. (Toldt.)

quite straight in direction, and dip down for a variable depth into the pyramids, constituting the *descending limb of Henle's loop*. Bending on themselves, they form what is termed the *loop of Henle*, and re-ascending, they become suddenly enlarged and again spiral in direction, forming the *ascending limb of Henle's loop*, and reënter the cortical structure. In the cortex the tubule again becomes slightly convoluted, and is called the *distal* or *second convoluted tubule* (Fig. 1099). This terminates in a narrow *arched collecting* or *junctional tubule*, which enters the *straight collecting tubule*.

Each *straight collecting tubule* (*tubulus renalis recta*) passes from the cortex into the medulla, receiving at various intervals in the cortical part of its course several *arched collecting tubules*. In the medullary pyramid, several straight collecting tubules unite to form from sixteen to twenty *papillary* or *excretory ducts*, which empty at the area cribrosa of the renal papilla. As they approach the papilla, their diameter gradually increases.

It will be seen from the above description that there is a continuous series of tubes from their commencement in the Malpighian bodies to their termination at the orifices on the apices of the pyramids of Malpighi, and that the urine, the excretion of which commences in Bowman's capsule, finds its way through these tubes into the calices of the ureter.

Structure of the Uriniferous Tubule.—The uriniferous tubule consists throughout of a single layer of epithelial cells resting upon a basement membrane which is supported by a delicate meshwork of retiform connective tissue. The tissue contains the vessels, nerves, and

lymphatics. The diameter of the tubule and the size of the cells vary in the different convolutions. The capsule of Bowman is lined with *simple squamous cells*, and the renal corpuscle has a diameter of 120 to 200 microns; the neck is lined by *simple squamous cells*, and has a diameter of about 15 microns; the *proximal convoluted* and *spiral tubules* are lined with *irregular columnar cells*;

the lumen of the tubule is irregular and the diameter averages about 40 microns; the *descending limb of Henle's loop* is lined with *simple squamous cells*, and the diameter is from 10 to 13 microns; the *loop and ascending limb* are lined with *regular cuboidal cells*, and the diameter averages from 23 to 28 microns; the *distal convoluted tubule* is lined with *irregular columnar cells*, the lumen is irregular, and the diameter about 45 microns; the *arched connecting tubule* is lined with *simple cuboidal cells*, and the diameter is about 45 microns; the *straight collecting tubule* is lined by *columnar cells*, and the diameter increases from 45 to 75 microns; the *papillary ducts* are lined with *tall columnar cells*, and the diameter reaches 200 to 300 microns. The protoplasm of these cells is granular at the basal end, while the luminal end is striated.

The parts of the kidney in which the various portions of the uriniferous tubules lie are as follows:

Cortex.—In the labyrinth are found the renal corpuscles, the neck, and the proximal and distal convoluted tubules.

In the medullary rays are found the upper ends of the descending and ascending limbs of Henle's loop, the arched collecting tubules, and the upper ends of the straight collecting tubules.

Medulla.—Here are found the lower ends of the descending and ascending limbs of Henle's loop, the loop, the straight collecting tubules, and the papillary ducts.

The Renal Bloodvessels.—The kidney is plentifully supplied with blood by the renal artery

(Figs. 1088 and 1096), a large branch of the abdominal aorta given off at the level of the articular disk between the first and second lumbar vertebræ. The importance of the kidney as an excretory organ is evidenced by the fact that the artery is three times as large as is necessary for the nutrition of an organ of the size of the kidney. Previously to entering the kidney, each artery

divides into four or five branches, which are distributed to its substance. At the hilum these branches lie between the renal vein and ureter, the vein being in front, the ureter behind. Each vessel gives off a small branch to the suprarenal glands, the ureter, and the surrounding tissue and muscles. It has been pointed out by Hyrtl (p. 668) that the renal artery gives off a branch which divides and supplies the dorsal portion of the kidney and a larger branch which divides and supplies the ventral portion of the kidney. Between these two vascular systems is a nonvascular

zone, called by Robinson the **exsanguinated renal zone of Hyrtl**. It "is one-half inch dorsal to the external border of the kidney." Frequently there is a second renal artery, which is given off from the abdominal aorta at a lower level, and supplies the lower portion of the kidney. It is termed the **inferior renal artery**. Within the sinus the renal artery divides into four or five branches, about three-fourths of the blood going to the anterior pyramids and the remainder to the posterior pyramids. Each extremity of the kidney is supplied by a branch

which divides into anterior, middle, and posterior branches, which do not anastomose with each other. The branches of the renal arteries pass to the kidney substance between the pyramids and are known as **interlobar arteries** (*arteriae interlobares renis*) (Figs. 1098 and 1104). At the junction of the cortical and medullary portions (the boundary zone) these vessels turn and for a short distance pursue a course parallel to the kidney surface. There are thus formed a series of incomplete vascular arches across the bases of the pyramids, the **arcuate arteries** (*arteriae arciformes*) (Figs. 1094 and 1102). From these arches two sets of vessels come. The vessels of one set go to the periphery and enter the cortex, the **intralobular arteries**, those of the other set pass

FIG. 1103.—Lobar circulation. FIG. 1104.—Interlobar circulation.
(Poirier and Charpy.)

toward the sinus and enter the medulla. These last vessels are the **arteriolae recti** (Figs. 1098 and 1102). As the **intralobular arteries** pass toward the capsule they give off branches to each renal corpuscle, the **vasa afferentia** or **afferent arterioles**. As the arteriole enters the corpuscle it divides into several branches, each of which forms a capillary plexus. The blood from each plexus is collected by a small branch which joins with its fellows to form the **vas efferens** or **efferent arteriole**. These various plexuses constitute a **glomerulus** or **Malpighian Tuft** (Fig. 1097). On leaving the glomerulus the arteriole forms a capillary network around the adjacent portions of the uriniferous tubule.

The blood is collected by various channels and emptied into the intralobular vein, which starts in the **venae stellatae**, beneath the capsule, and empties its blood into the arcuate vein.

The **arteriolae rectae** supply the medulla and are smaller in diameter than the intralobular arteries, and soon form a rich capillary plexus around the tubules of the medulla. The blood is collected by the **venae rectae**, which empty into the **arcuate vein** (*vena arciformis*) at the boundary zone. The blood is carried to the columns of Bertin, where it continues toward the sinus in the **interlobular veins**. In the sinus these veins unite to form the **renal vein** (*vena renalis*) (Fig. 1088).

The **nerves** of the kidney, although small, are about fifteen in number. They have small ganglia developed upon them, and are derived from the **renal plexus**, which is formed by branches from the solar plexus, the lower and outer part of the semilunar ganglion and aortic plexus, and from the lesser and smallest splanchnic nerves. They communicate with the spermatic plexus, a circumstance which may explain the occurrence of pain in the testicle in affections of the kidney. So far as they have been traced, they seem to accompany the renal artery and its branches, and they have been traced to the epithelium, but their exact mode of termination is not known.

The **Lymphatics** are described on page 799.

Variations and Abnormalities.—Congenital absence of the kidney has been observed. Not unusually one kidney is considerably larger than the other; occasionally one is very large and the other is very small, from atrophy, the large organ having become large in response to a functional need, which causes it to compensate for the insufficiency of the small kidney. If a kidney is removed surgically, the other kidney enlarges. As previously stated, the kidneys of the fetus and of the young child show distinct fissures which make each organ lobulated (Fig. 1105). The adult kidneys frequently exhibit remains of these fissures. A **horseshoe kidney** is a condition in which the lower extremities of the two kidneys are united by kidney structure, the bond of union crossing the middle line. The strip of kidney tissue which effects the junction may be slight, considerable, or extensive in amount. Sometimes the two kidneys are completely fused together into one large organ with two ureters.

Surface Form.—The kidneys, being situated at the back part of the abdominal cavity and deeply situated, cannot be felt unless enlarged or misplaced. They are situated on the confines of the epigastric and umbilical regions internally, with the hypochondriac and lumbar regions externally. The left is somewhat higher than the right. According to Morris, the position of the kidney may be thus defined: *Anteriorly*: "(1) A horizontal line through the umbilicus is

FIG. 1105.—Fetal kidney, showing lobulation. (Testut.)

below the lower edge of each kidney. (2) A vertical line carried upward to the costal arch from the middle of Poupart's ligament has one-third of the kidney to its outer side and two-thirds to its inner side—i. e., between this line and the median line of the body." In adopting these lines it must be borne in mind that the axes of the kidneys are not vertical, but oblique, and if continued upward would meet about the ninth thoracic vertebra. *Posteriorly*: The upper end of the left kidney would be defined by a line drawn horizontally outward from the spinous process of the eleventh thoracic vertebra, and its lower end by a point two inches (5 cm.) above the iliac crest. The right kidney would be half to three-quarters of an inch lower. Morris lays down the following rules for indicating the position of the kidney on the posterior surface of the body: "(1) A line parallel with, and one inch from, the vertebral column, between the lower edge of the tip of the spinous process of the eleventh thoracic vertebra and the lower edge of the spinous process of the third lumbar vertebra. (2) A line from the top of this first line outward at right angles to it for two and three-quarter inches. (3) A line from the lower end of the first transversely outward for two and three-quarter inches. (4) A line parallel to the first and connecting the outer extremities of the second and third lines just described."

The hilum of the **right** kidney is two inches from the mesal plane; the hilum of the **left** one and one-half inches from the mesal plane. A line joining the two hili crosses the vertebral column opposite the disk between the first and second lumbar vertebrae.

Applied Anatomy.—Cases of *congenital absence* of a kidney, of *atrophy* of a kidney, and a *horseshoe kidney* are of great importance, and must be duly taken into account when nephrectomy is contemplated. A more common malformation is where the two kidneys are *fused together*. They may be only joined together at their lower ends by means of a thick mass of renal tissue, so as to form a horseshoe-shaped body, or they may be completely united, forming a disk-like kidney, from which two ureters descend into the bladder. These fused kidneys are generally situated in the middle line of the abdomen, but may be misplaced as well.

One or both kidneys may be *misplaced* as a congenital condition, and remain fixed in this abnormal position. They are then very often misshapen. They may be situated higher or lower than normal or removed farther from the spine than usual or they may be displaced into the iliac fossa, over the sacroiliac joint, on to the promontory of the sacrum, or into the pelvis between the rectum and bladder or by the side of the uterus. In these latter cases they may give rise to very serious trouble. The kidney may also be misplaced as a congenital condition, but may not be fixed. It is then known as a *floating kidney*. It is believed to be due to the fact that the kidney is completely enveloped by peritoneum, which then passes backward to the vertebral column as a double layer, forming a *mesonephron*, which permits of movements taking place. The kidney may also be misplaced as an acquired condition; in these cases the kidney is mobile in the tissues by which it is surrounded, either moving in or moving with its fatty capsule. This condition is known as *movable kidney (nephroptosis)*, and is more common in the female than in the male, and on the right than the left side. If a displaced kidney becomes fixed in an abnormal position, it is said to be *dislocated*. Movable kidney cannot be distinguished from floating kidney until the kidney is exposed by incision. Other malformations are the persistence of the fetal lobulation; the presence of two pelves or two ureters to the one kidney. In some rare instances a third kidney may be present.

The kidney is embedded in a large quantity of loose fatty tissue, and is but partially covered by peritoneum; hence *rupture* of this organ is not nearly so serious an accident as rupture of the liver or spleen, since the extravasation of blood and urine which follows is, in the majority of cases, outside the peritoneal cavity. Occasionally the kidney may be *bruised* by blows in the loin or by being compressed between the lower ribs and the ilium when the body is violently bent forward. This is followed by a little transient *hematuria*, which, however, speedily passes off. Occasionally, when rupture involves the pelvis of the ureter or the commencement of the ureter, this duct may become blocked, and *hydronephrosis* follows.

The loose cellular tissue around the kidney may be the seat of suppuration, constituting *perinephritic abscess*. This may be due to injury, to disease of the kidney itself, or to extension of inflammation from neighboring parts. The abscess may burst into the pleura, causing empyema; into the colon or bladder; or may point externally in the groin or loin. *Tumors of the kidney*, of which, perhaps, *sarcoma* in children is the most common, may be recognized by their position and fixity; by the resonant colon lying in front of it; by their not moving with respiration; and by their rounded outline, not presenting a notched anterior margin like the spleen, with which they are most likely to be confounded. The *examination of the kidney* should be bimanual; that is to say, one hand should be placed in the flank and firm pressure made forward, while the other hand is buried in the abdominal wall, over the situation of the organ. Manipulation of the kidney frequently produces a peculiar sickening sensation and some faintness.

The kidney is frequently attacked surgically. It may be exposed and opened for exploration or the evacuation of pus (*nephrotomy*); it may be incised for the removal of stone (*nephrolithotomy*); it may be sutured when wounded (*nephrorrhaphy*); it may be fixed in place by sutures (*nephropexy*) or gauze pads when movable or floating; or it may be removed (*nephrectomy*).

The kidney may be exposed either by a *lumbar* or *abdominal incision*. The operation is best performed by a lumbar incision, except in a case of very large tumor or of wandering kidney with a loose mesonephron, on account of the advantages which it possesses of not opening the peritoneum and of affording admirable drainage. It may be performed either by an oblique, a vertical, or a transverse incision. A common incision for exposing the kidney begins an inch below the twelfth rib, at the margin of the Erector spinae muscle, and passes obliquely downward and forward, exposing the anterior border of the Latissimus dorsi and the posterior border of the Internal oblique. The surgeon divides the posterior leaflet of the lumbar fascia, draws aside or incises the Quadratus lumborum, and cuts the anterior leaflet of the lumbar fascia and also the transversalis fascia. He opens the fatty capsule down to the kidney and strips it from the true capsule, bringing the kidney outside of the body for inspection. The vertical incision at the edge of the Erector spinae muscle is frequently used. A gridiron or muscle-splitting operation is used by some in order to avoid the division of nerves, vessels, and muscle fibres.

The abdominal operation is best performed by an incision in the linea semilunaris on the side of the kidney to be removed, as recommended by Langenbuch; the kidney is then reached from the outer side of the colon, ascending or descending, as the case may be, and the vessels of the colon are not interfered with. If the incision were made in the linea alba, the kidney would be reached from the inner side of the colon, and the vessels running to supply the colon would necessarily be interfered with. The incision is made of varying length according to the size of the kidney, and commences just below the costal arch. The abdominal cavity is opened. The intestines are held aside, and the outer layer of the mesocolon incised, so that the fingers can be introduced behind the peritoneum and the renal vessels are sought for. These vessels are then to be ligated; if tied separately, care must be taken to ligate the artery first. The kidney must now be enucleated, and the vessels and the ureter divided, and the latter disinfected and tied, and, if it is thought necessary, stitched to the edge of the wound.

THE URETERS (Figs. 1087, 1096).

The ureters are the two tubes which convey the urine from the kidneys into the bladder. Each ureter commences within the sinus of the corresponding kidney by a number of short cup-shaped branches, the *minor calices* or *infundibula*, which unite either directly or indirectly to form a dilated pouch, the *pelvis* (Fig. 1096), from which the ureter, after passing through the hilum of the kidney, descends to the bladder. The *minor calices* encircle the apices of the renal papillæ; but inasmuch as one calix may include two or even more papillæ, their number is generally less than the pyramids themselves. The minor calices vary in number from ten to twenty or more. These calices converge into two or three tubular divisions, the *major calices*, which by their junction form the *pelvis* or *dilated portion of the ureter*, which is situated behind the renal vessels and which lies partly within and partly outside the renal sinus. It is usually placed on a level with the spinous process of the first lumbar vertebra.

The *ureter proper* is a cylindrical membranous tube, about ten to twelve inches (25 to 30 cm.) in length and about one-sixth inch (4 mm.) in diameter, directly continuous near the lower end of the kidney with the tapering extremity of the *pelvis*. Its walls are from 1 to 2 mm. thick, and its calibre varies. It exhibits four main constrictions—(1) at its junction with its *pelvis*; (2) as it passes over the brim of the *pelvis*; (3) as it enters the bladder; (4) at its termination. Its course is obliquely downward and inward through the lumbar region (*pars abdominalis*) (Fig. 1087), into the cavity of the *pelvis* (*pars pelvina*) (Fig. 1107), where it passes downward, forward, and inward across that cavity to the base of the bladder, into which it then opens by a constricted orifice (*orificium ureteris*) (Fig. 1117), after having passed obliquely for nearly an inch between the vesical muscular and mucous coats (Fig. 1106). The lower part of the abdominal portion of the ureter exhibits a spindle-shaped dilatation.

Relations (Fig. 1107).—The *abdominal part* lies behind the peritoneum on the inner part of the Psoas muscle, and is crossed obliquely by the spermatic or ovarian vessels. It enters the pelvic cavity by crossing either the termination of the common, or the commencement of the external, iliac vessels.

At its origin the **right** ureter is usually covered by the second part of the duodenum, and in its course downward lies to the right of the inferior vena cava and is crossed by the right colic artery, while near the pelvic brim it passes behind the lower part of the mesentery and the terminal part of the ileum. The **left** ureter is crossed by the left colic artery, and near the brim of the pelvis passes behind the pelvic colon and its mesentery.

The **pelvic part** runs at first downward on the lateral wall of the pelvic cavity under cover of the peritoneum, lying in front of the internal iliac vessels and on the inner side of the impervious part of the hypogastric artery and the obturator nerve and vessels. Opposite the lower part of the great sacrosciatic foramen it inclines inward behind the vas deferens (which crosses to its inner side) and reaches the base of the bladder, where in the **male** it is situated in front of the upper end of the seminal vesicle and at a distance of about two inches from the opposite ureter. Finally, the ureters run obliquely for about three-quarters of an inch through the wall of the bladder and open by slit-like apertures into the cavity of the viscus at the lateral angles of the trigone. When the bladder is distended the openings of the ureters are about two inches apart, but when it is empty and contracted the distance between them is diminished by one-half. Owing to their oblique course through the coats of the bladder, their upper and lower walls become closely applied to each other when the viscus is distended, and, acting as a valve, prevent regurgitation of urine from the bladder.

In the **female**, the ureter forms, as it lies in relation to the wall of the pelvis, the posterior boundary of a shallow depression named the ovarian fossa, in which the ovary is situated. It then runs inward and forward on the lateral aspect of the cervix of the uterus and of the upper part of the vagina to reach the base of the bladder. In this part of its course it is accompanied for

FIG. 1106. — Diagram showing method of entrance of the ureter into the bladder. (F. H. Gerrish.)

FIG. 1107.—The relations of the pelvic mesocolon with the wall, the iliac, sigmoid, and superior hemorrhoidal arteries, and the ureter. (Poirier and Charpy.)

about an inch by the uterine artery, which then crosses in front of the ureter and ascends between the two layers of the broad ligament. The ureter is distant about three-quarters of an inch from the lateral aspect of the neck of the uterus.

The ureter is sometimes double, and the two tubes may remain distinct as far as the base of the bladder. On rare occasions they open separately into the bladder cavity.

Structure.—The ureter is composed of three coats—**fibrous, muscular, and mucous.**

The **fibrous coat** (*tunica adventitia*) is the same throughout the entire length of the duct, being continuous at one end with the fibrous capsule of the kidney at the floor of the sinus, while at the other it is lost in the fibrous structure of the bladder.

In the pelvis of the ureter the **muscular coat** (*tunica muscularis*) consists of two layers, an internal longitudinal and an external circular; the longitudinal fibres become lost upon the sides of the papillæ at the extremities of the calices; while the circular fibres become more prominent and resemble a small sphincter. In the ureter proper the muscle layers are very distinct, and are three in number—an **external longitudinal** (*stratum externum*), a **middle circular** (*stratum medium*), and an **internal longitudinal layer** (*stratum internum*). The external longitudinal layer is found more prominent in the lower half or lower third of the ureter.

The **mucous coat** (*tunica mucosa*) is smooth, and presents a few longitudinal folds which become effaced by distention. It is continuous with the mucous membrane of the bladder below, while above it is prolonged over the papillæ of the kidney. Its epithelium is of a peculiar character, and resembles that found in the bladder. It is known by the name of **transitional epithelium**. It consists of several layers of cells, of which the innermost—that is to say, the cells in contact with the urine—are quadrilateral in shape, with concave margins on their outer surface, into which fit the rounded ends of the cells of the second layer. These, the intermediate cells, more or less resemble columnar epithelium, and are pear-shaped, with a rounded internal extremity, which fits into the concavity of the cells of the first layer, and a narrow external extremity which is wedged in between the cells of the third layer. The external or third layer consists of conical or oval cells varying in number in different parts, and presenting processes which extend down into the basement membrane. A few racemose glands are at times seen in the mucous coat.

Vessels and Nerves.—The arteries supplying the ureter are branches from the renal, spermatic, internal iliac, and inferior vesical.

The nerves are derived from the inferior mesenteric, spermatic, and pelvic plexuses.

Applied Anatomy.—*Subcutaneous rupture* of the ureter is not a common accident, but occasionally occurs from a sharp direct blow on the abdomen, as from the kick of a horse. The ureter may be either torn completely across, or only partially divided, and, as a rule, the peritoneum escapes injury. If torn completely across, the urine collects in the retroperitoneal tissues; if it is not completely divided, the lumen of the tube may become obstructed and hydronephrosis or pyonephrosis results. The ureter may be accidentally wounded in some abdominal operations; if this should happen, the divided ends must be sutured together, or, failing to accomplish this, the upper end must be implanted into the bladder or the intestine.

Stones (*calculi*) not uncommonly become impacted in the ureter. This may occur at any part, but most commonly either at the point where the tube is crossing the pelvic brim or at the termination, where it is passing obliquely through the muscular wall of the bladder. In the former case, an incision with its centre opposite and one inch internal to the anterior superior spine of the ilium dividing all the structures down to the peritoneum, enables the operator to reach the ureter by pushing the unopened peritoneum inward; the stone can then be felt in the ureter, the wall of which is incised, and the stone extracted, free drainage being provided for the escaping urine. When the stone is impacted at the vesical end of the tube a preliminary incision into the bladder is required, and by scratching through the mucous membrane overlying it the calculus can then be removed.

The diagnosis of ureteral calculus is sometimes made by an x-ray examination. In identifying any shadows in the picture thus secured, caution must be exercised not to mistake similar shadows thrown by *periureteral phleboliths* in the pelvic veins as ureteral calculi.¹

THE URINARY BLADDER (*VESICA URINARIA*) (Figs. 1110, 1111).

The **urinary bladder** is a musculomembranous sac situated in the pelvis, behind the pubes, and in front of the rectum in the male, the cervix uteri and vagina intervening between it and that intestine in the female. The shape, position, and relations of the bladder are greatly influenced by age, sex, and the degree of distention of the organ. During infancy it is conical in shape, and projects above the symphysis pubis into the hypogastric region. In the adult cadaver, when quite empty and collapsed (Figs. 1108 and 1109), it is cup-shaped, and on vertical median section its cavity, with the adjacent portion of the urethra, presents a Y-shaped cleft, the stem of the Y corresponding to the urethra. It is placed

¹ Consult article by George O. Clark in *Annals of Surgery*, 1909, p. 913.

deeply in the pelvis, flattened from before backward, and reaches as high as the upper border of the symphysis pubis. When empty and contracted, as seen immediately after death (as after electrocution), the bladder is nearly spherical in shape. When slightly distended, it has a rounded form, and is still contained within the pelvic cavity (Fig. 1109), and when greatly distended (Figs. 1109 and 1111), it is ovoid in shape, rising into the abdominal cavity, and often extending

FIG. 1108.—The empty bladder. (Poirier and Charpy.)

FIG. 1109.—Modifications of form of the bladder during distention. (Poirier and Charpy.)

nearly as high as the umbilicus. It is larger in its vertical diameter than from side to side, and its long axis is directed from above obliquely downward and backward, in a line directed from some point between the symphysis pubis and umbilicus (according to its distention) to the end of the coccyx. The bladder, when distended, is slightly curved forward toward the anterior wall of the abdomen, so as to be more convex behind than in front. In the *female* it is larger in the transverse than in the vertical diameter, and its capacity is said to be greater than in the male.¹ When moderately distended, it measures about five and one-half inches (14 cm.) in length, four and one-half inches (12 cm.) across, and three inches (10 cm.) antero-posteriorly, and the ordinary amount which it can contain without serious discomfort is about a pint.

The bladder is divided for purposes of description into a **superior**, an **antero-inferior**, and two **lateral surfaces**, a **base** or **fundus**, and a **summit** or **apex**.

Surfaces.—The **superior** or **abdominal surface** (Figs. 978 and 1087) is entirely free, and is invested throughout by peritoneum. It looks almost directly upward into the abdominal cavity, and extends in an antero-posterior direction from the apex to the base of the bladder. It is in relation with the small intestine and sometimes with the sigmoid flexure, and, in the *female*, with the uterus. On each side, in the *male*, a portion of the vas deferens is in contact with the hinder part of this surface, lying beneath the peritoneum. In the relaxed and empty condition of the bladder a transverse fold of peritoneum (*plica vesicalis transversa*) is formed on this surface.

FIG. 1110.—Mesal section through pelvis of newborn male. (Corning.)

¹ According to Henle, the bladder is considerably smaller in the female than in the male.

The **antero-inferior** or **pubic surface** (Figs. 339 and 1111) looks downward and forward. In the undistended condition it is uncovered by peritoneum, and is in relation with the Obturator internus muscle on each side, with the rectovesical fascia, and anterior true ligaments of the bladder. It is separated from the body of the pubis by a triangular interval, occupied by fatty tissue, the **pubovesical space of Retzius**. As the bladder ascends into the abdominal cavity during distention the distance between its apex and the umbilicus is necessarily diminished, and the urachus (Figs. 978 and 1111) is thus relaxed; so that, instead of passing directly upward to the umbilicus, it descends first on the upper part of the anterior surface of the bladder, and then curving upward, ascends on the back of the abdominal wall. The peritoneum, which follows the urachus, thus comes to form a pouch of varying depth between the anterior surface of the viscus and the

FIG. 1111.—Vertical section of bladder, penis, and urethra.

abdominal wall (Fig. 339). The pouch passes to the neighborhood of the internal abdominal rings. Thus, when the bladder is distended, the upper part of its anterior surface is in relation with the urachus and is covered by peritoneum. The lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is devoid of peritoneum, and is in contact with the abdominal wall.

The **lateral surfaces** are invested behind and above by peritoneum, which extends as low as the level of the impervious hypogastric artery; below and in front of this, these surfaces are uncovered by peritoneum, and are separated from the Levatores ani muscles and the walls of the pelvis by a quantity of loose areolar tissue containing fat. In front this surface is connected to the rectovesical fascia by a broad expansion on either side, the **lateral true ligaments**. The vas deferens crosses the

hinder part of the lateral surface obliquely, and passes between the ureter and the bladder. When the bladder is empty the peritoneum descends on the pelvic wall as low as the lateral border of the bladder and enters a groove known as the **paravesical fossa**. The lateral surfaces, the pubic surface, and the abdominal surface together constitute the **body of the bladder** (*corpus vesicae*).

The **fundus** or **base** (*fundus vesicae*) (Figs. 1111 and 1135) is directed downward and backward, and is partly covered by peritoneum. In the male the upper portion, to within about an inch and a half of the prostate, is covered by the **rectovesical pouch of peritoneum** (Fig. 982). The lower part is in direct contact with the anterior wall of the second part of the rectum, the seminal vesicles, and the vasa deferentia (Figs. 1111 and 1118). The ureters enter the bladder at the upper part of its base, about an inch and a half above the base of the prostate gland (Fig. 1111).

The portion of the bladder in relation with the rectum corresponds to a triangular space, bounded below, by the prostate gland; above, by the **rectovesical fold of the peritoneum**; and on each side, by the seminal vesicles and the vas deferens. It is separated from direct contact with the rectum by the **rectovesical fascia**. When the bladder is very full, the peritoneal fold is raised with it, and the distance between its reflection and the anus is about four inches; but this distance is much diminished when the bladder is empty and contracted. In the *female*, the base of the bladder is connected to the anterior aspect of the cervix uteri by areolar tissue, and is adherent to the anterior wall of the vagina (Fig. 980). Its upper surface is separated from the anterior surface of the body of the uterus by the **utero-vesical pouch of the peritoneum** (Fig. 980).

The so-called **neck** or **cervix of the bladder** (*collum vesicae*) is the point of commencement of the urethra; there is, however, no tapering part, which would constitute a true neck, but the bladder suddenly contracts to the opening of the urethra (Fig. 339). In the *male* it is surrounded by the prostate gland and its direction is oblique when the individual is in the erect posture (Figs. 339 and 1111). In the *female* its direction is obliquely downward and forward. The so-called neck is the most fixed portion of the bladder, and is located one inch (2.5 cm.) behind the junction of the inferior and middle thirds of the symphysis pubis; or two inches (5 cm.) behind and below the superior border of the symphysis.

The **summit** or **apex** (*vertex vesicae*) is the portion of the bladder which when that organ is empty or nearly empty is nearest to the upper border of the symphysis. It is directed upward and forward. In a distended bladder the apex is well above the pubes in the abdominal cavity.

The **urachus** or **middle umbilical ligament** (*ligamentum umbilicale medium*) (Fig. 978) is the impervious remains of the tubular canal of the **allantois**, which existed in the embryo, and a portion of which expanded to form the bladder. It passes upward, from the apex of the bladder, between the transversalis fascia and peritoneum, to the umbilicus, becoming thinner as it ascends. It is composed of fibrous tissue, mixed with plain muscle fibres.

The urachus causes the formation of a peritoneal fold, the **plica umbilicalis media** (Fig. 978). On each side of it is placed a fibrous cord, the impervious portion of the **hypogastric artery**, which, passing upward from the side of the bladder, approaches the urachus above its summit. Over each cord is the fold known as the **plica umbilicalis lateralis** (Fig. 978). In the infant, at birth, the urachus is occasionally found pervious, so that the urine escapes at the umbilicus, and calculi have been found in its canal.

Ligaments.—The bladder is retained in its place by ligaments, which are divided into true and false. The true ligaments are *five* in number—two anterior, two lateral, and the urachus. The false ligaments, also *five* in number, consist of folds of the peritoneum.

The two **anterior true ligaments** or **puboprostatic ligaments** (*ligamenta puboprostatica*) extend from the back of the ossa pubis, one on each side of the symphysis, to the front of the neck of the bladder, over the anterior surface of the prostate gland.

The two **lateral true ligaments**, formed by expansions from the fascia lining the lateral wall of the pelvis, are broader and thinner than the preceding. They are attached to the lateral parts of the prostate gland and to the sides of the base of the bladder.

The **urachus** or **middle umbilical ligament** is the fibromuscular cord already mentioned, extending between the summit of the bladder and the umbilicus.

The two **posterior false ligaments** pass forward, in the *male*, from the sides of the rectum (*plicae rectovesicales*); in the *female*, from the sides of the uterus (*plicae vesicouterinae*), to the posterior and lateral aspect of the bladder; they form in the *male* the lateral boundaries of the **rectovesical pouch** (*excavatio rectovesicalis*) (Figs. 339 and 1049); in the *female* the peritoneum is reflected from the rectum to the upper part of the posterior vaginal wall, forming the *rectovaginal pouch*

FIG. 1112.—Fibres of the external longitudinal layer. (Poirier and Charpy.)

FIG. 1113.—Fibres of the middle or circular layer. (Poirier and Charpy.)

FIG. 1114.—Fibres of the internal longitudinal layer. (Poirier and Charpy.)

or *pouch of Douglas* (Fig. 1050). It is continued over the posterior surface and fundus of the uterus on to its anterior surface and then to the bladder, forming here a second but shallower pouch, the *utero-vesical pouch*, bounded on either side by the utero-vesical or posterior false ligaments of the bladder. The posterior false ligaments contain the impervious hypogastric arteries and the ureters, together with vessels and nerves. In the base of each fold is smooth muscle fibre, the **Rectovesical muscle** (*m. rectovesicalis*).

The two **lateral false ligaments** are reflections of the peritoneum, from the iliac fossæ and lateral walls of the pelvis to the sides of the bladder. Each lateral false ligament (*ligamentum umbilicale laterale*) passes in front into the **plica umbilicalis lateralis** over the corresponding hypogastric artery. The two lateral reflections of peritoneum are continuous in front of the apex of the bladder, at which point the peritoneum passes upon the urachus.

The **superior or anterior false ligament** (*suspensory ligament; plica umbilicalis media*) is the prominent fold of peritoneum extending from the summit of the bladder to the umbilicus. It is carried off from the bladder by the urachus. The

Peritoneal fold over each impervious hypogastric artery is called the **plica umbilicalis lateralis** (Fig. 978), and is the prolongation forward of the ligamentum umbilicale laterale. Besides the true and false ligaments, the bladder receives support from the fibrous tissue and unstriated muscle about the seminal vesicles, and terminations of the ureters and vasa deferentia. In the female the connection with the anterior vaginal wall supports the base of the bladder. In both sexes the most solidly fixed part of the bladder is about the orifice of the urethra.

Structure.—The bladder is composed of three coats—**fibrous, muscular, and mucous.**

The **fibrous coat** (*tunica fibrosa*) consists of white fibrous tissue, which supports the other coats. It is partially invested by peritoneum.

The **muscular coat** (*tunica muscularis*) (Figs. 1112, 1113, and 1114) consists of three incompletely differentiated layers of unstriated muscular fibre—an **external layer**, composed of fibres having for the most part a longitudinal arrangement; a **middle layer**, in which the fibres are arranged, more or less, in a circular manner; and an **internal layer**, in which the fibres have a general longitudinal arrangement.

The **fibres of the external longitudinal layer** (*stratum externum*) arise from the posterior surface of the body of the os pubis in both sexes (*m. pubovesicalis*), and in the male arise also from the adjacent part of the prostate gland and its capsule. They pass, in a more or less longitudinal manner, up the anterior surface of the bladder, over its apex, and then descend along its posterior surface to its base, where they become attached to the prostate in the male and to the front of the vagina in the female. At the sides of the bladder the fibres are arranged obliquely and intersect one another. The external longitudinal layer has been named the **Detrusor urinæ muscle**.

The **middle circular layers** (*stratum medium*) are very thinly and irregularly scattered on the body of the organ, and, though to some extent placed transversely to the long axis of the bladder, are for the most part arranged obliquely. Toward the lower part of the bladder, around the neck and the commencement of the urethra, they are disposed in a thick circular layer, forming the **sphincter vesicæ**, which is continuous with the muscle fibres of the prostate gland.

The **internal longitudinal layer** (*stratum internum*) is thin, and its fasciculi have a reticular arrangement, but with a tendency to assume for the most part a longitudinal direction. Two bands of oblique fibres, originating behind the orifices of the ureters, converge to the back part of the prostate gland, and are *inserted*, by means of a fibrous process, into the so-called middle lobe of that organ. They are the **muscles of the ureters**, described by Sir C. Bell, who supposed that during the contraction of the bladder they served to retain the oblique direction of the ureters, and so prevent the reflux of the urine into them.

FIG. 1115.—Superficial layer of the epithelium of the bladder. Composed of polyhedral cells of various sizes, each with one, two, or three nuclei. (Klein and Noble Smith.)

FIG. 1116.—Deep layers of epithelium of bladder, showing large club-shaped cells above, and smaller, more spindle-shaped cells below, each with an oval nucleus. (Klein and Noble Smith.)

The **mucous coat** (*tunica mucosa*) is thin, smooth, and of a pale rose color. It is continuous above through the ureters with the lining membrane of the uriniferous tubes, and below with that of the urethra. Except at the trigone, it is connected very loosely to the muscular coat by a layer of areolar tissue, and is therefore thrown into folds or rugæ when the bladder is empty (Fig. 1118). The epithelial covering it is of the transitional variety, consisting of a superficial layer of polyhedral flattened cells, each with one, two, or three nuclei (Fig. 1115); beneath these is a stratum of large club-shaped cells with the narrow extremity of each cell directed downward and wedged in between smaller spindle-shaped cells, each with an oval nucleus (Fig. 1116). There are no true glands in the mucous membrane of the bladder, though certain mucous follicles

which exist, especially near the neck of the bladder, have been regarded as such. The epithelial cells rest upon a basement membrane, beneath which is the fibroelastic tunica propria, which contains diffuse lymphoid tissue, and in which solitary follicles have been found.

FIG. 1117.—The interior of the bladder, showing the vesical trigone. (Poirier and Charpy.)

The Interior of the Bladder.—Upon the inner surface of the bladder are seen the **mucoous membrane**, **orifices of the ureters**, the **trigone**, and the **commencement of the urethra**.

FIG. 1118.—The internal surface of the bladder. (Poirier and Charpy.)

The **mucoous membrane** of the empty bladder is thrown into folds or **rugæ**, except over the trigone, where it is firmly adherent to the muscular coat and is smooth (Figs. 1117 and 1118). The folds disappear when the bladder is distended.

The **vesical trigone** or the **trigonum vesicae** (Fig. 1118) is a smooth, triangular surface, with the apex directed forward, situated at the base of the bladder, immediately behind the urethral orifice. It represents an equilateral triangle, the sides measuring about one inch in the empty bladder and increasing to about one and one-half inches in the distended bladder. It is paler in color than the rest of the interior, and never presents any rugæ, even in the contracted condition of the organ, owing to the intimate adhesion of its mucous membrane to the subjacent tissue. It is bounded at each basal angle by the orifice of a ureter, and at its apex by the orifice of the urethra. Projecting from the lower and anterior part of the bladder, and reaching to the orifice of the urethra, is a slight elevation of mucous membrane, particularly prominent in old persons, called the **uvula vesicae**. It is formed by a thickening of the tunica propria.

Stretching from one ureteral opening to the other is a smooth, slightly curved ridge (**torus interuretericus**), the convexity of which is toward the urethra. It is produced by transverse muscle fibres beneath the mucous membrane. The outer prolongations of this ridge beyond the ureteral orifices are called the **ureteral folds** (**plicae uretericae**). They are formed by the ureters as they traverse the bladder wall. About the urethral orifice are slight radial folds of mucous membrane, which are continuous with the longitudinal folds of the prostatic urethra.

The **internal urethral orifice** (**orificium urethrae internum**) is sickle-shaped and is surrounded by a circular prominence (**annulus urethralis**), which is most distinct in the male.

Vessels and Nerves.—The **arteries** (Fig. 473) supplying the bladder are the **superior, middle, and inferior vesical** in the male, with additional branches from the **uterine and vaginal** in the female. They are all derived from the **anterior trunk of the interior iliac**. The **obturator and sciatic arteries** also supply small visceral branches to the bladder. The **veins** form a complicated plexus around the neck, sides, and base of the bladder (Fig. 525). The veins communicate below with the plexus about the prostate and terminate in the internal iliac vein.

The **lymphatics** are few in number; they form two plexuses, one in the muscular and another in the deep tissue of the mucous coat, and accompany the bloodvessels. The subepithelial portion of the mucous membrane of the bladder contains no lymphatics whatever (Sappey). The muscular tissue contains a few lymphatics. The subperitoneal tissues contain the usual number. The collecting trunks from the anterior surface terminate in the **external iliac nodes**. The trunks from the posterior surface terminate in the **internal iliac nodes**, the **hypogastric nodes**, and the nodes in front of the **sacral promontory**.

The **nerves** are derived from the **pelvic plexus of the sympathetic** and from the **third and fourth sacral nerves**; the former supplying the upper part of the organ, the latter its base and neck. According to F. Darwin, the sympathetic fibres have ganglia connected with them, which send branches to the vessels and to the muscular coat.

Surface Form.—The surface form of the bladder varies with its degree of distention and under other circumstances. In the young child it is represented by a conical figure, the apex of which, even when the viscus is empty, is situated in the hypogastric region, about an inch above the level of the symphysis pubis. In the adult, when the bladder is empty, its apex does not reach above the level of the upper border of the symphysis pubis, and the whole organ is situated in the pelvis; the neck, in the *male*, corresponding to a line drawn horizontally backward through the symphysis a little below its middle. As the bladder becomes distended, it gradually rises out of the pelvis into the abdomen, and forms a swelling in the hypogastric region, which is perceptible to the hand as well as to percussion. In extreme distention it reaches into the umbilical region. Under these circumstances the lower part of its anterior surface, for a distance of about two inches above the symphysis pubis, is closely applied to the abdominal wall, without the intervention of peritoneum, so that it can be tapped by an opening in the middle line just above the symphysis pubis, without any fear of wounding the peritoneum. When the rectum is distended, the prostatic portion of the urethra is elongated and the bladder lifted out of the pelvis and the peritoneum pushed upward. Advantage is taken of this by some surgeons in performing the operation of suprapubic cystotomy. The rectum is distended by a rubber bag, which is introduced into this cavity empty, and is then filled with ten or twelve ounces of water. If, now, the bladder is injected with about half a pint of some antiseptic fluid it will appear above the pubes plainly perceptible to the sight and touch. The peritoneum will be pushed out of the way, and an incision three inches long may be made in the linea alba, from the symphysis pubis upward, without any great risk of wounding the peritoneum. Other

surgeons object to the employment of this bag, as its use is not unattended with risk, since it causes pressure on the prostatic veins and hence produces congestion of the vessels over the bladder and a good deal of venous hemorrhage.

When distended, the bladder can be felt in the male, from the rectum, behind the prostate, and fluctuation can be perceived by a bimanual examination, one finger being introduced into the rectum and the distended bladder being tapped on the front of the abdomen with the finger of the other hand. This portion of the bladder—that is, the portion felt in the rectum by the finger—is uncovered by peritoneum.

Applied Anatomy.—A certain defect of development in which the bladder is implicated is known under the name of *extroversion of the bladder*. In this condition the lower part of the abdominal wall and the anterior wall of the bladder are wanting, so that the posterior surface of the bladder presents on the abdominal surface, and is pushed forward by the pressure of the viscera within the abdomen, forming a red, vascular protrusion, on which the openings of the ureters are visible. The penis, except the glans, is rudimentary, and is cleft on its dorsal surface, exposing the floor of the urethra—a condition known as *epispadias*. The pelvic bones are also arrested in development (see p. 220).

The bladder may be ruptured by violence applied to the abdominal wall when the viscus is distended without injury to the bony pelvis, or it may be torn in case of fracture of the pelvis. The rupture may be either intraperitoneal or extraperitoneal, that is—may implicate the superior surface of the bladder in the former case, or one of the other surfaces in the latter. Rupture of the antero-inferior surface alone is, however, very rare. Until recently intraperitoneal rupture was uniformly fatal, but now abdominal section and suturing the rent with Lembert sutures often saves the patient. The sutures are inserted only through the peritoneal and muscular coats in such a way as to bring the serous surfaces at the margin of the wound into apposition, and one is also inserted just beyond each end of the wound. The bladder should be tested as to whether it is water-tight before closing the external incision.

The muscular coat of the bladder undergoes *hypertrophy* in cases in which there is any persistent obstruction to the flow of urine. Under these circumstances the bundles of which the muscular coat consists become much increased in size, and, interlacing in all directions, give rise to what is known as the *fasciculated bladder*. Between these bundles of muscle fibres the mucous membrane may bulge out, forming sacculi, constituting the *sacculated bladder*, and in these little pouches phosphatic concretions may collect, forming *encysted calculi*. The mucous membrane is very loose and lax, except over the trigone, to allow of the distention of the viscus.

Various forms of tumors have been found springing from the wall of the bladder. The *innocent tumors* are the *papilloma* and the *mucous polypus*, arising from the mucous membrane; the *fibrous tumor*, from the deep mucous tissue; and the *myoma*, originating in the muscle tissue, and, very rarely, *dermoid tumors*, the exact origin of which it is difficult to explain. Of the *malignant tumors*, *epitheliomata* are the most common, but *sarcomata* are occasionally found in the bladders of children.

Puncture of the bladder is performed above the pubes without wounding the peritoneum. *Suprapubic cystotomy* is considered above under the heading of Surface Form. This operation may be employed to permit of the removal of a calculus, and is then called *suprapubic lithotomy*.

THE MALE URETHRA (URETHRA VIRILIS) (Figs. 1119, 1120).

The *urethra* in the male extends from the neck of the bladder at the **internal orifice of the urethra** (*orificium urethrae internum*) to the **meatus urinarius**, the **external orifice of the urethra** (*orificium urethrae externum*), at the end of the penis. The internal orifice has been described (p. 1365). The urethra presents a double curve in the flaccid state of the penis (Fig. 1111), but in the erect state of this organ it forms only a single curve, the concavity of which is directed upward. It presents three important constrictions—(1) at the beginning, (2) in the membranous portion, (3) at the end. Its length varies from seven to eight inches (17 to 20 cm.); and it is divided into three portions, the **prostatic**, **membranous**, and **spongy**, the structure and relations of which are essentially different. Except during the passage of the urine or semen, the urethra is a mere transverse, T-shaped, or crescentic cleft or slit (Fig. 1120), with its upper and under surfaces in contact. At the meatus urinarius the slit is vertical, and in the prostatic portion somewhat arched (Fig. 1120).

The **prostatic portion** (*pars prostatica*) (Figs. 1119 and 1154), the widest and most dilatable part of the canal, is about an inch in length. It is between the

internal orifice of the urethra and the deep layer of the triangular ligament and lies within the pelvic cavity. It passes almost vertically through the prostate gland from its base to its apex, lying nearer its anterior than its posterior surface. The gland *seems* to completely surround this portion of the urethra (Fig. 1149), but the glandular substance proper does not (Fig. 1152). The gland is like a clasp open in front, and the open part of the clasp is closed by the prostatic muscle. The form of the canal is spindle-shaped, being wider in the middle than at either extremity, and narrowest below, where it joins the membranous portion. Except during the passage of fluid, the canal is in a collapsed state and is horseshoe-shaped on trans-section, the anterior wall resting upon the posterior wall (Fig. 1120), and the mucous membrane exhibiting longitudinal folds. When distended, the largest portion of the prostatic urethra in the cadaver has a diameter of about one-half inch (12 mm.).

Upon the posterior wall or floor of the canal is a narrow longitudinal ridge, the *verumontanum* or *caput gallinaginis* (Figs. 1119 and 1154) (*crista urethralis*), formed by an elevation of the mucous membrane and its subjacent tissue (Fig. 1153). It is about 16 mm. in length and about 3 mm. in height, and contains, according to Kobelt, muscle and erectile tissues. On either side of the verumontanum is a slightly depressed fossa, the *prostatic sinus*, the floor of which is perforated by numerous apertures, the *orifices of the prostatic ducts* (Figs. 1119 and 1154), from the lateral lobes of the glands; the ducts of the middle lobe open behind the verumontanum. At the fore part of the verumontanum, in the middle line, is a depression, the *sinus pocularis* (*utricleus prostaticus*) (Figs. 339 and 1154), upon the margins of which are the slit-like openings of the *ejaculatory ducts* (Fig. 1154). The sinus pocularis forms a *cul-de-sac* about a quarter of an inch in length, which runs upward and backward in the substance of the prostate into the so-called middle lobe; its prominent anterior wall partly forms the verumontanum. Its walls are composed of fibrous tissue, muscle fibres, and mucous membrane, and numerous small glands open on its inner surface. It has been called the *uterus masculinus*, because it is developed from the united lower ends of the atrophied Müllerian ducts, and therefore is homologous with the uterus and vagina in the female.

The **membranous portion** (*pars membranacea*) (Figs. 1111 and 1119) lies between the two layers of the triangular ligament, and extends downward and forward between the apex of the prostate and the bulb of the corpus spongiosum. It is the narrowest part of the canal (excepting the meati), has a calibre of about one-third of an inch (8 mm.), and measures about half an inch (10 to 12 mm.) in length. Its anterior concave surface is placed about an inch below and behind

FIG. 1119.—The male urethra, laid open on its anterior (upper surface.) (Testut.)

the pubic arch, from which it is separated by the dorsal vessels and nerve of the penis, and some muscle fibres. Its posterior convex surface is separated from the rectum by a triangular mass of tissue which constitutes the perineal body. As it pierces the superficial layer of the triangular ligament the fibres around the opening are prolonged over the tube and fix the two structures firmly to each other. The membranous urethra is surrounded by cavernous tissue and by the Compressor urethrae muscle (*m. sphincter urethrae membranaceae*) (Fig. 340). On the floor of the membranous urethra is the anterior extremity of the verumontanum.

Behind this part of the urethra, on each side of the middle line, are **Cowper's glands** (Figs. 336 and 1111). When the urethra is empty the mucous membrane of this part is thrown into longitudinal folds, which are obliterated by distention.

The **penile or spongy portion** (*pars cavernosa*) (Figs. 1119 and 1121) is the longest part of the urethra, and is contained in the corpus spongiosum. It is about six inches (15 cm.) in length, and extends from the termination of the membranous portion to the meatus urinarius. Its proximal end is fixed in position and unchangeable in direction. Its distal end is movable and changeable in direction. Commencing just below the triangular ligament it is first directed forward through the bulb; it then passes downward and forward, the turn beginning at the point of attachment of the suspensory ligament of the penis (Fig. 1111). The direction of the spongy portion of the urethra is changed by alterations in the position of the penis. When the canal is closed the anterior and posterior walls are in contact (roof and floor), except in the glans penis, where the lateral walls

FIG. 1120. - Cross-section of the male urethra at various distances from its free end, showing marked alterations of form. (Testut.)

FIG. 1121. - The distal portion of the male urethra, laid open on its posterior (under) surface, showing the lacunae. (Testut.)

come together. The calibre of the spongy urethra varies in different portions of the tube. It is narrow and of uniform size in the body of the penis, measuring about one-third of an inch (9 mm.) in diameter; it is dilated behind, within the bulb (13 to 14 mm.), and again anteriorly within the glans penis (12 to 14 mm.), where it forms the **fossa navicularis** (*fossa navicularis urethrae*). In the roof of the fossa navicularis there is a transverse fold of mucous membrane,

the valve of Guerin (*valvulae fossae navicularis*), guarding a recess, the *lacuna magna*. The urethra opens anteriorly by the *meatus urinarius*.

The bulbous portion is a name sometimes given to the posterior part of the spongy portion contained within the bulb.

The *meatus urinarius* or *external orifice of the urethra* (*orificium urethrae externum*) (Figs. 1119 and 1121) is the most contracted part of the urethra; it is a vertical slit (Fig. 1120), about one-quarter of an inch in length, bounded on each side by a small lip or *labium*.

The inner surface of the lining membrane of the urethra, especially on the floor of the spongy portion, presents the orifices of numerous mucous glands (Fig. 1121) situated in the subepithelial tissue, and named the *glands of Littre* (*glandulae urethrales*). Besides these there are a number of little recesses or follicles, of varying sizes, called *lacunae* (*lacunae urethrales*). Their orifices are directed forward, so that they may easily intercept the point of a catheter in its passage along the canal. One of these lacunae, larger than the rest, is situated in the upper surface of the fossa navicularis, about half an inch from the orifice; it is called the *lacuna magna* (Fig. 1121). Into the bulbous portion are found opening the ducts of Cowper's glands.

Structure.—The male urethra is composed of three coats—*mucous*, *muscular*, and *fibrous*.

The *mucous coat* forms part of the urinogenital mucous membrane. It is continuous with the mucous membrane of the bladder, ureters, and kidneys; externally with the integument covering the glans penis; and is prolonged into the ducts of the glands which open into the urethra—viz., Cowper's glands and the prostate gland—into the vasa deferentia and the seminal vesicles through the ejaculatory ducts. The mucous membrane is arranged in longitudinal folds when the tube is empty. Small papillae are found upon it near the orifice, and its epithelial lining varies in the different divisions. The *prostatic portion* is lined by *transitional* cells, continued from the bladder, the *membranous portion* by *stratified columnar* cells, and the *penile portion* by *simple columnar* epithelium, except in the *fossa navicularis*, where *stratified squamous* cells are found. The cells rest upon a *basement membrane* supported by the *tunica propria*, composed of fibroelastic tissue. In the latter are found diffuse lymphoid tissue and racemose glands, the *urethral glands* (*glands of Littre*).

The *muscular layer* is continuous with the muscle of the prostate and bladder, and lies external to the mucous coat. It is composed of nonstriated muscle arranged in an outer layer of *circular fibres* (*stratum circulare*) and an inner layer of *longitudinal fibres* (*stratum longitudinale*). These layers are prominent in the prostatic urethra, less so in the membranous portion, and ultimately disappear in the spongy part. The longitudinal fibres, when contracted, shorten the urethra and increase its diameter. The circular fibres are in a state of tonic contraction and close the urethra, constituting, apparently, a real *sphincter* (Zeissl, Zuckerkandl). The so-called sphincter of the urethra, the *Accelerator urinae*, is a voluntary muscle and is not the real sphincter. Outside of the muscle layer of the urethra is the tissue of the corpus spongiosum.

The *fibrous coat* (*tunica fibrosa*) consists chiefly of white fibrous tissue supporting the preceding coats.

Applied Anatomy.—The urethra may be *ruptured* by the patient falling astride of any hard substance and striking his perineum, so that the urethra is crushed against the pubic arch. Bleeding will at once take place from the urethra, and this, together with the bruising in the perineum and the history of the accident, will at once point to the nature of the injury.

Rupture of the urethra leads to *extravasation of urine*. In rupture back of the superior layer of the triangular ligament the urine usually follows the rectum and reaches the margin of the anus. Rupture of the membranous part liberates urine between the two layers of the triangular ligament, where it remains until a path of exit is made by suppuration or the surgeon's knife. In rupture superficial to the anterior layer of the ligament the urine passes into the scrotum and may mount up to the abdomen between the symphysis and the pubic spine, between which points the deep layer of the superficial fascia is not attached. It cannot pass to the thigh nor cross the midline, because the fascia is attached to the fascia lata and at the midline.

The applied anatomy of the urethra is of considerable importance in connection with the passage of instruments into the bladder. Otis was the first to point out that the urethra is capable of great dilatation, so that, excepting through the external meatus, an instrument corresponding to 18 English gauge (29 French) can usually be passed without damage. The orifice of the urethra is not so dilatable, and therefore may require slitting, although the introduction of the Oberlander dilator, which is expanded after introduction, renders slitting of the meatus seldom necessary in cases of chronic gonorrhea. A recognition of this dilatability caused Bige-

low to very considerably modify the operation of lithotripsy and introduce that of litholapaxy. In passing a fine catheter, the point of the instrument after it has passed the lacuna magna should be kept as far as possible along the upper wall of the canal, as the point is otherwise very liable to enter one of the lacunæ. Stricture of the urethra is a disease of very common occurrence, and is generally situated in the spongy portion of the urethra, most commonly in the bulbous portion just in front of the membranous urethra, but in a very considerable number of cases in the penile part of the canal. Even in a normal urethra, and very markedly in an inflamed urethra, a bougie encounters resistance behind the bulb. This is usually supposed to be due to spasm of the Compressor urethræ muscle.

In irrigation of the urethra by gravity fluid tends to block at the same point, especially if it is thrown in suddenly or forcibly. If a reservoir is raised seven and one-half feet from the floor, and if a patient sits on a chair or lies upon a bed, fluid can be readily made to pass by hydraulic pressure from the meatus to the bladder. Spasm may temporarily prevent the inflow, but the weight of the column of fluid soon tires out the muscle and causes it to relax. Relaxation is favored by having the patient take slow, deep breaths, and make efforts at urination (Valentine).

Chronic gonorrhea is frequently kept up by persistent inflammation of the ducts and follicles in the mucous membrane. This condition is known as chronic glandular urethritis or para-urethritis. In these crypts and glands gonococci may remain when gonorrhea appears to have passed away, and from time to time reinfection of the urethra may arise from such a source.

Median urethrotomy or perineal section is opening of the membranous urethra. Through such an opening the bladder can be drained and explored, and the operation is sometimes called median cystotomy.

In lateral lithotomy the knife enters the membranous urethra and strikes the groove of the staff. Its edge is then turned toward the left ischial tuberosity and is carried along the groove into the bladder, dividing the membranous urethra, the prostatic urethra, the posterior layer of the triangular ligament, the Compressor urethræ muscle, anterior fibres of the Levator ani muscle and the left lobe of the prostate gland.

THE FEMALE URETHRA (URETHRA MULIEBRIS).

The female urethra is a narrow membranous canal, about an inch and a half in length, extending from the internal urethral orifice at the neck of the bladder to the meatus urinarius. It is placed behind the symphysis pubis, embedded in the anterior wall of the vagina, and its direction is obliquely downward and forward; its course is slightly curved and the concavity directed forward and upward. Ordinarily the wall is collapsed so that the lumen is of stellate outline; the urethra may be dilated to about a quarter of an inch (6 to 8 mm.); toward the bladder the calibre increases slightly. The urethra perforates both layers of the triangular ligament, and its external orifice is situated directly in front of the vaginal opening and about an inch behind the glans clitoridis.

Structure.—The female urethra consists of three coats—mucous, muscular, and fibrous.

The mucous coat (*tunica mucosa*) is pale, continuous externally with that of the vulva, and internally with that of the bladder. It is thrown into longitudinal folds, one of which, placed along the floor of the canal, extends from the vesical trigone almost to the external orifice of the urethra. It is called the **crest** (*crista urethralis*). The outline of the urethra is stellate when collapsed, because of the formation of numerous longitudinal folds. It is lined by laminated epithelium, which becomes transitional near the bladder. Many mucous glands open into the urethra, and there are numerous lacunæ. On either side of the terminal portion of the urethra lie a group of mucous glands (*glandulae paraurethrales*), each lateral group opening into the vestibule by a common duct (*ductus paraurethralis*) at the side of the urinary meatus. These glands are regarded as being homologous with the prostate in the male.

The mucous coat is lined by stratified squamous cells resting upon a basement membrane and by papillated *tunica propria*; the latter consists of fibroelastic tissue containing the smaller vessels, some lymphoid tissue, and a few racemose glands. In the deeper portion of the *tunica propria* the structure is very vascular, is of a spongy nature, and constitutes the *erectile tissue*.

The muscular coat (*tunica muscularis*) is continuous with that of the bladder; it extends the whole length of the tube, and consists of an internal layer of nonstriated longitudinal fibres (*stratum longitudinale*) and an external layer of nonstriated circular fibres (*stratum circulare*). In addition to these, between the two layers of the triangular ligament, the female urethra is surrounded by the Compressor urethræ muscle, as in the male.

The **fibrous coat** consists of white fibrous tissue which supports the other coats.

The urethra, because it is not surrounded by dense resisting structures, as in the male, admits of great dilatation, which enables the surgeon to remove with considerable facility calculi or other foreign bodies from the cavity of the bladder.

FIG. 1122.—Mesal section through the pelvis of a woman, aged twenty-one years. Peritoneum in blue. (Corning.)

THE MALE REPRODUCTIVE ORGANS.

The **male reproductive organs** (*organa genitalia virilia*) include the **testes**, the **vasa deferentia**, the **seminal vesicles**, the **ejaculatory ducts**, and the **penis**, together with the following accessory structures—viz., the **prostate** and **Cowper's glands**.

THE TESTICLES (TESTES) AND THEIR COVERINGS (Figs. 1123, 1124).

The **testes** are two glandular organs, which secrete the spermatozoa; they are situated in the scrotum, being suspended by the spermatic cords. At an early period of fetal life the testes are contained in the abdominal cavity, behind the peritoneum. Before birth they descend to the inguinal canal, along which they pass with the spermatic cord, and emerging at the external abdominal ring, they descend into the scrotum, becoming invested in their course by coverings derived

from the serous, muscular, and fibrous layers of the abdominal parietes as well as by the scrotum proper.

The coverings of the testis are the following:

Skin } Scrotum.
Dartos }
Intercolumnar or External spermatic fascia.
Cremasteric fascia.
Infundibulum or Internal spermatic fascia.
Tunica vaginalis.

FIG. 1123.—The scrotum. On the left side the cavity of the tunica vaginalis has been opened; on the right side only the layers superficial to the Cremaster have been removed. (Testut.)

The **scrotum**¹ (Figs. 1123 and 1124) is a cutaneous pouch which contains the testes and part of the spermatic cords. It is divided on its surface into two lateral portions by a median line or **raphe** (*raphe scroti*), which is continued forward to the under surface of the penis and backward along the middle line of the perineum to the anus. Of these two lateral portions, the left is usually longer than the right, to correspond with the usual greater length of the left spermatic cord. Its external aspect varies under different circumstances; thus, under the influence of warmth and in old and debilitated persons it becomes elongated and flaccid but under the influence of cold or sexual excitement and in the young

¹ Originally *scortum*, a bag of leather or skin; through a blunder two of the letters in the word have become transposed.

and robust it is short, corrugated, and closely applied to the testes. The wrinkles in the scrotum are called *rugæ*.

The scrotum consists of two layers, the *integument* and the *dartos*.

The *integument* is very thin, of a brownish color, and generally thrown into folds or *rugæ*. It is provided with sebaceous follicles, the secretion of which has a peculiar odor, and is beset with thinly scattered, crisp hairs, the roots of which may be seen through the skin.

FIG. 1124.—The scrotum. The penis has been turned upward, and the anterior wall of the scrotum has been removed. On the right side, the spermatic cord, the infundibuliform fascia, and the Cremaster muscle are displayed; on the left side, the infundibuliform fascia has been divided by a longitudinal incision passing along the front of the cord and the testicle, and a portion of the parietal layer of the tunica vaginalis has been removed to display the testicle and a portion of the head of the epididymis, which are covered by the visceral layer of the tunica vaginalis. (Toldt.)

The *dartos* (*tunica dartos*) (Figs. 1123 and 1125) is a thin layer of loose vascular tissue, containing smooth muscle tissue but no fat; it forms the proper tunic of the scrotum, is continuous around the base of the scrotum, with the two layers of the superficial fascia of the groin and perineum, and sends inward a distinct mesal septum, the *septum of the scrotum* (*septum scroti*) (Fig. 1123), which divides it into two cavities for the two testes, the septum extending between the raphe and the under surface of the penis as far as its root.

The dartos is closely united to the skin externally, but connected with the subjacent parts by delicate areolar tissue, upon which it glides with the greatest facility.

The **intercolumnar** or **external spermatic fascia** (Fig. 1123) is a thin membrane derived from the margin of the pillars of the external abdominal ring, during the descent of the testis in the fetus, which is prolonged downward around the surface of the cord and testis. It is separated from the dartos by loose areolar tissue, which allows of considerable movement of the latter upon it, but is intimately connected with the succeeding layers.

The **cremasteric fascia** (*fascia cremasterica*) (Figs. 1123 and 1124) consists of scattered bundles of muscle fibres, the **cremaster muscle** (*m. cremaster*) (Figs. 1123 and 1124) derived from the lower border of the Internal oblique and collected within a continuous covering by intermediate areolar tissue.

FIG. 1125.—Transverse section through the left side of the scrotum and the left testis. The sac of the tunica vaginalis is represented in a distended condition. (Delépine.)

The **infundibuliform fascia** (*tunica vaginalis communis [testis et funiculi spermatici]*) (Figs. 1123 and 1124) is a thin membranous layer, which loosely invests the surface of the cord. It is a continuation downward of the fascia transversalis. Beneath it is a quantity of loose connective tissue which connects this layer of fascia with the spermatic cord and posterior parts of the testicle. This connective tissue is continuous above with the subserous areolar tissue of the abdomen. These two layers, the infundibuliform fascia and the tissue beneath it, are known collectively as the **fascia propria**. The infundibuliform fascia completely encloses the testicle and epididymis and is fused with the parietal lamina of the tunica vaginalis propria testis.

The **tunica vaginalis** (*tunica vaginalis propria testis*) is described with the testis (p. 1381).

Vessels and Nerves.—The **arteries** supplying the coverings of the testis are the superficial and deep external pudic, from the femoral; the superficial perineal branch of the internal pudic; and the cremasteric branch from the deep epigastric. The **veins** follow the course of the corresponding arteries. The **lymphatics** terminate in the inguinal nodes. The **nerves** are the ilioinguinal and genital branch of the genitofemoral nerve and of the lumbar plexus, the two superficial perineal branches of the internal pudic nerve, and the inferior pudendal branch of the small sciatic nerve.

The **inguinal or spermatic canal** (*canalis inguinalis*) (Figs. 332 and 1127) contains the spermatic cord in the male and the round ligament in the female. It is an oblique canal, about an inch and a half in length, directed downward and inward and placed parallel with, and a little above, Poupart's ligament. It commences above at the internal or deep abdominal ring, which is the point where the cord enters the inguinal canal, and terminates below at the external or superficial ring. It is bounded, *in front*, by the integument and superficial fascia, by the aponeurosis of the External oblique throughout its whole length, and by the Internal oblique for its outer third; *behind*, by the triangular fascia, the conjoined tendon of the Internal oblique and Transversalis, transversalis fascia, and the subperitoneal fat and peritoneum; *above*, by the arched fibres of the Internal oblique and Transversalis; *below*, by the union of the transversalis fascia with Poupart's ligament.

FIG. 1126.—The arteries of the testis and the cord. (Poirier and Charpy.)

FIG. 1127.—The spermatic cord and the ligament of Cloquet. (Poirier and Charpy.)

The **spermatic cord** (*funiculus spermaticus*) (Figs. 1123 and 1127) extends from the internal abdominal ring, where the structures of which it is composed

converge, to the back part of the testicle. In the abdominal wall the cord passes obliquely along the inguinal canal, lying at first beneath the Internal oblique muscle and upon the fascia transversalis; but nearer the pubes it rests upon Poupart's ligament, having the aponeurosis of the External oblique in front of it and the conjoined tendon behind it. It then escapes at the external ring, and descends nearly vertically into the scrotum. The left cord is usually rather longer than the right, consequently the left testis generally hangs somewhat lower than its fellow.

FIG. 1128.—The spermatic cord in the inguinal canal. (Poirier and Charpy.)

Structure.—The spermatic cord contains the spermatic duct or vas deferens, the deferential artery and veins, the spermatic artery, the pampiniform plexus of veins, the spermatic plexus, and the deferential plexus of the sympathetic nerve, lymphatics, and the cord-like remnant of the funicular process of peritoneum called the **ligament of Oloquet** (Fig. 1127). All the above structures are held together by connective tissue. These structures are ensheathed by the **infundibuliform process of the transversalis fascia** (Fig. 1127 and p. 438). This fascia is thin above and thicker below, and encloses the testicle and epididymis, as well as the cord, being firmly adherent to the parietal layer of the vaginal tunic of the testicle and with the posterior portion of the testicle and epididymis. Upon this fascia are the fibres of the Cremaster muscle, which spring from the Internal oblique, and in this fascia are the cremasteric artery, the genital branch of the genitofemoral nerve, and external spermatic veins. This fascia is surrounded by the **intercolumnar or spermatic fascia**, which is distinct above, but not below.

Vessels and Nerves of the Spermatic Cord.—The **arteries** (Figs. 1124 and 1126) of the cord are the spermatic, from the aorta; the artery of the vas deferens, from the superior vesical; the cremasteric, from the deep epigastric.

The **spermatic artery** (*a. spermatica interna*) arises from the abdominal aorta below the renal artery, descends by the Psoas muscle, crosses the ureter and external iliac vessels, meets the vas deferens at the internal abdominal ring, escapes from the abdomen at the internal or deep abdominal ring, and lying in front of the vas deferens accompanies the other constituents of the spermatic cord along the inguinal canal and through the external abdominal ring into the scrotum. It then descends to the testis, and, becoming tortuous, divides into several branches, two or three of which, the **epididymal branches**, accompany the vas deferens and supply the epididymis, anastomosing with the artery of the vas deferens and the cremasteric artery; others, the **glandular branches**, pierce the back of the tunica albuginea and supply the substance of the testis.

The **artery of the vas deferens** (*a. deferentialis*), a branch of the superior vesical, is a long slender vessel which accompanies the vas deferens, ramifying upon the coats of that duct, and anastomosing with the spermatic artery and the cremasteric artery near the testis.

The **cremasteric artery** (*a. spermatica externa*) is a branch of the deep epigastric artery. It accompanies the spermatic cord and supplies the Cremaster muscle and other coverings of the cord, anastomosing with the spermatic and deferential arteries.

The **spermatic veins** (Figs. 524 and 1129) emerge from the back of the testis and receive tributaries from the epididymis; they unite and form a convoluted plexus, the **pampiniform plexus** (*plexus pampiniformis*), which forms the chief mass of the cord; the vessels composing this plexus are very numerous, and ascend along the cord in front of the vas deferens; below the external or superficial abdominal ring they unite to form three or four veins, which pass along the inguinal canal, and, entering the abdomen through the internal or deep abdominal ring, coalesce to form two veins. These again unite to form a single vein, which opens on the right side into the inferior vena cava at an acute angle, and on the left side into the left renal vein at a right angle.

The **lymphatic vessels** of the scrotum terminate in the superficial inguinal nodes. The lymphatics of the testicle join the lymphatics of the epididymis and of the visceral layer of the vaginal tunic of the testicle, and ascend in the spermatic cord. They reach the lumbar region along the spermatic bloodvessels and terminate in the **lateral aortic nodes**, and sometimes in the nodes in front of the aorta. The lymphatics of the seminal duct pass to the external iliac nodes.

The **nerves** are the **spermatic plexus** from the sympathetic, joined by filaments from the **pelvic plexus** which accompany the artery of the vas deferens.

FIG. 1129.—Spermatic veins. (Testut.)

The **testes** (Figs. 1124 and 1129) are suspended in the scrotum by the spermatic cords, the left testis hanging somewhat lower than its fellow. The average dimensions of this gland are from one and a half to two inches (4 cm.) in length, one inch (2.5 cm.) in breadth, and an inch and a quarter (3 cm.) in the antero-posterior diameter, and the weight varies from six to eight drams (25 to 30 grams). It is of a grayish-white color, and of resilient consistency. Each gland is of an oval

form, compressed laterally, and having an oblique position in the scrotum, the **upper extremity** (*extremitas superior*) being directed forward and a little outward, the **lower extremity** (*extremitas inferior*), backward and a little inward; the **anterior convex border** (*margo anterior*) looks forward and downward; the **posterior or straight border** (*margo posterior*), to which the cord is attached, backward and upward.

The **anterior border** and **lateral surfaces** (*facies lateralis et facies medialis*), as well as both extremities of the organ, are convex, free, smooth, and invested by the visceral layer of the tunica vaginalis. The posterior border, to which the cord is attached, receives only a partial investment from that membrane. To the inferior part of the posterior border is attached the **gubernaculum testis** (see p. 1426), which anchors the testis firmly to the scrotum. Lying upon the outer edge of this posterior border is a long, narrow, flattened body, named, from its relation to the testis, the **epididymis** (Figs. 1130 and 1131), which curves outward and backward.

FIG. 1130.—The testis *in situ*, the tunica vaginalis having been laid open.

FIG. 1131.—Frontal section of the testis and epididymis. (Poirier and Charpy.)

The **epididymis** consists of a **central portion** or **body** (*corpus epididymidis*); an upper enlarged extremity, the **head** or **globus major** (*caput epididymidis*); and a lower pointed extremity, the **tail** or **globus minor** (*cauda epididymidis*). The globus major is directed inward and is intimately connected with the upper end of the testicle by means of its efferent ducts, and the globus minor is connected with its lower end by cellular tissue and a reflection of the tunica vaginalis. The globus minor bends suddenly and passes into the **seminal duct**, the direction of which is upward and backward. The outer surface and upper and lower ends of the epididymis are free and covered by serous membrane; the body is also completely invested by it, excepting along its inner border, and between the body and the posterior part of the outer surface of the testis is a pouch or *cul-de-sac*, named the **digital fossa** (*sinus epididymidis*). Above this fossa is a fold of the tunica vaginalis, which is called the **ligamentum epididymidis superior**, and below it is another fold, the **ligamentum epididymidis inferior**. The epididymis is connected to the back of the testis by a fold of the serous membrane. Attached to the upper end of the testis, close to the globus major, is a small body; it is oblong in shape and has a broad base, and is called the **sessile hydatid** (*appendix testis* [*Morgagnii*]) (Figs. 1123 and 1130). Attached to the globus major of the epi-

didymis is another small, pear-shaped body—the **pedunculated hydatid** (*appendix epididymidis*). These bodies are the remains of embryonic structures. When the testis is removed from the body, the position of the vas deferens, on the posterior surface of the testis and inner side of the epididymis, marks the side to which the gland has belonged.

Structure of the Epididymis.—The epididymis is surrounded by a capsule of white fibrous tissue. The globus major consists of from ten to fifteen tubules, which are convoluted and lined by stratified ciliated epithelial cells. The body and globus minor are composed of the convolutions of a single tubule, which if straightened would measure upward of twenty feet. These parts are lined by stratified ciliated cells and continue as the vas deferens.

The Tunics of the Testicle.—The testis is invested by two tunics—the **tunica vaginalis** and the **tunica albuginea**.

The **tunica vaginalis** (*tunica vaginalis propria testis*) (Figs. 1130 and 1133) is the serous covering of the testis and epididymis. It is a pouch of serous membrane, derived from the peritoneum (*processus vaginalis peritonaei*) during the descent of the testis in the fetus from the abdomen into the scrotum. After its descent that portion of the pouch which extends from the internal ring to near the upper part of the gland, the *funicular process*, becomes obliterated, the lower portion remaining as a shut sac, which invests the outer surface of the testis, and is reflected to the internal surface of the scrotum; hence it may be described as consisting of a visceral and parietal portion.

The **visceral portion** (*lamina visceralis*) of the tunica vaginalis propria covers the outer surface of the testis, as well as the epididymis, connecting the latter to the testis by means of a distinct fold. From the posterior border of the gland it is reflected to the internal surface of the infundibuliform process of the transversalis fascia, and between the tunic and the fascia is a layer of unstriated muscle fibres, the **Internal cremaster muscle** (Fig. 1125).

The **parietal portion** (*lamina parietalis*) of the tunica vaginalis propria is the reflected portion. It is far more extensive than the visceral portion, extending upward for some distance in front and on the inner side of the cord, and reaching below the testis. The inner surface of the tunica vaginalis is free, smooth, and covered by a layer of endothelial cells. The interval between the visceral and parietal layers of this membrane constitutes the **cavity of the tunica vaginalis** and contains a small amount of serous fluid.

The obliterated portion of the pouch may generally be seen as a fibrocellular thread, the **ligament of Cloquet** (*rudimentum processus vaginalis*) (Fig. 1127), lying in the loose areolar tissue around the spermatic cord; sometimes this may be traced as a distinct band from the upper end of the inguinal canal, where it is

FIG. 1132.—Vertical section of the testis, to show the arrangement of the ducts.

connected with the peritoneum, down to the tunica vaginalis; sometimes it gradually becomes lost on the spermatic cord. Occasionally no trace of it can be detected. In some cases it happens that the pouch of peritoneum does not become obliterated, but the peritoneal cavity communicates with the tunica vaginalis. This may give rise to one of the varieties of oblique inguinal hernia or hydrocele; or in other cases the pouch may contract, but not become entirely obliterated; it then forms a minute canal leading from the peritoneum to the tunica vaginalis.

The **tunica albuginea** (Figs. 1131 and 1132) is the fibrous covering of the testis. It is a dense fibrous membrane, of a bluish-white color, composed of bundles of white fibrous tissue, which interlace in every direction. Its outer surface is covered by the tunica vaginalis, except at the points of attachment of the epididymis to the testis, and along its posterior border, where the spermatic vessels enter the gland. It consists of two portions, the **tunica fibrosa** and the **tunica vasculosa**; the former is the thicker of the two and contains few vessels, while the latter contains many small vessels. The tunica vasculosa sends septa into the organ which divide it into compartments. These septa converge and end at the mediastinum. This membrane surrounds the glandular structure of the testis, and at its posterior border forms a projection, triangular in shape and cellular in structure, which is reflected into the interior of the gland, forming an incomplete vertical septum, called the **mediastinum testis**.

The **mediastinum testis** (*corpus Highmori*) (Figs. 1131 and 1132) extends from the upper, nearly to the lower, extremity of the gland, and is wider above than below. From the front and sides of this septum numerous slender fibrous cords and imperfect septa—*septula testis* (Fig. 1132)—are given off, which radiate toward the surface of the organ, and are attached to the inner surface of the tunica albuginea. This scaffolding of connective tissue divides the **parenchyma** (*parenchyma testis*) of the organ into a number of incomplete spaces, which are somewhat cone-shaped, being broad at their bases at the surface of the gland, and becoming narrower as they converge to the mediastinum. The mediastinum supports the bloodvessels, lymphatics, and ducts of the testis in their passage to and from the substance of the gland, and contains numerous fine canals, into which open the very small tubules of the proper substance of the testis.

Structure of the Testis (Fig. 1132).—The glandular structure of the testis consists of numerous **lobules** (*lobuli testis*). Their number, in a single testis, is estimated to be about 200. They differ in size according to their position, those in the middle of the gland being larger and longer. The lobules are pyramidal in shape, the base of each being directed toward the circumference of the organ, the apex toward the mediastinum. Each lobule is contained in one of the intervals between the fibrous cords and vascular processes which extend between the mediastinum testis and the tunica albuginea, and consists of from one to three or more minute convoluted tubes $2\frac{1}{2}$ feet in length and 140 to 200 μ in diameter, the **tubuli seminiferi contorti**, which usually end blindly beneath the tunica albuginea. The contorted tubes unite at the apex of the lobules and form several **straight tubes** (*tubuli recti*), which pass into the mediastinum testis and form the network known as the **rete testis** (Fig. 1132). The **efferent ducts** (*ductuli efferentes testis*) (Fig. 1132), about twelve to fifteen in number, arise from the rete and continue into the globus major as the **coni vasculosi**. The total number of tubes is considered by Lauth to be about 840. The tubuli recti and rete testes are lined by simple squamous or cuboidal cells, while the vasa efferentia are lined by simple columnar cells which are either ciliated or non-ciliated. The convoluted tubules are pale in color in early life, but in old age they acquire a deep yellow tinge from containing much fatty matter. Each tube consists of a basement layer, formed of epithelial cells united edge to edge, outside of which are other layers of flattened cells arranged in interrupted laminae, which give to the tube an appearance of striation in cross-section. The cells of the outer layers gradually pass into the interstitial tissue. Within the basement membrane are epithelial cells arranged in several irregular layers, which are not always clearly separated, but which may be arranged in different groups that do not form clearly defined layers. The various groups cannot be seen in a single cross-section, but may be discerned in successive sections. Among these cells may be seen the **spermia** in different stages of development. (1) Lining the basement membrane and forming the outer zone is a layer of cubical cells, **spermatogonia**, containing small nuclei and pyramidal cells, the **columns of Sertoli**. The

nucleus of the former may be seen to be in the process of indirect division (*karyokinesis*), and in consequence of this daughter cells are formed, which constitute the second zone. (2) Within this first layer is to be seen a number of larger cells with clear nuclei, arranged in two or three strata; these are the **spermatocytes of the first order, or mother cells**. Most of the cells are in a condition of karyokinetic division, and the cells which result from this division form those of the next layer, the **spermatocytes of the second order, or daughter cells**. (3) The latter by division give rise to the **spermids**, which change into the **spermia** or **spermatozoa**. In addition to these three layers of cells, others are seen, which are termed the **supporting cells, or cells of Sertoli**. They are elongated and columnar, and project inward from the basement membrane toward the lumen of the tube. They give off numerous lateral branches, which form a reticulum for the support of the three groups of cells just described. As development of the spermia proceeds, the latter group themselves around the inner extremities of the supporting cells. The nuclear part of the spermid, which is partly embedded in the supporting cell, is differentiated to form the head of the spermium, while the cell protoplasm becomes lengthened out to form the middle piece and tail, the latter projecting into the lumen of the tube. Ultimately the heads are separated and the spermia are set free.

The process of spermatogenesis bears a close relation to that of maturation of the ovum. The spermatocyte is equivalent to the immature ovum. It undergoes subdivision, and ultimately gives origin to four spermia, each of which contains, therefore, only one-fourth of the chromatin elements of the nucleus of the spermatocyte (see Ovum, p. 1402).

FIG. 1133.—Vaginal tunics of the testicle. (Poirier and Charpy.)

FIG. 1134.—Ligament of the scrotum or gubernaculum testis. (Poirier and Charpy.)

The tubules are enclosed in a delicate plexus of capillary vessels, and are held together by an intertubular connective tissue, which presents large interstitial spaces lined by endothelium, which are believed to be the rootlets of lymphatic vessels of the testis. In this interstitial tissue are groups of large granular cells, the **interstitial cells**. These contain pigment, fat, and crystalloids, and are more numerous before and after sexual activity.

The **aberrant ducts of the epididymis** (*ductuli aberrantes*) are tortuous and end in blind extremities. The **superior aberrant duct** (*ductus aberrans superior*) is in the globus major and joins the rete testis. The **inferior aberrant duct** (*ductus aberrans inferior*) (Fig. 1132) is in the tail of the epididymis, and takes origin from the duct of the epididymis or the seminal duct. It is a persistent canal of the Wolffian body. It extends up the cord for two or three inches and terminates by a blind extremity, which is occasionally bifurcated. It may be as much as fourteen inches in length when unravelled. Its structure is similar to that of the vas deferens.

The **descent of the testis** will be described on page 1426.

The Semen.—The semen is the viscid, whitish, or opalescent fluid, of alkaline reaction and characteristic odor, which is secreted by the testes, prostate, seminal vesicles, and Cowper's glands. It contains water and about 18 per cent. of solid matter, chiefly consisting of proteids, salts, and nitrogenous substances. The semen serves to convey and maintain the vitality of the spermia in their course along the seminal passages.

The **Spermatozoa, or Spermia**, are present in enormous numbers in the seminal fluid. Each consists of a **head, neck, body, and tail**.

The **head** is oval, but flattened so that when viewed in profile it is pear-shaped. Its anterior part is covered by a layer of modified tissue called the *head-cap* or *perforator*.

The **neck** and **body** together form a cylindric or rod-like segment, the neck containing the two centrosomes. From the posterior centrosome proceeds the *axial filament*, which in the body of the spermium is encircled by a *spiral thread*.

The **tail** is about four times the combined length of the head and body, and consists of the axial filament surrounded by a delicate sheath of protoplasm. The terminal portion of the tail is named the *end piece*, and consists of the axial filament only.

By virtue of their tails, which act as propellers, the spermia, in the fresh condition, are capable of free movement, and if placed in favorable surroundings (*e. g.*, in the female passages) may retain their vitality for several days.

FIG. 1135.—Spermium of man. At the left a surface view is shown; at the right a lateral view. $\times 1200$. (Symonowicz, after Retzius.)

Applied Anatomy.—The scrotum forms an admirable covering for the protection of the testicle. This body, lying suspended and loose in the cavity of the scrotum, and surrounded by a serous membrane, is capable of great mobility, and can therefore easily slip about within the scrotum, and thus avoid injuries from blows or squeezes. The skin of the scrotum is very elastic and capable of great distention, and on account of the looseness and amount of subcutaneous tissue, the scrotum becomes greatly enlarged in cases of *edema*, to which this part is especially liable on account of its dependent position. The scrotum is frequently the seat of *epithelioma*; this is no doubt due to the rugæ on its surface, which favor the lodgement of dirt, and this, causing irritation, is the exciting cause of the disease. Cancer was especially common in chimney-sweeps from the lodgement of soot. The scrotum is also the part most frequently affected by *elephantiasis*.

On account of the looseness of the subcutaneous tissue considerable *extravasations of blood* may take place from very slight injuries. It is therefore generally recommended never to apply leeches to the scrotum, since they may lead to considerable *ecchymosis*, but rather to puncture one or more of the superficial veins of the scrotum in cases where local bloodletting from this part is judged to be desirable. The muscle fibre in the dartos causes contraction and considerable diminution in the size of a *wound of the scrotum*, as after the operation of castration, and is of assistance in keeping the edges together and covering the exposed parts.

Abnormalities in the formation and in the descent of the testes may occur. The testis may fail to be developed, or it may be fully developed and the vas deferens may be undeveloped in whole or in part; or, again, both testes and vas deferens may be fully developed, but the duct may not become connected to the gland. The testis may fail in its descent (*cryptorchismus*) or it may descend into some abnormal position (*ectopia testis*). Thus, it may be retained in the position where it was primarily developed, below the kidney; or it may descend to the internal abdominal ring, but fail to pass through this opening; it may be retained in the inguinal canal, which is, perhaps, the most common position; or it may pass through the external abdominal ring and remain just outside it, failing to pass to the bottom of the scrotum. On the other hand, it may get into some abnormal position; it may pass the scrotum and reach the perineum, or it may fail to enter the inguinal canal, and may find its way through the femoral ring into the crural canal, and present itself on the thigh at the saphenous opening. Ectopia testis is due to the absence, overdevelopment, or malposition of some portion of the gubernaculum. There is still a third class of cases of abnormality in the position of the testis, where the organ has descended in due course into the scrotum, but is misplaced. The most common form of this is where the testis is *inverted*; that is to say, the organ is rotated, so that the epididymis is connected to the front of the scrotum, and the body, surrounded by the tunica vaginalis, is directed backward. In these cases the vas deferens is to be felt in the front of the cord. The condition is of importance in connection with hydrocele and hematocele, and the position of the testis should always be carefully ascertained before performing any operation for these affections. Again, more rarely, the testis may be *reversed*. This is a condition in which the top of the testis, indicated by the globus

major of the epididymis, is at the bottom of the scrotum, and the vas deferens comes off from the summit of the organ.

The testis may require removal for *malignant disease, tuberculous disease, cystic disease*, in cases of large *hernia testis*, and in some instances of *incompletely descended or misplaced testes*. The operation of castration is a comparatively simple one. An incision is made into the cavity of the tunica vaginalis from the external ring to the bottom of the scrotum. The coverings are shelled off the organ, and the mesorchium, stretching between the back of the testis and the scrotum, divided. The cord is then isolated, and an aneurism needle, armed with a double ligature, passed under it, as high as is thought necessary, and the cord tied in two places, and divided between the ligatures. Sometimes, in cases of malignant disease, it is desirable to open the inguinal canal and tie the cord as near the internal abdominal ring as possible.

A collection of serous fluid in the sac of the vaginal tunic of the testicle is known as an *ordinary or testicular hydrocele*. In *congenital hydrocele* a communication remains between the tunica vaginalis testis and the peritoneal cavity. This communication should have closed during development. In *infantile hydrocele* the tunica vaginalis and part of the funicular process are distended with fluid, but the funicular process is closed above and the cavity of the hydrocele does not communicate with the peritoneal cavity. In *encysted hydrocele of the cord* the funicular process is closed above and below, but between these points is not obliterated. In *funicular hydrocele* the funicular process is closed below and open above. Congenital hydrocele can usually be cured by the application of a truss. This obliterates the upper end of the funicular process, and the obliteration once begun may proceed to completion. If it does not, the condition has become an infantile hydrocele. An infantile hydrocele can usually be cured by multiple puncture or tapping. The same is true of encysted hydrocele of the cord. In hydrocele of the funicular process a truss should be worn for a time and the fluid then evacuated by tapping. In ordinary testicular hydrocele incise and pack, or incise and suture the cut edge of the parietal layer of the tunic to the skin, or extirpate the parietal layer of the tunic. A successful method is that of Longuet. He makes an incision, pulls out the testis, and allows all the coats except the skin to fall behind and make a sheath for the cord. These coats are held behind by one catgut suture. A bed is made for the testis beneath the skin toward the septum of the scrotum. The testicle is rotated on its long axis, and placed in the bed, and the skin is sutured above it. This operation is known as *extraserous transposition*. If a portion of bowel enters an open vaginal process the condition is *congenital hernia*.

In *infantile hernia* the funicular process is closed above but not below, and the hernia descends in a special sac back of the vaginal tunic. If the hernia pushes down on the vaginal process and causes it to double on itself the condition is *encysted infantile hernia*.

THE VAS DEFERENS (DUCTUS DEFERENS) (Figs. 1128, 1136).

The *vas deferens*, or *seminal duct*, the excretory duct of the testis, is the continuation of the epididymis. Commencing at the lower part of the globus minor, it ascends along the posterior border of the testis and inner side of the epididymis, and along the back part of the spermatic cord, through the inguinal canal to the internal or deep abdominal ring. From the ring it curves around the outer side of the deep epigastric artery, and ascends for about an inch in front of the external iliac artery. It is next directed backward and slightly downward, and, crossing the external iliac vessels obliquely, enters the pelvic cavity, where it lies between the peritoneal membrane and the lateral wall of the pelvis, and passes on the inner side of the impervious hypogastric artery and the obturator nerve and vessels. It then crosses in front of the ureter, and, reaching the inner side of this tube, bends at an acute angle, and runs inward and slightly forward between the base of the bladder and the upper end of the seminal vesicle. Reaching the inner side of the seminal vesicle, it is directed downward and inward in contact with this structure and gradually approaches the vas of the opposite side. Here the vas deferens lies between the base of the bladder and the rectum, where it is enclosed, together with the seminal vesicle, in a sheath derived from the rectovesical fascia.

At the base of the bladder it becomes enlarged and sacculated, forming the *ampulla (ampulla ductus deferentis)* (Fig. 1136), and then, becoming narrowed at the base of the prostate, it is joined by the duct of the seminal vesicle to form

the **ejaculatory duct** (Fig. 1137). The vas deferens offers a hard and cord-like sensation to the fingers; it is about two feet in length, of cylindrical form, and about 2 mm. in diameter. Its walls are dense, measuring 0.7 mm., and its canal is extremely small, measuring about 0.5 mm.

Structure.—The vas deferens consists of three coats: (1) An **external or areolar coat** (*tunica adventitia*). (2) A **muscular coat** (*tunica muscularis*), which in the greater part of the tube consists of three layers of unstriated muscle fibre; an *inner* layer of thin longitudinal fibres (*stratum internum*), a thick *middle* layer of circular fibres (*stratum medium*), and a thick *external* layer of longitudinal fibres (*stratum externum*). (3) An **internal or mucous coat** (*tunica mucosa*), which is pale, and arranged in longitudinal folds; its epithelial cells are chiefly of the stratified columnar variety of which the superficial layer is ciliated.

Organ of Giral  s (*paradidymis*).—This term is applied to a small body of rounded shape in the lower end of the spermatic cord, in front of the bloodvessels. It consists of a small collection of minute vesicles and a small collection of convoluted tubules. These tubes are lined with columnar ciliated epithelium, and probably represent the remains of a part of the Wolffian body.

THE SEMINAL VESICLES (VESICULAE SEMINALES) (Figs. 1135, 1136).

The **seminal vesicles** are two convoluted membranous pouches placed between the base of the bladder and the rectum, serving as reservoirs for the spermia, and secreting a fluid to be added to the secretion of the testes. Each sac is some-

FIG. 1136.—The urinary bladder, distended, with surrounding structures, viewed from behind. (Spalteholz.)

what pyramidal in form, the broad end being directed backward and the narrow end forward toward the prostate. It measures about two and a half inches (6.25 cm.) in length, about 10 mm. in breadth, and 4 to 6 mm. in thickness. They vary, however, in size, not only in different individuals, but also in the same individual on the two sides. The *anterior surface* is in contact with the base of the bladder, extending from near the termination of the ureters to the base of the prostate gland. The *posterior surface* rests upon the rectum, from which it is separated by the recto-vesical fascia. Their *upper extremities* diverge from each other. Their *lower extremities* are pointed, and converge toward the base

of the prostate gland, where each joins with the corresponding vas deferens to form the ejaculatory duct. Along the inner margin of each vesicle runs the ampulla of the vas deferens. The inner border of the vesicle and the correspond-

ing vas deferens form the lateral boundaries of a triangular space, limited behind by the rectovesical peritoneal fold; the portion of the bladder included in this space rests on the rectum.

Each vesicle consists of a single tube, coiled upon itself and giving off several irregular cecal diverticula (Fig. 1137), the separate coils, as well as the diverticula, being connected by fibrous tissue. When uncoiled this tube is about the diameter of a quill, and varies in length from four to six inches (10 to 15 cm.); it terminates above in a *cul-de-sac*; its lower extremity becomes constricted into a narrow straight duct, the **excretory duct** (*ductus excretorius*) (Fig. 1137), which joins with the corresponding vas deferens to form the ejaculatory duct.

FIG. 1137.—The ejaculatory ducts viewed from in front and above. (Spalteholz.)

Structure.—The **seminal vesicles** are composed of three coats—an **external** or **fibrous** (*tunica adventitia*); a **middle** or **muscular coat** (*tunica muscularis*), which is thinner than in the seminal duct, and is arranged in two layers, an **outer**, longitudinal, and an **inner**, circular; an **internal** or **mucous coat** (*tunica mucosa*), which is usually thrown into waves or folds, and which is pale, of a whitish-brown color, and of a delicate reticular structure, like that seen in the gall-bladder. The epithelium is of the columnar variety, and, in the diverticula, goblet cells are present, the secretion of which increases the bulk of the seminal fluid.

Vessels and Nerves.—The **arteries** supplying the seminal vesicles are derived from the **middle** and **inferior vesical** and **middle hemorrhoidal**. The **veins** and **lymphatics** accompany the arteries. The lymphatics anastomose on the surface of the vesicle. The trunks from this network anastomose with the lymphatics of the bladder and prostate, and pass to the **external** and **internal iliac nodes**. The **nerves** are derived from the **pelvic plexus**.

Applied Anatomy.—The seminal vesicles are often the seat of an extension of the disease in cases of *tuberculosis* of the testis, and should always be examined through the rectum before coming to a decision with regard to castration in this affection. The vesicles have been deliberately *extirpated* for local tuberculosis. In gonorrhea the seminal vesicles may become acutely inflamed (*acute seminal vesiculitis*). *Chronic seminal vesiculitis* may follow the acute form or may arise insidiously during gonorrhea.

THE EJACULATORY DUCTS (DUCTUS EJACULATORII) (Fig. 1137).

The **ejaculatory ducts** are two in number, one on each side. Each duct is formed by the junction of the duct of the seminal vesicle with the vas deferens. Each duct is about three-quarters of an inch (2 cm.) in length; it commences at the base of the prostate, and runs forward and downward between the middle and lateral

lobes of that gland, and along the side of the sinus pocularis, to terminate by a separate slit-like orifice close to the margins of the sinus. The ducts diminish in size and also converge toward their terminations.

Structure.—The coats of the ejaculatory ducts are extremely thin. They are an *outer fibrous layer*, which is almost entirely lost after the entrance of the duct into the prostate; a *layer of muscle fibres*, consisting of an *outer* thin circular and an *inner* longitudinal layer; and the *mucous membrane*, lined by simple columnar epithelial cells.

THE PENIS (Figs. 1138, 1139).

The **penis** is a pendulous organ suspended from the front and sides of the pubic arch and containing the greater part of the urethra. In the flaccid condition it is cylindrical in shape, but when erect assumes the form of a triangular prism with rounded sides, one side of the prism forming the dorsum. It is composed of three cylindrical masses of erectile tissue bound together by fibrous tissue and covered with skin. Two of the masses are lateral, and are known as the *corpora cavernosa*; the third is median, and is termed the *corpus spongiosum* (Figs. 1138 and 1146).

The two *corpora cavernosa* (*corpora cavernosa penis*) (Figs. 1138 and 1139) form the greater part of the body of the penis. They consist of two fibrous cylindrical tubes, placed side by side, and intimately connected along the median line for their anterior three-fourths, while at their back part they separate from each other to form the *crura penis*, which are two strong tapering fibrous processes or *roots* firmly connected to the rami of the os pubis and ischium (Figs. 1138 and 1139). Each *crus* commences by a blunt-pointed process in front of the tuberosity of the ischium, and before its junction with its fellow to form the body of the penis it presents a slight enlargement, named by Kobelt the *bulb of the corpus cavernosum*. Just beyond this point they become constricted, and retain an equal diameter to their anterior extremity, where they form a single rounded end (*digital process*) which is received into a fossa in the base of the glans penis (Fig. 1138). A median groove on the upper surface lodges the dorsal arteries, nerves, and veins of the penis (Figs. 1144 and 1146), and the groove on the under surface receives the corpus spongiosum (Fig. 1138).

The corpora cavernosa are surrounded by a strong fibrous envelope (*tunica albuginea*) consisting of superficial and deep fibres. The *superficial* fibres are longitudinal in direction, being common to the two corpora cavernosa, and investing them in a common covering; the other, *deep*, circular in direction, and being proper to each corpus cavernosum. The internal circular fibres of the two corpora cavernosa form, by their junction in the mesal plane, an incomplete partition or septum (*septum penis*) between the two bodies. This is thick and complete behind, but in front it is incomplete, and consists of a number of vertical bands, which are arranged like the teeth of a comb. It is therefore named the *septum pectiniforme*. These bands extend between the dorsal and the urethral surface of the corpora cavernosa. The fibrous investment of the corpora cavernosa is extremely dense, of considerable thickness, and consists of bundles of shining white fibres, with an admixture of well-developed elastic fibres, so that it is possessed of great elasticity.

The *corpus spongiosum* (*corpus cavernosum urethrae*) (Figs. 1138 and 1139) contains the urethra, and is situated in the groove on the under surface of the corpora cavernosa penis. Behind, it is expanded to form the *urethral bulb* (*bulbus urethrae*) and lies in apposition with the superficial layer of the triangular ligament, from which it receives a fibrous investment. The urethra enters the bulb nearer to the upper than to the lower surface. On the latter there is a depressed

median **raphé** (*sulcus bulbi*), from which a thin fibrous septum projects into the substance of the bulb and divides it imperfectly into two lateral lobes or **hemispheres** (*hemisphaeria bulbi urethrae*).

The portion of the corpus spongiosum in front of the bulb lies in a groove on the under surface of the conjoined corpora cavernosa. It is cylindrical in form and tapers slightly from behind forward. Its anterior extremity is expanded in the form of an obtuse cone, flattened from above downward. This expansion, termed

FIG. 1138.—The penis, with the pubic bones, seen from before and below. (Toldt.)

FIG. 1139.—The penis, with the urethra, Cowper's glands, the prostate gland, and the seminal vesicles seen from below and behind. (Toldt.)

the **glans penis**, is moulded on the rounded ends of the corpora cavernosa, extending farther on their upper than on their lower surfaces. At the summit of the glans

is the vertical, slit-like urethral orifice or **meatus**. The circumference of the base of the glans forms a rounded projecting border, the **corona glandis**, overhanging a deep sulcus (*sulcus retroglandularis*), behind which is the **neck** of the penis (*collum penis*).

For descriptive purposes it is convenient to divide the penis into three parts—the root, the body, and the extremity.

The **root** (*radix penis*) of the penis is triradiate in form, consisting of the diverging crura, one on either side, and the mesal bulb of the corpus spongiosum. Each crus is covered by the Erector penis muscle, while the bulb is surrounded by the Accelerator urinæ muscle. The root of the penis lies in the perineum between the superficial layer of the triangular ligament and the fascia of Colles. In addition to being attached to the pubic rami and to the triangular ligament, the root is bound to the front of the symphysis pubis by the **suspensory ligament** (*lig. suspensorium penis*). The upper fibres of this ligament pass downward from the lower end of the linea alba, and the lower fibres from the symphysis pubis; together they form a strong, fibrous band which extends to the upper surface of the root, where it splits into two fasciculi and blends with the fascial sheath of the organ.

FIG. 1140.—The penis, proximal portion, seen from below. (Testut.)

FIG. 1141.—Glans penis, under surface. (Testut.)

The **body of the penis** (*corpus penis*) extends from the root to the ends of the corpora cavernosa between the root and extremity. In the flaccid condition of the organ it is cylindrical, but when erect it has a triangular prismatic form with rounded angles, the broadest side being turned upward, and called the **dorsum penis**. The lower surface of the body of the penis is called the **urethral surface** (*facies urethralis*). The body is covered by integument, and contains in its interior a large portion of the urethra.

The **extremity** is formed by the glans penis, the expanded anterior (distal) end of the corpus spongiosum. It is separated from the body by the constricted neck, which is surmounted by the corona glandis.

The integument covering the penis is remarkable for its thinness, its dark color, its looseness of connection with the deeper parts of the organ, and for the absence of adipose tissue. At the root of the penis the integument is continuous with that upon the pubes, scrotum, and perineum. At the neck of the glans it leaves the surface and becomes folded upon itself to form the **prepuce** (*præputium*) (Fig. 1144). The internal layer of the prepuce is directly continuous, along the line of the neck, with the integument over the glans. Immediately behind the

urinary meatus it forms a small, secondary reduplication, attached along the bottom of a depressed median raphé, which extends from the meatus to the neck; this fold is termed the **frenulum** (*frenulum praeputii*). The integument covering the glans is continuous with the urethral mucous membrane at the meatus; it is devoid of hairs, but projecting from its free surface are a number of small,

FIG. 1142.—a. Capillary network.
b. Cavernous spaces.

FIG. 1143.—Connection of the arterial twigs (a) with the cavernous spaces.

FIGS. 1142 AND 1143.—From the peripheral portion of the corpus cavernosum penis under a low magnifying power. (Copied from Langer.)

highly sensitive papillae. In the retroglandular sulcus numerous small glands, the **glandulae Tysonii odoriferae** (*glandulae praeputii*) have been described. They secrete a sebaceous material of very peculiar odor, called *smegma praeputii*, which probably contains casein, and readily undergoes decomposition.

The prepuce covers a variable amount of the glans and is separated from it by a potential sac—the *preputial sac*—which presents two shallow recesses (*fossae frenuli*), one on either side of the frenulum.

Structure.—From the internal surface of the fibrous envelope of the corpora cavernosa, as well as from the sides of the septum, are given off a number of bands or cords which cross the interior of each crus in all directions, subdividing it into a number of separate compartments, and giving the entire structure a spongy appearance. These bands and cords are called **trabeculae corporum cavernosum**, and consist of white fibrous tissue, elastic fibres, and smooth muscle tissue. In them are continued numerous arteries and nerves.

The component fibres of which the trabeculae are composed are larger and stronger around the circumference than at the centre of the corpora cavernosa; they are also thicker behind than in front. The interspaces, on the contrary, are larger at the centre than at the circumference their long diameter being directed transversely; they are largest anteriorly. They are called **cavernous spaces** and are occupied by blood during erection, and are lined by a layer of flattened endothelial cells (Fig. 1142).

The arteries bringing the blood to these spaces are the **arteries of the corpora cavernosa** and branches from the **dorsal artery of the penis**, which perforate the fibrous capsule, along the upper surface, especially near the fore part of the organ.

FIG. 1144.—The penis, distal end, in sagittal section 2 mm. at left of middle line. (Testut.)

On entering the cavernous structure the arteries divide into branches which are supported and enclosed by the trabeculae. Some of these terminate in a capillary network, the branches of which open directly into the cavernous spaces (Fig. 1143); others assume a tendril-like appearance, and form convoluted and somewhat dilated vessels, which were named by Müller *helicine arteries* (*arteriae helicinae*). They project into the spaces, and from them are given off small capillary branches to supply the trabecular structure. They are bound down in the spaces by fine fibrous processes, and are more abundant in the back part of the corpora cavernosa.

FIG. 1145.—Diagram of the arteries of the penis. (Testut.)

The blood from the cavernous spaces is returned by a series of vessels, some of which emerge in considerable numbers from the base of the glans penis and converge on the dorsum of the organ to form the **deep dorsal vein**; others pass out on the upper surface of the corpora cavernosa and join the dorsal vein; some emerge from the under surface of the corpora cavernosa, and, receiving branches from the corpus spongiosum, wind around the sides of the penis to terminate in the dorsal vein; but the greater number pass out at the root of the penis and join the **prostatic plexus**.

The fibrous envelope of the corpus spongiosum is thinner, whiter in color, and more elastic than that of the corpora cavernosa. The trabeculae are more delicate, more nearly uniform in size, and the meshes between them smaller than in the corpora cavernosa, their long diameter, for the most part, corresponding with that of the penis. The external envelope or outer coat of

the corpus spongiosum is formed partly of unstripped muscle tissue, and a layer of the same tissue immediately surrounds the canal of the urethra. The corpus spongiosum receives its blood through the bulbourethral branch of the internal pudic artery.

The **lymphatics** of the skin of the penis terminate in the inguinal nodes. The lymphatics of the *penile* portion of the urethra accompany those of the glans penis and terminate with them in the deep inguinal and external iliac nodes. Those of the *membranous* and *prostatic* portions pass to the internal iliac nodes.

The **nerves** are derived from the internal pudic nerve and the pelvic plexus. On the glans and bulb some filaments of

FIG. 1146.—The penis in transverse section, showing the bloodvessels. (Testut.)

the cutaneous nerves have Pacinian bodies connected with them, and, according to Krause, many of them terminate in peculiar end-bulbs (see p. 821).

Applied Anatomy.—It is occasionally necessary to *remove* a penis for malignant disease. Usually, removal of the antescrotal portion is all that is necessary, but sometimes it is requisite to remove the whole organ from its attachment to the rami of the ossa pubis and ischia. The former operation is performed either by cutting off the whole of the anterior part of the penis with one sweep of the knife, or, what is better, cutting through the corpora cavernosa from the dorsum, and then separating the corpus spongiosum from them, dividing it at a level nearer the glans penis. The mucous membrane of the urethra is then slit up, and the edges of the flap attached to the external skin, in order to prevent contraction of the orifice, which would other-

wise take place. The vessels which require ligation are the two dorsal arteries of the penis, the arteries of the corpora cavernosa, and the artery of the septum. When the entire organ requires removal the patient is placed in the lithotomy position, and an incision is made through the skin and subcutaneous tissue around the root of the penis, and carried down the median line of the scrotum as far as the perineum. The two halves of the scrotum are then separated from each other, and a catheter having been introduced into the bladder as a guide, the spongy portion of the urethra below the triangular ligament is separated from the corpora cavernosa and divided, the catheter having been withdrawn just behind the bulb. The suspensory ligament is now severed, and the crura separated from the bone with a periosteum scraper, and the whole penis removed. The membranous portion of the urethra, which has not been removed, is now to be attached to the skin at the posterior extremity of the incision in the perineum. The remainder of the wound is to be brought together, free drainage being provided for.

THE PROSTATE GLAND (PROSTATATA) (Figs. 1136, 1139, 1149).

The **prostate gland** is a structure accessory to the true generative organs and secretes a viscid, opalescent secretion in which spermia will live and which furnishes a medium in which they maintain the motile activity necessary to carry them to their destination. It is a pale, firm, partly glandular and partly muscular body, which is placed immediately below the neck of the bladder and about the commencement of the urethra.

It is situated in the pelvic cavity below the lower part of the symphysis pubis, above the deep layer of the triangular ligament, and in front of the rectum, through which it may be distinctly felt, especially when enlarged. It is about the size of a horse chestnut and somewhat conical in shape, and presents for examination a base, an apex, an anterior, a posterior, and two lateral surfaces.

The **base** (*basis prostatae*) is directed upward, and is applied to the under surface of the bladder. The greater part of this surface is directly continuous with the bladder wall; the urethra penetrates it nearer to its anterior than to its posterior border.

The **apex** (*apex prostatae*) is directed downward and rests upon the deep layer of the triangular ligament. The apex is fixed, except for the slight mobility of the triangular ligament; the rest of the gland is somewhat movable.

Surfaces.—The **posterior surface** (*facies posterior*) is flattened from side to side and convex from above downward; it rests on the rectum, and is distant about an inch and a half from the anus. Near its upper border there is a depression through which the two common ejaculatory ducts enter the prostate. This depression serves to divide the posterior surface into a lower larger and upper smaller part. The upper smaller part constitutes the so-called "**middle lobe**" of the prostate and intervenes between the ejaculatory ducts and the urethra; it varies greatly

FIG. 1147.—Veins of the penis. (Testut.)

in size and in some subjects is destitute of glandular tissue. The lower larger portion sometimes presents a shallow median furrow which imperfectly separates it into a **right** and a **left lateral lobe**; these form the main mass of the gland and are

FIG. 1148.—Male pelvic organs seen from right side. Bladder and rectum distended; relations of peritoneum to the bladder and rectum shown in blue. The arrow points to the rectovesical pouch. (Corning.)

FIG. 1149.—Prostate with seminal vesicles and seminal ducts, viewed from in front and above. (Spalteholz.)

directly continuous with each other behind the urethra. In front of the urethra they are connected by a band which is named the **anterior commissure**; this consists of the same tissues as the capsule and is devoid of glandular substance.

The **anterior surface** (*facies anterior*) measures about one inch (2.5 cm.) from above downward, but is narrow and convex from side to side. It is placed about three-fourths of an inch behind the pubic symphysis, from which it is separated by a plexus of veins and a quantity of loose fat. It is connected to the pubic bone on either side by the **puboprostatic ligaments**. The urethra emerges from this surface a little above and in front of the apex of the gland.

The **lateral surfaces** are prominent, and are covered by the anterior portions of the Levatores ani muscles, which are, however, separated from the gland by a plexus of veins.

FIG. 1150.—Diagrammatic representation of the male organs of reproduction and their relations to the bladder and the urethra. Lateral view. (Toldt.)

The prostate measures about an inch and a half (3.75 cm.) transversely at the base, three-quarters of an inch (1.8 cm.) in its antero-posterior diameter, and an inch and a quarter (3 cm.) in its vertical diameter. Its weight is about four and a half drams. It is held in position by the **anterior ligaments of the bladder** (*ligamenta puboprostatica*); by the deep layer of the triangular ligament, which invests the commencement of the membranous portion of the urethra and prostate gland; and by the anterior portions of the Levatores ani muscles, which pass backward from the os pubis and embrace the sides of the prostate. These portions of the Levatores ani, from the support they afford to the prostate, are named the **Levatores prostatae**.

The prostate gland is perforated by the urethra and the ejaculatory ducts. The urethra usually lies along the junction of its anterior with its middle third. The ejaculatory ducts pass obliquely downward and forward through the posterior part of the prostate, and open into the prostatic portion of the urethra.

Structure.—The prostate is immediately enveloped by a thin but firm musculo-fibrous **capsule**, distinct from the *prostatic fascia* derived from the rectovesical fascia, and separated from it by a plexus of veins. The capsule is firmly adherent to the prostate and is structurally continuous with the stroma of the gland, being composed of the same tissues—viz., smooth muscle and fibrous tissue. The prostatic fascia, distinct and dense, does not cover the apex and at the

attachment of the base to the under surface of the bladder. The substance of the prostate is of a pale, reddish-gray color, of great density, and not easily torn. It consists of glandular substance and muscle tissue.

The **muscle tissue**, according to Kölliker, constitutes the proper stroma of the prostate, the connective tissue being very scanty, and simply forming thin trabeculae between the muscle fibres, in which the vessels and nerves of the gland ramify. The muscle tissue is arranged as follows: Immediately beneath the fibrous capsule is a dense layer, which forms an investing sheath for the gland; secondly, around the urethra, as it lies in the prostate, is another dense layer of circular fibres, continuous *above* with the internal layer of the muscle coat of the bladder, and *below* blending with the fibres surrounding the membranous portion of the urethra. Between these

FIG. 1151.—Sagittal section of the lower part of a male trunk, the right segment. (Testut.)

two layers strong bands of muscle tissue, which decussate freely, form meshes in which the glandular structure of the organ is embedded. In that part of the gland which is situated in *front* of the urethra the muscle tissue is especially dense, and there is here little or no gland tissue; while in that part which is *behind* the urethra the muscle tissue presents a wide-meshed structure, which is densest at the base of the gland—that is, near the bladder—and becomes looser and more sponge-like toward the apex of the organ.

The **glandular substance** is composed of lobules containing numerous branched tubular glands opening into elongated canals, which join to form from twelve to twenty small excretory ducts. The glands are held together by areolar tissue, supported by prolongations from the fibrous capsule and muscle stroma, and enclosed in a delicate capillary plexus. The epithelium which lines the canals and the terminal tubules is of the columnar variety. The prostatic ducts

open into the floor of the prostatic portion of the urethra, and are lined by two layers of epithelium, the inner layer consisting of columnar and the outer of small cubical cells.

Vessels and Nerves.—The arteries supplying the prostate are derived from the **internal pudic, inferior vesical, and middle hemorrhoidal**. Branches of the vessels enter the gland in the septa between the lobules and send off minute branches to the lobules (Walker). The veins form a plexus around the sides and base of the gland between the layers of the fascial sheath; they receive in front the **dorsal vein of the penis**, and terminate in the **internal iliac vein**. The lymphatics of the prostate are described on page 799. The nerves are derived from the pelvic plexus.

Applied Anatomy.—The relation of the prostate to the rectum should be noted; by means of the finger introduced into the rectum the surgeon detects enlargement or other disease of the prostate; he can feel the apex of the gland, which is the guide to *Cock's operation* for stricture; he is enabled also by the same means to direct the point of a catheter when its introduction is attended with difficulty either from injury or disease of the membranous or prostatic portions of the urethra. When the finger is introduced into the bowel the surgeon may, in some cases, especially in boys, learn the position, as well as the size and weight, of a calculus in the bladder. In the operation for the removal of a calculus, if, as is not infrequently the case, the stone should be lodged behind an enlarged prostate, it may be displaced from its position by pressing upward the base of the bladder from the rectum. The prostate gland is occasionally the seat of *suppuration*,

FIG. 1152.—Section of the prostate. (Jarjavay.)

FIG. 1153.—Transverse section of normal prostate through the middle of the verumontanum, from a subject aged nineteen years: *a*. Zone of striated voluntary muscle on superior surface. (Drawn with Edinger projection apparatus.) (Taylor.)

either due to injury, gonorrhea, or tuberculous disease. The gland is enveloped in a dense unyielding capsule, which determines the course of an abscess, and also explains the great pain which is present in acute inflammation. The abscess most frequently bursts into the urethra, the direction in which there is least resistance, but may occasionally burst into the rectum, or more rarely in the perineum. In advanced life the prostate often becomes considerably *enlarged*, and may project into the bladder so as to impede the passage of the urine. According to Dr. Messer's

researches, conducted at Greenwich Hospital, it would seem that such obstruction exists in 20 per cent. of all men over sixty years of age. The prostate may be enlarged by the growth of *innocent tumors*, adenomata, fibromata, myomata, and myofibromata. The entire gland may be *hypertrophied*. A tumor may be encapsulated, but often is surrounded by an area of hyperplasia of prostatic tissues, and usually the area of hyperplasia is much more extensive than the tumor. A tumor may be beneath the mucous membrane, deep in the gland, or beneath the sheath. The growth called the *third lobe* is submucous. In some cases the enlargement affects principally the lateral lobes, which may undergo considerable enlargement without causing much inconvenience. In other cases it would seem that the nodule forms the so-called middle lobe, and even a small enlargement of this character may act injuriously, by forming a sort of valve over the urethral orifice, preventing the passage of the urine, and the more the patient strains, the more completely will it block the opening into the urethra. In consequence of the enlargement of the prostate a *pouch* is formed at the base of the bladder behind the projection, in which urine collects and cannot be entirely expelled. The urine becomes decomposed and ammoniacal, and leads to cystitis. If the prostate enlarges the urethra is lengthened, often dilated, altered in shape, or distorted.

The relation of the enlarged prostate to the neck of the bladder is greatly altered from the relation of the normal prostate. Normally, it is extravescical; when enlarged it may encapsule "the neck of the bladder in a cuff-like manner, extending several inches upward on its wall," and often it protrudes "into the vesical cavity, carrying on its surface the mucosa vesicae." In many cases of prostatic enlargement the gland should be removed (*prostatectomy*). One method is enucleation through a suprapubic incision; another method is enucleation through a perineal incision; another method is carried out by both incisions (the combined method).

In elderly individuals the gland tubules may form round, indurated, and sometimes calcified masses, about 1 mm. in diameter, and called *prostatic stones*.

FIG. 1154.—Proximal portion of the urethra, laid open by a median, anterior cut. (Testut.)

COWPER'S GLANDS (GLANDULAE BULBOURETHRALES) (Fig. 1154).

Cowper's glands are two small, rounded, and somewhat lobulated bodies of a yellow color, about the size of peas, placed behind the fore part of the membranous portion of the urethra, between the two layers of the triangular ligament.

They lie close above the bulb, and are enclosed by the transverse fibres of the Compressor urethræ muscle. Their existence is said to be constant; they gradually diminish in size as age advances.

The **excretory duct** of each gland, nearly an inch in length, passes obliquely forward beneath the mucous membrane, and opens by a minute orifice on the floor of the bulbous portion of the urethra.

Structure.—Each gland consists of several lobules held together by a fibrous investment. Each lobule consists of a number of acini lined by columnar epithelial cells, opening into one duct, which, joining with the ducts of other lobules outside the gland, form the single **excretory duct**.

THE FEMALE REPRODUCTIVE ORGANS.

The **female reproductive organs** (*organa genitalia muliebria*) consist of an internal and an external group. The **internal organs** are situated within the pelvis, and consist of the ovaries, the Fallopian tubes or oviducts, the uterus, and the vagina. The **external organs** are placed superficial to the triangular ligament of the urethra and below and in front of the pubic arch. They comprise the mons veneris, the labia majora et minora, the clitoris, the bulbi vestibuli, and the glands of Bartholin.

THE OVARIES (OVARIA) (Figs. 1155, 1160).

The **ovaries** are homologous with the testes in the male. They are two nodular, oval-shaped bodies of an elongated form, situated one on either side of the uterus, in the posterior layer of the broad ligament behind and below the Fallopian tube.

FIG. 1155.—Female pelvis and its contents, seen from above and in front.

The ovaries are of a grayish-pink color, and present either a smooth or a puckered, uneven surface. They are each about an inch and a half (3.75 cm.) in length three-quarters of an inch (2 cm.) in width, and about a third of an inch (8 mm.) thick, and weigh from one to two drams (4 to 8 grams).

Each ovary (*ovarium*) presents an outer and an inner surface, an upper and a lower extremity, and an anterior and a posterior border. It lies in a shallow depression, named the *fossa ovarii*, on the lateral wall of the pelvis; this fossa is bounded above by the external iliac vessels, in front by the impervious hypogastric artery, and behind by the ureter. The exact position of the ovary has been the subject of considerable difference of opinion, and the description here given applies to the nulliparous woman. The ovary becomes displaced during the first pregnancy and probably never again returns to its original position.

In the erect posture the long axis of the ovary is nearly vertical. The *upper* or *tubal extremity* is near the external iliac vein; to it is attached the ovarian fimbria of the Fallopian tube and a fold of peritoneum, the **suspensory ligament of the ovary**, which is directed upward over the iliac vessels and contains the ovarian vessels. The *lower* or *uterine end* is directed toward the pelvic floor; it

FIG. 1156.—Female pelvic organs *in situ*, seen from above. (Bardeleben.)

is usually narrower than the upper end and is attached to the lateral angle of the uterus, immediately behind the Fallopian tube, by a rounded cord termed the **ligament of the ovary**, which lies within the broad ligament and contains some non-striated muscle fibres. The *outer surface* is in contact with the parietal peritoneum which lines the *fossa ovarii*, the *inner surface* is to a large extent covered by the fimbriated extremity of the Fallopian tube. The *anterior* or *straight border* is directed toward the impervious hypogastric artery, and is attached to the back of the broad ligament by a short fold named the **mesovarium**. Between the two layers of this fold the bloodvessels and nerves pass to enter the hilum of the ovary. The *posterior* or *convex border* is free and is directed toward the ureter. The Fallopian tube arches over the ovary, running upward in relation to its anterior border, then curving over its upper or tubal pole, and finally passing downward on its posterior border and inner surface.

The Descent of the Ovary is described on page 1427.

The Ovary at Different Ages.—The ovary of childhood is smooth and even. The scars of many ruptured Graafian follicles cause this surface of the ovary to become pitted, puckered, fibrous, and uneven in old age. The surface of the ovary is grayish red in color. The corpus luteum of a nonpregnant woman slowly degenerates and disappears. The corpus luteum of an impregnated woman enlarges during pregnancy.

FIG. 1157.—Diagrammatic representation of the female reproductive organs and their relations to the bladder and urethra, lateral view. (Toldt.)

Structure (Figs. 1158, 1159, and 1167).—The ovary consists of the cortex and medulla, in the former of which are found the Graafian follicles and their remains and the hilum of the ovary. The **cortex** consists of **stroma** and **Graafian follicles**. Peripherally, the stroma is condensed to form a **capsule**, the **tunica albuginea**, which is covered by a layer of cuboidal epithelial cells called the **germinal epithelium**, and is often referred to as the serous covering of the organ. These cells are sharply marked off by a whitish line, at the hilum of the ovary, from the endothelium of the peritoneum. The **stroma** consists of a delicate white fibrous tissue meshwork, containing many small bloodvessels and groups of large polygonal epithelial cells called **interstitial cells**.

In the stroma are found the **Graafian follicles** (Fig. 1158) and their remains. The follicles are of different sizes; the smallest are beneath the tunica albuginea, the medium-sized follicles are found toward the medulla, while the largest extend from the innermost part of the cortex and beyond its ordinary limit, thus causing the nodular appearance of the surface of the ovary. A large follicle consists of a sheath of stroma called the **theca folliculi**, the inner portion of which is quite vascular. Lining the theca are several layers of granular cells, the **zona granulosa**. The greater part of the follicle is devoid of cells, but contains a liquid, the **liquor folliculi**, and the

FIG. 1158.—Section of the ovary: 1. Outer covering, 1'. Attached border, 2. Central stroma, 3. Peripheral stroma, 4. Bloodvessels, 5. Graafian follicles in their earliest stage, 6, 7, 8. More advanced follicles, 9. An almost mature follicle, 9'. Follicle from which the ovum has escaped, 10. Corpus luteum. (After Schron.)

space occupied by this is termed the **antrum**. At one point the **zona granulosa** forms a mass which projects into the antrum; this mass, the **discus proligerus**, contains the ovum and its membrane. Beneath the granular cells of the discus is a layer of radially placed tall columnar cells, the **corona radiata**, within which lies a broad clear membrane, the **zona pellucida**, or **zona radiata**. Between the zona pellucida and the ovum, which lies within it, is a narrow space, the **perivitelline space**.

The ovum consists of an outer membrane, the **vitelline membrane**, internal to which is the protoplasm or **vitellus**. Embedded in the latter is a large, pale-staining, eccentrically placed nucleus, the **germinal vesicle**, which contains a large, deeply staining nucleolus, or **germinal spot**. Although the ovum is usually described as a typical cell, the matured ovum, since it does not contain a centrosome, cannot be so designated.

When a follicle enlarges it ruptures and the ovum usually escapes into the oviduct. This process constitutes **ovulation**. When the ovum escapes, the vessels of the follicle rupture and fill the antrum with blood and form thus the **corpus hemorrhagicum**. As this becomes organized, the hemoglobin is absorbed and this body becomes yellowish, due to the presence of a great number of large yellow elements, the **lutein cells**, and thus the **corpus luteum** is formed. If pregnancy

FIG. 1159.—Section through a Graafian follicle from an ape's ovary. $\times 90$. (Szymonowicz.)

supervenes, this body persists almost the entire period of gestation; if the ovum is not impregnated, the corpus luteum soon becomes contracted and whitish, and forms the **corpus albicans**.

The **medulla** consists of a loose network of coarse bundles of white fibrous tissue, which supports many large bloodvessels; here are also seen *smooth muscle* tissue and **interstitial cells**.

The **hilum** is a scar-like depression at which the medulla comes to the surface; here the vessels, nerves, and lymphatics enter and emerge.

Each ovum, before it can be fertilized, must undergo **maturation**. In this process the oöcyte undergoes two divisions, resulting in four cells, each of which contains one-fourth the amount of chromatin in the form of *one-half the number of chromosomes*. Three of these, the **polar bodies**, are small and unimportant and disappear. The fourth is the large **matured ovum**.

The development and maturation of the Graafian vesicles and ova continue uninterruptedly from puberty to the end of the fruitful period of woman's life, while their formation commences before birth. Before puberty the ovaries are small, the Graafian vesicles contained in them are disposed in a comparatively thick layer in the cortical substance; here they present the appearance of a large number of minute closed vesicles, constituting the early condition of the Graafian vesicles; many, however, never attain full development, but shrink and disappear. At puberty the ovaries enlarge and become more vascular, the Graafian vesicles are developed in greater abundance, and their ova are capable of fecundation.

Vessels and Nerves.—The **arteries of the ovaries** (Figs. 1168 and 1170) are the **ovarian** from the aorta, corresponding to the spermatic arteries in the male. The ovarian artery on each side enters the pelvis in the fold of broad ligament known as the suspensory ligament of the ovary and enters the attached border, or hilum, of the ovary. The ovarian vessels anastomose about the hilum with branches of the **uterine artery**. The **veins** follow the course of the arteries; they form a plexus near the ovary, the **pampiniform plexus**, corresponding to a like structure near the testis of the male. The **lymphatics** (Fig. 1169) terminate in the nodes to the corresponding side of the aorta, and they anastomose in their course with trunks from the uterine fundus and oviduct. The **nerves** come from the **ovarian plexus**, which is a continuation of the **renal plexus** along the ovarian artery, and from the **aortic plexus**.

The **epoöphoron**, **parovarium** or **organ of Rosenmüller** (Figs. 1160, 1163, and 1164) is placed in the mesosalpinx, between the ovary and tube. It consists of a number of epithelial-lined closed tubes. This structure can be readily seen if the mesosalpinx is stretched and held in front of the light. One of these tubes runs parallel to the Fallopian tube, and is called **Gärtner's duct** (*ductus epoophori longitudinalis*). A number of tubes (*ductuli transversi*) ascend from near the ovary and each empties into Gärtner's duct at a right angle. Gärtner's duct is a portion of the Wolffian duct, which has persisted and is represented in the male by the canal of the epididymis. The tubules which join the duct are persistent mesonephric tubules and are the homologues of the *vasa efferentia* and *coni vasculosi* of the testis, and probably also the aberrant ducts of the canal of the epididymis.

The **paroöphoron** is within the mesosalpinx, but is nearer to the uterus than is the epoöphoron. It consists of several small tubules, which can be seen in an adult only by the aid of a pocket lens. They are visible to the naked eye in a child at birth. It represents the organ of Giralde's in the male and is derived from the mesonephros.

Applied Anatomy.—An ovary may fail to descend and remain well above the pelvic brim; it may *prolapse* into Douglas' pouch; it may enter the sac of a hernia; it may inflame; a *tumor* or *cyst* may arise from it. A *solid tumor* of the ovary may be a fibroma, a sarcoma, or a carcinoma. "Cysts may originate in any part of the tuboövarian structure; as the cortical, medullary, or parenchymatous portions of the ovary; in the structure between the tube and ovary known as the Rosenmüller organ or parovarian structures; and in the hydatid of Morgagni." Cysts may be simple, proliferating, or dermoid; unilocular or multilocular. Glandular proliferous cysts, papillary proliferous cysts, dermoid cysts, and parovarian cysts may attain a large or even an enormous size. The operation for the removal of an ovarian cyst is one of the most successful of the major procedures of surgery.

THE FALLOPIAN TUBE, OR OVIDUCT (TUBA UTERINA [FALLOPII]) (Figs. 1160, 1161).

The **Fallopian tubes** or **oviducts** convey the ova from the ovaries to the cavity of the uterus. They are two in number, one on each side, situated in the upper margin of the broad ligament, extending from each superior angle of the uterus to the side of the pelvis. Each tube is about four inches (10 cm.) in length, and is described as consisting of three portions—(1) the **isthmus** (*isthmus tubae uterinae*) (Fig. 1160), or inner constricted third; (2) the **ampulla** (*ampulla tubae uterinae*) (Fig. 1160), or outer dilated portion, which curves over the ovary; and (3) the **infundibulum** (*infundibulum tubae uterinae*), the funnel-like expansion of the tube, at the bottom of which is the **abdominal orifice** or **pavilion** (*ostium abdominale tubae uterinae*) (Fig. 1160). The abdominal orifice has a small diameter (2 mm. when relaxed to its full extent). The margin of the infundibulum is rendered irregular by the presence of numerous small processes, the **fimbriae** (*fimbriae tubae*). This end of the tube is called the **fimbriated extremity** (Fig. 1160), because of these processes. The surfaces of the fimbriae looking into the cavity of the infundibulum are covered with mucous membrane continuous with the tubal mucous membrane. The outer surfaces are covered with peritoneum. One of the fimbriae is attached to the ovary and is called the **ovarian fimbria** (*fimbria ovarica*) (Fig. 1160). The uterine opening (*ostium uterinum tubae*) is even smaller than the abdominal opening, and will admit only a small bristle. In connection with the fimbriae of the Fallopian tube or with the broad ligament close to them

there are frequently one or more small pedunculated vesicles. These are termed the **hydatids of Morgagni** (*appendices vesiculosi*).

The course pursued by the Fallopian tube has been given in its relations to the ovary on page 1400.

Structure.—The Fallopian tube consists of three coats—**serous**, **muscular**, and **mucous**.

The **external** or **serous coat** (*tunica serosa*) is peritoneal. Beneath this lies the **tunica adventitia**, composed of lax connective tissue.

The **middle** or **muscular coat** (*tunica muscularis*) consists of an **external longitudinal layer** (*stratum longitudinale*), and an **internal circular layer** (*stratum circulare*) of smooth muscle fibres continuous with those of the uterus; near the uterine end of the tube an **inner longitudinal layer** is found.

The **internal** or **mucous coat** (*tunica mucosa*) is continuous with the mucous lining of the uterus and, at the free extremity of the tube, with the peritoneum. It is thrown into branched **longitudinal folds** or **villi** (*plicae tubariae*), which in the outer, larger part of the tube or **ampulla** (*plicae ampullares*) are much more extensive than in the narrow canal of the isthmus (*plicae isthmicae*). The lining epithelium is simple ciliated. This form of epithelium is also found on the inner surface of the fimbriae, while on the outer or serous surfaces of these processes the epithelium gradually merges into the endothelium of the peritoneum.

FIG. 1160.—Dissection of uterine appendages, seen from behind. (Henle.)

Vessels and Nerves.—The chief artery of the tube is the **tubal branch of the uterine artery** (*ramus tubarius*) (Fig. 1168). It also receives branches from the ovarian (Fig. 1168). Some of the **tubal veins** empty into the uterine veins, some into the ovarian veins. The **lymphatics** (Fig. 1169) coming from the tube unite with the trunks coming from the uterus and ovary and terminate in the lateral aortic nodes. The **nerves** come from the same plexuses that send branches to the uterus and ovary.

Applied Anatomy of the Appendages.—*Extrauterine pregnancy* most commonly occurs in the ampulla of the tube. The product of the conception may escape through the ostium abdominale or the walls of the tube may rupture, a violent hemorrhage resulting. *Pelvic peritonitis* is a not uncommon sequence of tubal disease. *Salpingitis* is inflammation of the mucous coat of the tube—*interstitial salpingitis* of the middle coat; *perisalpingitis* of the peritoneal coat. If inflammation closes the uterine and the abdominal ends of the tube, mucus gathers and distends the tube (*hydrosalpinx*). If purulent matter gathers, the condition is known as *pyosalpinx*.

THE UTERUS, OR WOMB (Figs. 1161, 1164).

The **uterus** is the organ of gestation, receiving the fecundated ovum in its cavity, retaining and supporting it during the development of the fetus, and becoming the principal agent in its expulsion at the time of parturition. It is a hollow

muscular organ. The nonpregnant uterus is contained in the cavity of the pelvis between the bladder and the rectum (Figs. 1166 and 1171). It is rarely placed exactly in the midline, but inclines to one side or the other, more often to the left than to the right. The walls of the organ are extremely thick. The uterus is movable as a whole, and the body of the uterus is movable upon the neck. Its position varies with the condition of adjacent parts, especially of the bladder and rectum. The cervix is more firmly fixed than the body and fundus, and hence the latter vary more in position than the former. Normally, in an erect individual, with the bladder and rectum empty, the external os is at the level of the upper surface of the pubic symphysis (Fig. 1157) and in a frontal plane passing through the ischiatic spines. The long axis of the uterus is directed forward and upward (Fig. 1157) and is angled where the body and cervix join. Hence, normally, with the bladder empty, the uterus is *anteverted* and *anteflexed*. When the bladder fills, the anteversion and anteflexion are almost abolished. If the bladder is overdistended and the rectum is empty, the uterus is pushed strongly backward; so that its long axis corresponds to the long axis of the vagina; in other words, it is *retroverted*.

FIG. 1161.—The uterus, the left Fallopian tube, and the left ovary in their connection with the broad ligament of the uterus, which has been fully unfolded. Seen from behind. From a virgin, aged nineteen years. (Toldt.)

In the virgin state it is pear-shaped, flattened from before backward, and is retained in its position by the round and broad ligaments on each side, and projects into the upper end of the vagina below (Figs. 1161 and 1162). Its upper end, or base, is directed upward and forward; its lower end, or apex, downward and backward, in the line of the axis of the inlet of the pelvis. It therefore forms an angle of about 110 degrees with the vagina, since the direction of the vagina corresponds to the axis of the cavity and outlet of the pelvis. The nonpregnant adult uterus measures about three inches (7.5 cm.) in length, two inches (5 cm.) in breadth at its upper part, and nearly an inch (2.5 cm.) in thickness, and it weighs from an ounce to an ounce and a half (30 to 45 grams).

It consists of two parts (Fig. 1161): (1) An upper and larger portion, consisting of the body and fundus. This portion is flattened from before backward. (2) A lower, smaller, and cylindrical portion, the cervix.

On the surface, about midway between the base and apex, a slight constriction, known as the *isthmus uteri*, and a corresponding narrowing of the uterine cavity, the internal os, serve to demarcate the two portions.

The **fundus** (*fundus uteri*) (Fig. 1161) is the upper broad extremity of the uterus. If a line is drawn from the uterine opening of one Fallopian tube to the other, the portion above the line is the fundus. The fundus is directly continuous with the body.

The **body of the uterus** (*corpus uteri*) (Fig. 1161) gradually narrows from the fundus to the isthmus. In outline, when seen from in front or behind, it resembles a triangle, the base being above and the apex being absent. The **anterior surface** (*facies vesicales*) is so slightly rounded as to appear flattened. It is covered by

FIG. 1162.—The external genital organs of a virgin attached to the vagina, which has been isolated and opened, and a portion of the cervix uteri. (Toldt.)

peritoneum (Fig. 1161), which becomes reflected from it at its isthmus to form the **utero-vesical pouch**, which lies between the uterus and bladder (Fig. 1165). Its posterior surface is more rounded than the anterior, being convex transversely. It is covered by peritoneum throughout (Fig. 1166), and separated from the rectum by some convolutions of the small intestine (Fig. 1165). The peritoneum which covers the posterior surface forms most of the anterior wall of Douglas'

cul-de-sac (Figs. 1164 and 1165, and p. 1256). Its lateral margins (Figs. 1161 and 1164) are slightly convex. At the upper angle the Fallopian tube joins the body of the uterus; immediately below this the round ligament is attached, and behind the latter is the attachment of the ligament of the ovary; behind both of

Fig. 1163.—The parovarium. The mesosalpinx is partly removed. (Poirier and Charpy.)

these structures, and from the side of the womb the broad ligament passes. The division between the body and the cervix is indicated externally by the isthmus and by the reflection of the peritoneum from the anterior surface of the uterus on to the bladder, and internally by a narrowing of the canal called the **internal os** (Fig. 1164).

The **neck** or **cervix uteri** (Figs. 1161 and 1164) is the lower constricted segment of the uterus; around its circumference is attached the upper end of the vagina (Figs. 1161 and 1165), which extends upward a greater distance behind than in front. The neck is spindle-shaped in the nulliparous and cylindrical in parous women.

Fig. 1164.—The uterus and the right Fallopian tube opened from behind. (Toldt.)

The **supravaginal portion** (*portio supravaginalis [cervicis]*) (Figs. 1161 and 1165) is not covered by peritoneum in front; a pad of cellular tissue is interposed between it and the bladder. Behind, the peritoneum is extended over it.

The **vaginal portion** (*portio vaginalis [cervicis]*) (Figs. 1161 and 1165) is the lower end projecting into the vagina. It is round or elliptical, the long axis of the

elliptical figure being transversely placed. On its surface is a small aperture, the **external os** or **os uteri** (*orificium externum uteri*) (Figs. 1161 and 1164), generally linear in shape, but sometimes oval or almost circular. If a woman has borne children, the opening is transverse and the margins are irregular. The margin of the opening is, in the absence of parturition or disease, quite smooth. This aperture divides the vaginal portion of the cervix into two lips, an **upper** or **posterior lip** (*labium posterius*) and an **anterior lip** (*labium anterius*). On each side of the cervix and upper portion of the vagina there is a space containing bloodvessels and filled with loose cellular tissue. This loose tissue passes upward between the layers of

FIG. 1165.—The cervix uteri and upper end of the vagina, showing their relations to the peritoneum. Diagrammatic. (Testut.)

the broad ligament, and is called **parametrium**. On each side of the cervix and three-quarters of an inch away is the terminal portion of the corresponding ureter.

FIG. 1166.—Douglas' pouch. (From a preparation in the Museum of the Royal College of Surgeons of England.)

Folds and Ligaments.—The ligaments of the uterus are eight in number. Some are simple folds of peritoneum; others contain connective tissue and muscle. The ligaments are as follows: one anterior, one posterior, two lateral or broad,

two sacrouterine—all these being formed of peritoneum—and, lastly, two round ligaments.

The **anterior ligament** or the **utero-vesical fold** is reflected on to the bladder from the front of the uterus, at the junction of the cervix and body. It forms the **utero-vesical pouch** (*excavatio vesicouterina*) (Figs. 1165 and 1166).

The **posterior ligament** or the **rectovaginal fold** passes from the posterior wall of the uterus over the upper fourth of the vagina, and thence on to the rectum and sacrum. It thus forms a pouch, called the **rectovaginal pouch** or **Douglas' pouch** (Figs. 1165 and 1166), the boundaries of which are, *in front*, the posterior wall of the uterus, the supravaginal portion of the cervix, and the upper fourth of the vagina; *behind*, the rectum and sacrum; *above*, the small intestine; and *laterally*, the folds of Douglas or rectouterine folds, which contain the sacrouterine ligaments.

The **broad ligament** (*ligamentum latum uteri*) (Figs. 1166 and 1167) is a peritoneal fold which passes from each side of the uterus to the lateral wall of the pelvis as high as the external iliac vein. From this region comes the peritoneal fold called the suspensory ligament of the ovary (Fig. 1156). The two broad ligaments form a septum across the pelvis, which divides that cavity into two portions. In the anterior part are contained the bladder, urethra, and vagina; in the posterior part, the rectum. With the uterus normally placed the anterior surface of the broad ligament faces forward and downward, and the posterior surface faces upward and backward. The ligament is more nearly vertical at its pelvic attachment. The two layers of the broad ligament are mostly near to each other, to the side and below they separate and pass into the peritoneum of the lateral pelvic wall, the bladder, and the rectum.

Between the two layers of each broad ligament are contained (1) the Fallopian tube superiorly; (2) the round ligament; (3) the ovary and its ligament; (4) the parovarium or organ of Rosenmüller, and the paroöphoron; (5) loose connective tissue, which is called **parametrium**; (6) unstriped muscle tissue; and (7) bloodvessels and nerves. The Fallopian tube is in the free edge of the broad ligament, and is contained in a special fold, which is attached to the part of the ligament near the ovary, and is known by the

FIG. 1167.—The broad ligament of the uterus, with the mesovarium, the mesosalpinx, the ovary, and the Fallopian tube in transverse section. (Toldt.)

name of the **mesosalpinx** (Figs. 1164 and 1167). If the mesosalpinx is spread out, it is seen to be roughly triangular; the base of the triangle is outward, the apex at the upper and outer angle of the uterus; the upper boundary is the Fallopian tube, and the lower boundary is the ovary and its ligament. Between the two layers of the mesosalpinx are the parovarium and the paroöphoron. Between the fimbriated extremity of the tube and the lower attachment of the broad ligament is a concave rounded margin, called the **infundibulopelvic ligament** (Fig. 1160).

The **mesovarium** passes upward from the posterior surface of the broad ligament (Fig. 1167). Beneath the mesovarium is a larger and thicker portion of the broad ligament, called the **mesometrium** (Fig. 1167).

The **sacrouterine** or **uterosacral ligaments** (*plicae rectouterinae*) are contained in the peritoneal folds of Douglas. They pass from the second and third segments of the sacrum, downward and forward on the lateral aspects of the rectum, to be attached one on each side of the uterus at the junction of the supravaginal cervix and the body, this point corresponding internally to the position of the os internum.

They contain fibrous tissue and unstriated muscle fibre. Muscle fibres from the uterine wall to the rectal wall constitute the **Rectouterinus muscle** (*musculus rectouterinus*). This muscle is part of the sacrouterine ligaments.

A **round ligament** (*ligamentum teres uteri*) (Figs. 1161 and 1166) is attached on each side of the uterus. The two ligaments are rounded cords between four and five inches in length, each situated between the layers of the broad ligament in front of and below the Fallopian tube. Commencing at the superior angle of the uterus, this ligament passes forward, upward, and outward through the internal abdominal ring, along the inguinal canal, to the labium majus, in which it becomes lost. The round ligament consists principally of muscle tissue prolonged from the uterus; also of some fibrous and areolar tissue, besides bloodvessels and nerves, enclosed in a duplicature of peritoneum, which in the fetus is prolonged in the form of a tubular process for a short distance into the inguinal canal. This process is called the **canal of Nuck**. It is generally obliterated in the adult, but sometimes remains pervious even in advanced life. It is analogous to the peritoneal pouch which precedes the descent of the testis.

The **cavity of the uterus** (*cavum uteri*) (Fig. 1164) is small in comparison with the size of the organ, because of the great thickness of the wall. That portion of the cavity which corresponds to the body is triangular, flattened from before backward, so that its anterior and posterior walls are closely approximated, and having its base directed upward toward the fundus. At each superior angle is the minute orifice of the Fallopian tube. At the inferior angle of the uterine cavity is a small constricted opening, smaller and more nearly circular than the external os uteri, the **internal os uteri** (*orificium internum uteri*) (Fig. 1164), which leads into the cavity of the cervix.

The **cavity of the cervix** (*canalis cervicis uteri*) (Fig. 1164) extends from the internal os uteri to the external os uteri. It is somewhat fusiform, flattened from before backward, broader at the middle than at either extremity, and communicates below with the vagina. The wall of the canal presents, anteriorly and posteriorly, a longitudinal column, from which proceed a number of small oblique columns, giving the appearance of branches from the stem of a tree; and hence the name **uterine arbor vitæ** (*plicae palmatae*) applied to it. The longitudinal ridges are not exactly apposed, but fit against each other so as to close the cervical canal. These folds usually become very indistinct after the first labor.

The total length of the uterine cavity from the external os to the fundus is about two and a half inches.

The Uterus at Different Ages.—The uterus of the fetus is in the abdominal cavity projecting above the brim of the pelvis. The cervix is considerably larger than the body. At birth the cervix is larger relatively than in the adult; there is no distinct internal os distinguishing the cavity of the body of the uterus from the cavity of the cervix. The arbor vitæ is distinct and extends to the upper part of the cavity of the organ. The growth of the uterus is slow until puberty is almost reached, when for a time the growth is rapid. The growth of the uterine body causes the mucous membrane of this part to lose its folds, hence the arbor vitæ disappears from the body. In a woman who has had children the uterine cavity is larger than in a woman who has never borne a child. In advanced years the uterine wall becomes paler and hard and rigid from atrophic fibrous changes. A more distinct constriction separates the body and cervix. The internal os frequently and the external os occasionally are obliterated in old age.

Abnormalities.—Very rarely the uterine cavity is divided into two by a septum. Occasionally the condition known as **bicornate uterus** exists. In this condition each lateral angle is prolonged into a horn or cornu. The uterus is formed by the union of the two ducts of Müller, and failure of fusion of these ducts makes a double uterus or a bicornate uterus.

Changes at a Menstrual Period.—For several days before the menstrual flow begins the mucous membrane increases in thickness and vascularity and its surface is cast into folds. After these preparatory changes the superficial portions of the mucous membrane break down and are cast off, and bleeding begins. At the termination of menstruation the mucous membrane rapidly regenerates. At each menstrual period from four to five fluidounces of blood are discharged. The meaning of menstruation is uncertain. Pflüger believes the wall of the uterus

is made raw, so that if an impregnated ovum arrives it will adhere. Reichert believes that menstruation means that no impregnated ovum has arrived in the womb, and hence no bed is needed for one.

Changes Induced by Pregnancy.—The muscle fibres hypertrophy enormously and become vastly longer and broader. There is a great increase in connective tissue, and new connective-tissue fibres pass between bundles of muscle. The peritoneal coat undergoes hyperplasia. It remains closely adherent to the uterus, except over the lower segment, from which region it can be easily stripped. The bloodvessels become large and tortuous. The nerves are increased in length and new filaments form. The lymphatics undergo hypertrophy and hyperplasia. The uterus becomes spherical, and after the fourth month ovoidal. Early in pregnancy the increase in weight causes the uterus to descend in the pelvis. After the third month it rises progressively, and during the ninth month the fundus reaches the epigastrium. "Before term (four weeks in primiparæ, ten days or one week in multiparæ) the fundus sinks again, as the presenting part and lower uterine segment become engaged in the pelvic cavity. This phenomenon is explained by contraction of the overstretched abdominal walls."¹ The womb is acutely anteflexed during the first three months of pregnancy. After this period, as the womb rises, the anteflexion is diminished, but some degree remains, because the abdominal walls are too lax to hold the organ straight. The uterus passes somewhat to the right side and undergoes a rotation on its longitudinal axis, so that the anterior surface looks front and to the right. These changes in position are caused by fecal distention of the sigmoid. The intestines are above and back of the uterus. During the first four months the cervix softens and enlarges somewhat. The length of the cervical canal is not altered during pregnancy, and the canal does not dilate until labor begins. During pregnancy the cervical glands secrete thick mucus, which coagulates and occludes the cervical canal; the round ligaments become stronger, and the layers of the broad ligaments are separated toward their inner portions by the enlarging womb.

After parturition the uterus nearly regains its former size, usually weighing something over one and a half ounces; but its cavity is larger than in the virgin state, the external orifice is more marked, its edges present a fissured surface, its vessels are very tortuous, and its muscle layers are more defined.

Structure.—The uterus is composed of three coats—an **external** or **serous coat**, a **middle** or **muscular coat**, and an **internal** or **mucous coat**.

The **serous coat** or **perimetrium** (*tunica serosa*) is derived from the peritoneum; it invests the fundus and the whole of the posterior surface of the uterus; but covers the anterior surface only as far as the junction of the body and cervix. In the lower fourth of the posterior surface the peritoneum, though covering the uterus, is not closely connected with it, being separated from it by a layer of loose cellular tissue and some large veins. At the lateral margins of the uterus the serous coat passes on to the broad ligaments. The serous coat adheres closely to the uterus, and it is very difficult to separate it from the muscle.

The **muscular coat** (*tunica muscularis*) (Fig. 1164) forms the chief bulk of the substance of the uterus. In the unimpregnated state it is dense, firm, of a grayish color, and cuts almost like cartilage. It is thick opposite the middle of the body and fundus, and thin at the orifices of the Fallopian tubes. It consists of bundles of unstriated muscle tissue, disposed in layers, intermixed with areolar tissue, bloodvessels, lymphatic vessels, and nerves. The muscle tissue is disposed in three layers—**external**, **middle**, and **internal**.

The **external layer** is placed beneath the peritoneum, disposed as a thin plane on the anterior and posterior surfaces. It consists of fibres which pass transversely across the fundus, and, converging at each superior angle of the uterus, are continued on the Fallopian tube, the round ligament, the ligament of the ovary; some passing at each side of the broad ligament, and others running backward from the cervix into the sacrouterine ligaments. The fibres of the external portion of the outer layer (*stratum subserosum*) are longitudinal. The fibres of the inner portion of the outer layer (*stratum supravasculare*) are partly circular and partly longitudinal.

The **middle layer of fibres** (*stratum vasculare*), which is thickest, presents bundles of circular fibres closely connected with bloodvessels. In this layer are most of the large bloodvessels. The circular fibres about the internal os form a distinct sphincter. Those which surround the orifices of the Fallopian tubes are arranged in the form of two hollow cones, the apices of which surround the orifices of the Fallopian tubes, their bases intermingling with one another on the middle of the body of the uterus.

The **internal** or **deep layer** (*stratum mucosum*) consists of longitudinal fibres. Some consider the deeper portion of the muscle tissue of the uterus to be the *muscularis mucosae*. But the deep portion of the muscle substance is continuous with the more superficial portion, and there is no submucous coat between the muscle and the mucous membrane. The deeper layer of muscle fibres of the uterus contains connective tissue and elastic fibres. The muscle tissue of the cervix contains more connective and elastic tissue than does the body of the uterus; hence, the cervix is harder and stiffer than the body.

¹ A Text-book of Obstetrics. By Prof. Barton Cooke Hirst.

The **mucous membrane** (*tunica mucosa*) (Fig. 1164) is thin, smooth, and closely adherent to the subjacent muscle tissue. It is continuous, through the fimbriated extremity of the Fallopian tubes, with the peritoneum, and through the os uteri with the lining of the vagina.

In the body of the uterus it is smooth, soft, of a pale red color, lined with simple ciliated epithelium, and presents, when viewed with a lens, the orifices of numerous tubular glands arranged perpendicularly to the surface. It is not provided with any submucosa, but is intimately connected with the innermost layer of the muscular coat. In structure its tunica propria differs from ordinary mucous membrane, consisting of an embryonic nucleated and highly cellular form of connective tissue, in which run numerous large lymphatics. In it are the tube-like **uterine glands** (*glandulae uterinae*), which are of small size in the unimpregnated uterus, but shortly after impregnation become enlarged and elongated, presenting a contorted or waved appearance toward their closed extremities, which reach into the muscularis, and may be single or bifid. The uterine glands consist of a delicate membrane, lined with epithelium, which becomes ciliated toward the orifices.

In the **cervix** the mucous membrane is sharply differentiated from that of the uterine cavity. It is thrown into numerous oblique ridges, which diverge from an anterior and posterior longitudinal raphé, presenting an appearance which has received the name of **arbor vitae** (*plicae*

FIG. 1168.—The arteries of the internal reproductive organs of the female, seen from behind. (After Hyrtl.)

palmatae). In the upper two-thirds of the canal the mucous membrane is provided with numerous deep glands (*glandulae cervicales uteri*), which secrete a clear viscid alkaline mucus; and in addition, extending through the whole length of the canal, are a variable number of little cysts, presumably glands, which have become occluded and distended with retained secretion. They are called the **ovules of Naboth**. The mucous membrane covering the lower half of the cervical canal presents numerous papillæ. The epithelium of the upper two-thirds is ciliated, but below this it loses its cilia, and close to the external os gradually changes to squamous epithelium.

Vessels and Nerves (Fig. 1168).—The **arteries of the uterus** are the **uterine**, from the internal iliac, and the **ovarian**, from the aorta. They are remarkable for their tortuous course in the substance of the organ and for their frequent anastomoses. The uterine artery reaches the lower part of the uterus at the side and is prolonged as a large artery to the body and fundus, which ascends between the layers of the broad ligament. The uterine artery gives off a smaller branch, the **cervical**, which descends to supply the cervix and sends **cervicovaginal** branches to the vagina. The **azygos arteries of the vagina** come from the cervicovaginal reinforced by branches of the vaginal arteries (Fig. 1170). A median longitudinal vessel is formed in front and behind, which descends in the vaginal wall. The termination of the ovarian artery meets the termination of the uterine artery, and forms an anastomotic trunk from which branches are given off to

supply the uterus. Dr. Robinson, instead of describing the uterine and ovarian arteries as two vessels, describes them as parts of one vessel, the *arteria uterina ovarica* (p. 675). The **veins** are of large size, and correspond with the arteries. In the impregnated uterus these vessels form the **uterine sinuses**, consisting of the lining membrane of the veins adhering to the walls of the canals channelled through the substance of the uterus. They terminate in the **uterine plexuses**, which empty into the **internal iliac veins**. The **lymphatics** (Fig. 1169) are described on page 800. The **nerves** come chiefly from the **uterovaginal plexus**, which continues into the **hypogastric plexus** and receives filaments from the **third and fourth sacral nerves**. The uterus also receives direct fibres from the **hypogastric plexus** and from the **vesical plexus**.

FIG. 1169.—The lymphatics of the internal organs of generation in the female. (Poirier and Charpy.)

Applied Anatomy.—*Pelvic cellulitis (parametritis)* is inflammation of the pelvic cellular tissue. It is due to sepsis, and its usual antecedent is uterine sepsis. A laceration of the cervix may admit bacteria. An abscess may form. If it points in the vagina it should be incised through the vaginal wall. The uterus may require removal (*hysterectomy*) in cases of *malignant disease* or for *fibroid tumors*. *Carcinoma* is the most common form of malignant disease of the uterus, though cases of *sarcoma* do occur. *Carcinoma* may show itself either as a columnar carcinoma or as a squamous carcinoma, the former commencing either in the cervix or body of the uterus, the latter always commencing in the epithelial cells of the mucous membrane covering of the vaginal surface of the cervix. The columnar form may be treated in the early stage, before fixation has taken place, by removal of the uterus, either through the vagina or by means of abdominal section. The former operation is attended by the smaller death rate. Vaginal hysterectomy

may be performed in any case in which the uterus or the uterus and tumor are not too large to be withdrawn through the vagina. It is difficult in this operation to deal with adhesions and other complications in the upper part of the pelvis, and for this reason many surgeons prefer the abdom-

FIG. 1170.—The uterus and its appendages. Posterior view. The parts have been somewhat displaced from their proper position in the preparation of the specimen; thus, the right ovary has been raised above the fallopian tube, and the fimbriated extremities of the tube have been turned upward and outward. (From a preparation in the Museum of the Royal College of Surgeons of England.)

inal operation. *Vaginal hysterectomy* is performed by placing the patient in the lithotomy position and introducing a large duckbill speculum into the vagina. The cervix is then seized with a volsellum and pulled down as far as possible and the mucous membrane of the vagina incised around the cervix as near to it as the disease will allow, especially in front, where the ureters are in danger of being wounded. A pair of dressing forceps are then pushed through into Douglas'

FIG. 1171.—Relations between uterus, ureter, and uterine artery. (Schematic.)

enclosed in a ligature. This is tied tightly, and the operation is repeated on the other side. The broad ligament is then divided on either side, between the ligature and the uterus, to the extent to which it has been constricted. By traction on the volsellum which grasps the cervix, the uterus

pouch and opened sufficiently to allow of the introduction of the two forefingers, by means of which the opening is dilated laterally as far as the sacrouterine ligaments. A somewhat similar proceeding is adopted in front, but here the bladder has to be separated from the anterior wall of the uterus for about an inch before the vesicouterine fold of peritoneum can be reached. This is done by carefully burrowing upward with a director and stripping the tissues from the anterior uterine wall. When the vesicouterine pouch has been opened and the opening dilated laterally, the uterus remains attached only by the broad ligaments, in which are contained the vessels that supply the uterus. Before division of the ligaments these vessels have to be dealt with. The forefinger of the left hand is introduced into Douglas' pouch and an aneurism needle, armed with a long silk ligature, is inserted into the vesicouterine pouch, and is pushed through the broad ligament of one side about an inch above its lower level and at some distance from the uterus. One end of the ligature is now pulled through the anterior opening, and in this way we have the lowest inch of the broad ligament, in which is contained the uterine artery,

can be pulled considerably farther down in the vagina, and a second inch of the broad ligament is treated in a similar way. This second ligature will embrace the pampiniform plexus of veins, and, when the broad ligament has been divided on either side, it will be found that a third ligature can be made to pass over the Fallopian tube and top of the broad ligament, after the uterus has been dragged down as far as possible. After the third ligature has been tied and the structure between it and the uterus divided, this organ will be freed from all its connections and can be removed from the vagina. This canal is then sponged out and lightly dressed with gauze, no sutures being used. The gauze may be removed at the end of the second day. In squamous epithelioma, amputation of the cervix is done by some in those cases where the disease is recognized before it has invaded the walls of the vagina or the neighboring broad ligaments. The operation consists in removing a wedge-shaped piece of the uterus, including the cervix, through the vagina and attaching the cut surface of the stump to the anterior and posterior vaginal walls, so as to prevent retraction. In view, however, of the continuity of the lymphatic network of the cervix with the lymphatics of the body, the operation is insufficient and should be condemned. Complete *abdominal hysterectomy* is rarely necessary, except for malignant disease. In this operation the entire uterus is removed. The preliminary introduction of bougies into the ureters as practised by Kelly and Clark enables the surgeon to readily recognize the situations of these tubes. After the abdomen has been opened the uterine vessels are secured and the broad ligaments divided in a similar manner to that employed in vaginal hysterectomy, except that the proceeding is commenced from above. When the first two ligatures have been tied and the broad ligament divided, it will be found that the uterus can be raised out of the pelvis. A transverse incision is now made through the peritoneum, where it is reflected from the anterior surface of the uterus on to the back of the bladder and the serous membrane peeled from the surface of the uterus until the vagina is reached. The anterior wall of this canal is cut across. The uterus is now turned forward and the peritoneum at the bottom of Douglas' pouch incised transversely, and the posterior wall of the vagina cut across until it meets the incision on the anterior wall. The uterus is now almost free, and is held only by the lower part of the broad ligament on either side, containing the uterine artery. A third ligature is made to encircle this, and, after having been tied, the structures are divided between the ligature and the uterus. The organ can now be removed. The vagina is plugged with gauze, and the external wound closed in the usual way. The vagina acts as a drain, and therefore the opening into it is usually left unsutured. In some cases of uterine fibroid the abdomen is opened and the tumor is removed, but the uterus is not taken away. This operation is called *myomectomy*. This operation is suited only to solitary subperitoneal or interstitial tumors (Penrose).

The common operation for uterine fibroids is *supravaginal amputation*. The uterus is cut away and the cervical flaps are sutured. Before the technique of hysterectomy was perfected and before myomectomy was devised the favorite operation for uterine fibroids was *salpingo-oophorectomy*, and by it a large majority of cases operated upon were cured. When it succeeds, a premature menopause is induced and the tumor shrinks. The operation is useless if a woman is past the menopause, and is apt to fail if the tumor is very soft or very large.

THE VAGINA (Figs. 1157, 1175).

The **vagina** (*vulvovaginal canal*) is a musculomembranous passage, which extends from the vulva to the uterus. It is situated in the cavity of the pelvis, behind the bladder and in front of the rectum. Its direction is curved upward and backward, at first in the line of the pelvic outlet, and afterward in that of the axis of the cavity of the pelvis. Its walls are ordinarily in contact, and its usual shape on transverse section is that of an H, the transverse limb being slightly curved forward or backward, while the lateral limbs are somewhat convex toward the median line. Its length is about two and a half inches (6.25 cm.) along its anterior wall (*paries anterior*), and three and a half inches (8.75 cm.) along its posterior wall (*paries posterior*), and its wall is about 2 mm. thick. It is constricted at its commencement, and becomes dilated medially, and narrowed near its uterine extremity; it surrounds the vaginal portion of the cervix uteri, a short distance from the os, its attachment extending higher up on the posterior than on the anterior wall of the uterus (Fig. 1165). To the recess behind the cervix the term **posterior fornix** is applied, while the smaller recess in front is termed the **anterior fornix**.

Relations (Figs. 1157 and 1175).—The upper part of the anterior wall of the vagina is in relation with the base of the bladder, being separated from that viscus by lax connective tissue. Lower down the middle line of the anterior wall and closely joined to it is the urethra. The upper part of the posterior wall, near the middle line, is covered for a quarter of an inch or more with peritoneum, which forms the anterior wall of the depths of the **rectovaginal pouch of peritoneum** or **pouch of Douglas** (*excavatio rectouterina* [Douglasi]) (Fig. 1165), between the uterus and vagina and the rectum. The portion of the posterior wall below the level of the pouch of Douglas is placed close to the rectum, a layer of pelvic fascia intervening. As the vaginal orifice is approached, the rectum and vagina separate, and interposed between them is a mass of fibrofatty tissue called the **perineum** or **perineal body**. Its sides are enclosed between the *Levatores ani* muscles. The ureter toward its termination (Fig. 1166) lies near the lateral wall of the vagina, passing at this point in a direction downward, inward, and slightly forward to reach the bladder. The vagina near its termination passes through the triangular ligament, and upon its sides are the bulbs of the vestibule, the glands of Bartholin, and the Bulbocavernosus muscle.

Structure.—The vagina consists of an **internal mucous lining**, a **muscular coat**, and a **fibrous coat**; between the first two is found a **layer of erectile tissue**.

FIG. 1172.—The lymphatics of the vagina. Schematic. (Poirier and Charpy.)

The **mucous membrane** (*tunica mucosa*) (Fig. 1162) is continuous above with that lining the uterus. Its inner surface presents, along the anterior and posterior walls, a longitudinal ridge or raphé, called the **rugous columns of the vagina** (*columna rugarum anterior et posterior*). The anterior column extends downward as far as the external orifice of the urethra, forming the **carina urethralis vaginae**. Numerous transverse ridges or **rugæ** (*rugæ vaginales*) extend outward from the raphé on either side. These rugæ are divided by furrows of variable depth, giving to the mucous membrane the appearance of being studded over with conical projections or papillæ; they are most numerous near the orifice of the vagina, especially in females before parturition. The epithelium covering the mucous membrane is of the stratified squamous variety. The subepithelial tissue is very loose and contains numerous large veins, which by their anastomoses form a plexus, together with smooth muscle fibres from the muscular coat; it is regarded by Gussenbauer as an erectile tissue. It contains a number of mucous crypts, but no true glands.

The **muscular coat** (*tunica muscularis*) consists of two layers, an external longitudinal, which is far the stronger, and an internal circular layer. The longitudinal fibres are continuous with the superficial muscle fibres of the uterus. The strongest fasciculi are those attached to the rectovesical fascia on each side. The two layers are not distinctly separable from each other, but

are connected by oblique decussating fasciculi which pass from the one layer to the other. Above the triangular ligament the fibres are nonstriated; in the region of the ligament they show striations. In addition to this, the vagina at its lower end is surrounded by a band of striped muscle tissue, the *Sphincter vaginæ* (p. 446).

The **fibrous coat** is composed of dense white fibrous connective tissue, which connects the vagina to the surrounding organs. It contains a large plexus of bloodvessels.

The **erectile tissue** consists of a layer of loose connective tissue situated between the mucous membrane and the muscular coat; embedded in it is a plexus of large veins, and numerous bundles of unstriated muscular fibres derived from the circular muscular layer. The arrangement of the veins is similar to that found in other erectile tissues.

Bloodvessels, Nerves, and Lymphatics.—The arteries of the vagina are branches of the **vesicovaginal artery**, the **vaginal branch of the uterine artery** (p. 674), and branches of the **internal pudic** and **middle hemorrhoidal**. The veins form an abundant plexus around the wall of the vagina and pass to the **internal iliac veins**. The **lymphatics** (Fig. 1172) arise from two communicating networks, one of which is below the mucous membrane, the other in the muscular wall. There is a third network around the vaginal wall, from which the collectors arise. The trunks from the upper third of the vagina pass to the **external iliac nodes**; those from the middle third pass to the **internal iliac nodes**; those from the lower third terminate in the **nodes at the promontory of the sacrum** or in the **lateral sacral nodes**. The nerves come from the **third and fourth sacral nerves** and from the **uterovaginal** and **vesical plexuses of the sympathetic**.

THE EXTERNAL ORGANS (PARTES GENITALES EXTERNAE MULIEBRES).

The **external reproductive organs** in the female are the **mons Veneris**, the **labia majora** and **minora**, the **vestibule**, the **clitoris**, the **vaginal bulb**, and the **glands of Bartholin**. The term **vulva** (*pudendum muliebre*), as generally applied, includes all of these parts. In examining the structures entering into the formation of the vulva we find the homologues of most of the structures which make up the male genitals.

Labia majora	=	Scrotum.
Clitoris	=	Corpora cavernosa.
Bulbus vestibuli	=	Corpus spongiosum.
Vestibular glands (of Bartholin).	=	Bulbourethral glands (of Cowper).

The **mons Veneris** (*commissura labiorum anterior*) is the rounded eminence in front of the pubic symphysis formed by a collection of fatty tissue beneath the integument. It becomes covered with hair at the time of puberty.

The **labia majora** (*labia majora pudendi*) (Figs. 1173 and 1174) are two prominent longitudinal cutaneous folds, narrow behind but fuller and larger toward the mons Veneris, and enclosing the **pudendal slit** (*rima pudendi*) or common urinogenital opening. Each **labium majus** has two surfaces, an outer, which is covered by pigmented skin with numerous sebaceous glands and strong, crisp hairs, and an inner, which is smooth and moist and is continuous with the genitourinary mucous tract. In the subcutaneous areolofatty tissue of each labium majus the round ligament of the uterus ends. The labia are joined with each other anteriorly by the mons Veneris or anterior commissure. Posteriorly they appear to become lost in the neighboring integument, although sometimes connected by a slight transverse fold in front of the anus, the **posterior commissure** (*commissura labiorum posterior*), or posterior boundary of the vulvar orifice. The interval between the posterior commissure and the anus, about an inch in length, constitutes the **obstetric perineum**.

Bloodvessels, Nerves, and Lymphatics.—The arteries of the labia majora are derived from the **superficial external pudic arteries** and from perineal branches of the **internal pudic arteries**. Homologous with the scrotum, the nerve supply is derived from branches of the **ilioinguinal**, **internal pudic**, and **perineal branches of the small sciatic**. The lymphatics drain into the **superficial inguinal** and **internal iliac lymph nodes**.

The **labia minora**, or **nymphæ** (*labia minora pudendi*) (Figs. 1174, 1175), are two smaller, narrower longitudinal folds, with a delicate covering of modified skin, and usually hidden from view unless the labia majora are separated. They end posteriorly by gradually joining the labia majora, although in the young there is usually a transverse fold, the **fourchette** or **frenulum** (*frenulum labiorum pudendi*). Traced forward each labium minus divides into an outer and an inner portion or limb. The outer parts of the two labia unite over the glans clitoridis to form the **prepuce of the clitoris** (*praeputium clitoridis*) (Fig. 1174). The internal limbs unite at an acute angle beneath the glans clitoridis and are attached to the under surface of the glans to form the **frenulum clitoridis**. The two labia minora are in contact, flanked by the labia majora, and are covered by modified skin,

1173.—The female pudendum or vulva with the labia majora. (Toldt.)

with numerous, sebaceous glands (*glandulae vestibulares minores*), resembling the smooth, moist, pink-colored integument of the inner surface of the labia majora. The cleft between the labia minora is called the **vestibule**, the structures of which are seen only on separating the labia.

The **vestibule** (*vestibulum vaginae*) (Figs. 1157 and 1174) is the cleft between the labia minora, between the glans clitoridis in front and the fourchette behind. On separating the labia minora the following structures in the vestibule are seen: (1) The external urethral orifice and the minute openings, one on each side, of the paraurethral ducts; (2) the vaginal orifice; and (3) the openings of the ducts of the vestibular glands (of Bartholin). The recess between the fourchette and the vaginal orifice is called the **fossa navicularis**.

The **external orifice of the urethra**, or **urinary meatus** (*orificium urethrae externum*) (Figs. 1174 and 1177), is situated immediately in front of the vaginal orifice and about an inch behind the glans clitoridis. The orifice usually presents the appearance of a vertical slit, and is surrounded by a prominent elevation of the mucous membrane. On each side of the urinary meatus there may sometimes be seen the minute orifice of the duct of the paraurethral glands, supposed to be the homologues of the prostate.

1174.—The vulva. External female organs of generation.

The **vaginal opening** is situated behind the urethral orifice, and its appearance varies with the condition of the hymen, a membranous fold which more or less closes the aperture in the virgin.

The **hymen** varies much in shape. Its commonest form is that of a ring, generally broadest posteriorly; sometimes it is represented by a semilunar or crescentic fold, with its concave margin turned toward the pubes. A complete septum stretched across the lower part of the vaginal orifice is called an **imperforate hymen**. Occasionally the hymen is *cribriform*, or its free margin forms a *membranous fringe*, or it may be entirely *absent*. It may persist after copulation, so that it cannot be considered as a test of virginity. After rupture of the hymen the small

rounded nodular elevations known as the **carunculae myrtiformes** (*carunculae hymenales*) are found as the remains of the structure.

The **clitoris** (Figs. 1174, 1175) is an erectile structure which is the morphologic homologue of the penis; unlike the penis, however, it is not traversed by the urethra. It is situated beneath the anterior commissure (or mons Veneris) and is partly hidden between the anterior extremities of the labia minora. It is composed of a body and two crura; the extremity of the body is surmounted by a small glans.

FIG. 1175.—Sagittal section of the lower part of a female trunk, right segment. SM. INT. Small intestine. (Testut.)

The **body of the clitoris**, composed of erectile tissue, is about an inch and a quarter in length (3 cm.), and is bent upon itself so that the angle opens downward. It tapers toward the glans, is enclosed by a dense fibrous coat, and is divided by an incomplete **septum corporum cavernosorum** into two semicylindrical **corpora cavernosa clitoridis**, homologous with the corpora cavernosa of the male. A **suspensory ligament** passes from the pubic symphysis to the fibrous coat of the body of the clitoris. Each corpus cavernosum diverges from its fellow to form the **crus clitoridis**. Each crus is attached to the pubic arch (pubis and ischium) and is covered by the Ischiocavernosus muscle (*m. erector clitoridis*).

The **glans clitoridis** is a minute mass of erectile tissue, surmounting the tapering apex of the body of the clitoris. It is covered by a very sensitive epithelium, and its erectile tissue, like that of the glans penis, is continuous with the erectile tissue

of the bulbus vestibuli, the homologue of the corpus spongiosum of the male. The **præputium clitoridis** and the **frenulum clitoridis** have already been described (p. 1418) as divisions of the labia minora.

Arteries and Nerves of the Clitoris.—The body and the crura of the clitoris derive their blood supply from the **deep artery of the clitoris** (*arteria profunda clitoridis*), a branch of the **internal pudic artery**. Another branch of this artery, the **dorsal artery of the clitoris** (*arteria dorsalis clitoridis*) supplies the glans. The nerve supply is derived from the **dorsal nerve of the clitoris**, from the internal pudic, and from the **hypogastric sympathetic plexus**.

The **vaginal bulb** (*bulbus vestibuli*) (Fig. 1177) may be regarded as the homologue of the bulb portions of the corpus spongiosum of the male. The principal morphological difference lies in the fact that the two halves are fused in the male, but remain separated in the female. The bulbus vestibuli consists of a mass of minute convoluted bloodvessels, of such plexiform arrangement as to be often called **erectile tissue**, arranged in two halves on either side of the vaginal and urethral orifices. Each half is thicker or more massive posteriorly, while anteriorly it is attenuated and joins its fellow of the opposite side to form the **pars intermedia**, continuous with the erectile tissue of the **glans clitoridis**. Each half of the bulbus vestibuli rests against the lateral wall of the vagina and lies superficial to the triangular ligament. Externally and inferiorly it is covered by the **Bulbocavernosus muscle**.

Arteries and Nerves of the Bulbus Vestibuli.—The blood is supplied by the **artery to the bulb** (*arteria bulbi vestibuli*), a branch of the **internal pudic artery**. The nerve supply is by branches of the **hypogastric sympathetic plexus**.

The Glands of Bartholin (*glandula vestibularis major* [*Bartholini*]) (Fig. 1177).—On each side of the posterior part of the commencement of the vagina is a round or oblong body, of a reddish-yellow color, and of the size of a horse-bean, analogous to Cowper's gland in the male. It is called the **gland of Bartholin**, the **gland of Duverney**, the **vulvovaginal gland**, or the **suburethral gland**. Bartholin's gland lies partly in the inferior or anterior leaf of the triangular ligament. The posterior portion of the bulbus vestibuli and the Bulbocavernosus muscle partly cover it. Each gland opens by means of a long single duct immediately external to the hymen, in the angle or groove between it and the nymphæ (Fig. 1176).

DEVELOPMENT OF THE URINARY AND GENERATIVE ORGANS.

The permanent organs of the adult are preceded by a set of purely embryonic structures which, with the exception of their ducts, almost entirely disappear before birth. These embryonic structures, all developed from the intermediate cell mass of mesodermal tissue, are on either side; the pronephros, the mesonephros, the Wolffian (mesonephric) duct, and the Müllerian duct (oviduct). The pronephros disappears very early; the structural elements of the mesonephros mostly atrophy, but in their place is developed the genital gland, in association with which the mesonephric duct remains as the duct of the male genital gland, the oviduct as that of the female.

The **pronephros** is an early embryonic structure in all vertebrates. It develops at about the level of the heart by a proliferation of the mesodermal cells of the intermediate cell mass. In it appear (a) a longitudinal cord of cells, which later acquires a lumen to form the **pronephric duct**; (b) two transverse **pronephric tubules** develop as invaginations of the coelomic mesothelium. Of these, the cephalic one acquires a lumen and opens into the coelomic cavity; the other remains a solid cord of cells. Neither tubule becomes connected with the pronephric duct. The pronephric duct remains to become the Wolffian duct of the next stage, while the tubules are represented, in the adult, by the hydatids at the fimbriated end of the Fallopian tube in the female, and by the stalked hydatid at the upper end of the testis in the male.

The Mesonephros, Müllerian Duct, and Genital Gland.—On the inner side of the Wolffian duct a series of tubules, the *Wolffian tubules*, are developed. Each tubule opens laterally into the duct, while its opposite end is invaginated by a tuft of capillary bloodvessels to form a glom-

erulus. These tubules increase in number, and collectively constitute the **mesonephros** or **Wolffian body** (Figs. 1178, 1179). At the beginning of the second month this body forms an elongated spindle-shaped structure, which projects into the coelomic cavity at the side of the dorsal mesentery, and reaches from the septum transversum cephalad to the fifth lumbar somite caudad. The Wolffian body persists and forms the permanent kidney in fishes and amphibians, but in

FIG. 1178.—Section of the urogenital area of a chick embryo of the fourth day. (Waldeyer.)

reptiles, birds, and mammals it is superseded by the **metanephros**, which forms the permanent kidney in these animals. The anterior tubules of the Wolffian body become attached to the sexual eminence or **genital ridge**, from which the ovary in the female and the testicle in the male are developed. During the development of the permanent kidneys the Wolffian bodies atrophy, and this process proceeds to a much greater extent in the female than in the male.

FIG. 1179.—Enlarged view from the front of the left Wolffian body before the establishment of the distinction of sex. *a, a, b, d.* Tubular structure of the Wolffian body. *e.* Wolffian duct. *f.* Its upper extremity. *g.* Its termination in *x*, the urogenital sinus. *h.* The duct of Müller. *i.* Its upper, funnel-shaped extremity. *k.* Its lower end, terminating in the urogenital sinus. *l.* The mass of blastema for the reproductive organ, ovary, or testicle. (From Furrer, after Kobelt.)

FIG. 1180.—Urogenital sinus of female human embryo of eight and a half to nine weeks old.

In the **male** the Wolffian duct persists, and forms the tube of the epididymis, the vas deferens, and common ejaculatory duct, while the seminal vesicle arises as a lateral diverticulum from its caudal end. The cephalic Wolffian tubules form the rete testis, vasa efferentia, and con vasculosi of the testis; while the caudal tubules atrophy or are represented by the occasional vasa aberrantia of the globus minor and by the paradidymis.

In the **female**, the Wolffian bodies and ducts atrophy. The remains of the Wolffian tubules are represented by the epoöphoron and the paroöphoron (p. 1409), while the cephalic portion of the Wolffian duct sometimes persists as the functionless duct of Gärtner (Fig. 1164).

The Müllerian Ducts.—Shortly after the formation of the Wolffian ducts a second pair of ducts is developed. These are named the **Müllerian ducts**. Each arises on the outer aspect of the corresponding Wolffian body as a tubular invagination of the cells lining the coelom (Fig. 1177). The orifice of the invagination remains patent, and undergoes enlargement and modification to form the abdominal ostium of the Fallopian tube. The ducts pass backward on the outer aspects of the Wolffian bodies, but toward the posterior end of the embryo they cross to the inner side of the Wolffian ducts, and thus come to lie side by side between and behind the latter—the four ducts forming what is termed the *genital cord* (Fig. 1180).

Ultimately, the Müllerian ducts open into the ventral part of the cloaca between the orifices of the Wolffian ducts, and terminate on an elevation named the *Müllerian eminence* (Fig. 1180).

In the male the Müllerian ducts atrophy, but traces of their anterior ends are represented by the sessile hydatids of the epididymis, while their terminal fused portions form the uterus masculinus or sinus pularis in the floor of the prostatic portion of the urethra (Fig. 1183).

In the female, the Müllerian ducts persist and undergo further development. The portions which lie in the genital cord fuse to form the uterus and vagina; the parts in front of this cord remain separate, and each forms the corresponding Fallopian tube—the abdominal ostium of which is developed from the anterior extremity of the original tubular invagination from the coelom (Fig. 1182). The fusion of the Müllerian ducts begins in the third month, and the septum formed by their fused mesal walls disappears from below upward, and thus the cavities of the vagina and uterus are produced. About the fifth month an annular constriction marks the position of the neck of the uterus, and after the sixth month the walls of the uterus begin to thicken. The development of the vagina in the manner just described would necessitate the growth of a septum between it and the urethra; but Wood-Jones maintains that no such septum exists, and that “the vagina is, for a great part of fetal life, a solid rod, and not an open canal at all.” He says: “Early in the history of the embryo the Müllerian ducts open into the urogenital sinus at its upper part; late in its history they open at the hind-end of the vagina, and for a considerable interval they have no opening at all—the old one being lost and the new one not yet formed. No septal division is employed in this change; but as the hindgut, when its cloacal opening is lost, reestablishes communication with the exterior by a new downgrowth, so the Müllerian ducts, when their cloacal opening becomes obliterated, tunnel a new passage to the hind end.”

Genital Gland.—The first appearance of the genital gland is essentially the same in the two sexes, and consists in a thickening of the epithelial layer which lines the peritoneal or body cavity on the inner side of the Wolffian ridge. Beneath the thickened epithelium an increase in the mesoderm takes place, forming a distinct projection. This is termed the *genital ridge* (Fig. 1118), and from it the testis in the male and the ovary in the female are developed. At first the Wolffian body and genital ridge are suspended by a common mesentery, but as the embryo grows the genital ridge gradually becomes pinched off from the Wolffian body, with which it is at first continuous, though it still remains connected to the remnant of this body by a fold of peritoneum, the *mesorchium* or *mesovarium* (Fig. 1184). About the seventh week the distinction of sex in the genital ridge begins to be perceptible.

The **ovary**, thus formed from the genital ridge, consists of a central part of connective tissue covered by a layer of epithelium, the *germinal epithelium*. Between the cells of the germinal epithelium a number of larger cells, the *primitive ova*, are found, and these are carried into the subjacent stroma by bud-like ingrowths of the germinal epithelium, the cells of which surround the primitive ova; in this manner the primitive Graafian follicles are formed. The rest of the germinal epithelium on the surface of the ovary forms the permanent epithelial covering of this organ (Fig. 1185). According to Beard, the primitive ova are early set apart during the segmentation of the ovum and migrate into the germinal ridge.

Waldeyer taught, and for many years his views have been accepted, that the primitive germ cells are derived from the “germinal epithelium” covering the genital ridge. Beard,¹ on the

FIG. 1184.—Transverse section of human embryo of eight and a half to nine weeks old. (From model by Keibel.)

¹ Journal of Anatomy and Physiology, vol. xxxviii.

other hand, maintains that in the skate they are not derived from this epithelium, but are probably formed during the later stages of cell cleavage, before there is any trace of an embryo; and a similar view was advanced by Nussbaum as to their origin in amphibia. Beard says: "At the close of segmentation many of the future germ cells lie in the segmentation cavity just beneath the site of the future embryo, and there is no doubt they subsequently wander into it." The germ cells, "after they enter the resting phase, are sharply marked off from the cells of the embryo by entire absence of mitoses among them." They can be further recognized by their irregular form and amoeboid processes, and by the fact that their cytoplasm has no affinity for ordinary stains, but assumes a brownish tinge when treated by osmic acid. The path along which they travel into the embryo is a very definite one—viz., "from the yolk sac upward between the splanchnopleure and gut in the hinder portion of the embryo." This pathway, named by Beard the *germinal path*, "leads them directly to the position which they ought finally to take up in the 'germinal ridge.'" A considerable number apparently never reach their proper destination, since "vagrant germ cells are found in all sorts of places, but more particularly on the mesentery." Some of these may possibly find their way into the germinal ridge; some probably undergo atrophy, while others may persist and become the seat of dermoid tumors.

FIG. 1185. —Section of the ovary of a newly born child. (Waldeyer.)

The **testis** is developed in a very similar way to the ovary. Like the ovary, in its earliest stages it consists of a central mass of connective tissue covered by germinal epithelium, among which larger cells, the *primitive sperm cells*, are seen. These are carried into the subjacent stroma by tubes of germinal epithelium, which form the lining of the seminiferous tubules, while the primitive sperm cells form the spermatogonia. The seminiferous tubules become connected with outgrowths from the Wolffian body, which, as before mentioned, form the rete testis and vasa efferentia.

Descent of the Testes.—The testes, at an early period of fetal life, are placed at the back part of the abdominal cavity, behind the peritoneum and a little below the kidneys; their anterior surfaces and sides are invested by peritoneum. About the third month of intrauterine life a peculiar structure, the **gubernaculum testis**, makes its appearance. This is at first a slender band, extending from that part of the skin of the groin which afterward forms the scrotum through the inguinal canal to the body and epididymis of the testis, and is then continued upward in front of the kidney toward the Diaphragm. As development advances, the peritoneum covering the testis encloses it and forms a mesentery, the *mesorchium*, which encloses also the gubernaculum and forms two folds, one above the testis and the other below it. The one above the testis is the *plica vascularis*, and contains ultimately the spermatic vessels; the one below, the *plica gubernatrix*, contains the lower part of the gubernaculum, which has now grown into a thick cord; it terminates below at the internal ring in a tube of peritoneum, the *processus vaginalis*, which protrudes itself down the inguinal canal. The lower part of the gubernaculum by the fifth month has become a thick cord, while the upper part has disappeared. The lower part can now be seen to consist of a central core of unstripped muscle fibre, and outside this of a firm layer of striped elements, connected, behind the peritoneum, with the abdominal wall. As the scrotum develops, the main portion of the lower end of the gubernaculum is carried with the skin to which it is attached to the bottom of this pouch; other bands are carried to the inner side of the thigh and to the perineum. The fold of peritoneum, constituting the *processus vaginalis*, projects itself downward into the inguinal canal, and emerges at the external abdominal ring,

pushing before it a part of the Internal oblique and the aponeurosis of the External oblique, which form, respectively, the Cremaster muscle and the external spermatic fascia. It forms a gradually elongating pouch or *cul-de-sac*, which eventually reaches the bottom of the scrotum, and behind this the testis is drawn by the growth of the body of the fetus, for the gubernaculum does not grow commensurately with the growth of other parts, and therefore the testis, being attached by the gubernaculum to the bottom of the scrotum, is prevented from rising as the body grows, and is drawn first into the inguinal canal and eventually into the scrotum. It seems certain also that the gubernacular cord becomes shortened as development proceeds, and this assists in causing the testis to reach the bottom of the scrotum. By the eighth month the testis has reached the scrotum, preceded by the lengthened pouch of peritoneum, the processus vaginalis, which communicates by its upper extremity with the peritoneal cavity. Just before birth the upper part of the pouch usually becomes closed, and this obliteration extends gradually downward to within a short distance of the testis. The process of peritoneum surrounding the testis is now entirely cut off from the general peritoneal cavity and constitutes the *tunica vaginalis*.¹

In the *female* there is also a gubernaculum, which effects a considerable change in the position of the ovary, though not so extensive a change as in that of the testis in the male. The gubernaculum in the female, as it lies on either side in contact with the fundus of the uterus, contracts adhesions to this organ, and thus the ovary is prevented from descending below this level. The

FIG. 1186.—Tail end of human embryo of twenty-five to twenty-nine days old. (From model by Keibel.)

FIG. 1187.—Tail end of human embryo of thirty-two to thirty-three days old. (From model by Keibel.)

upper part of the gubernaculum, *i. e.*, the part between the ovary and the uterus, becomes ultimately the rounded ligament of the ovary, while the lower part, *i. e.*, the part between the attachment of the cord to the uterus and its termination in the labius majum, ultimately forms the round ligament of the uterus. A pouch of peritoneum accompanies it along the inguinal canal, analogous to the processus vaginalis in the male; it is called the *canal of Nuck*. In rare cases the gubernaculum may fail to contract adhesions to the uterus, and then the ovary descends through the inguinal canal into the labium majum, extending down the canal of Nuck, and under these circumstances its position resembles that of the testis in the male.

The Metanephros or Permanent Kidney.—The rudiments of the permanent kidneys make their appearance about the end of the first or beginning of the second month. Each arises as a diverticulum from the hind end of the Wolffian duct, close to where the latter opens into the cloaca (Figs. 1186, 1187). This diverticulum grows upward and forward into the posterior part of the intermediate cell mass, where its blind or anterior extremity becomes dilated and subsequently divides into several buds, which form the rudiments of the pelvis and calyces of the ureter. By further subdivisions it gives rise to the collecting tubules of the kidney. The secretory tubules are developed from condensations of the nephrogenic tissue. At first these are spherical masses of cells which become hollowed, forming the *renal vesicles*. These become elongated and S-shaped; one end of the S-shaped tube becomes continuous with the lumen of a renal diverticular branch, the other end becomes cup-shaped and then spherical, being invaginated by a tuft of capillaries derived from the renal artery to form a glomerulus. The intervening portions of the tube become convoluted and looped to form the uriniferous tubule. The mesoderm around the subdivisions of the diverticulum becomes condensed to form the connective tissue and vessels of the kidney. The diverticulum is elongated to form the ureter, the posterior extremity of which opens at first into the hind end of the Wolffian duct; after the sixth week it separates from the Wolffian duct, and opens independently into the part of the

¹ The obliteration of the process of peritoneum which accompanies the cord, and is hence called the *funicular process*, is often incomplete.

cloaca which ultimately becomes the bladder (Fig. 1126). The manner in which this separation is brought about is not fully known.¹

The secretory tubules of the kidney become arranged into pyramidal masses or lobules, and the lobulated condition of the kidneys exists for some time after birth, while traces of it may be found even in the adult. The kidney of the ox and many other animals remains lobulated throughout life.

The Urethra.—In the female the urethra is formed from the upper part of the urogenital sinus—viz., that part which lies above the openings of the Wolffian and Müllerian ducts. The portion of the sinus below these openings becomes gradually shortened, and it is ultimately opened out to form the vestibule, and in this manner the urethra and vagina come to open separately on the surface. Wood-Jones regards the female urethra as “the cloacal remnant in its simplest form,” and points out that “it does not remain tubular throughout fetal life, but is for a time obliterated more or less completely by the proliferation of the vaginal bulbs.” Developmentally considered, the male urethra consists of two parts—(1) the prostatic and membranous portions, which are derived from the urogenital sinus, and correspond to the whole of the female urethra; (2) the penile portion, which is formed by the fusion of the inner genital folds.

The **prostate gland** originally consists of two separate portions, each of which arises as a series of diverticular buds from the epithelial lining of the urogenital sinus, between the third and fourth months. These buds become tubular, and form the glandular substance of the two

lobes, which ultimately meet and fuse behind the urethra and also extend on to its ventral aspect. The third or middle lobe is formed as an extension of the lateral lobes between the common ejaculatory ducts and the bladder. *Skene's ducts* in the female urethra are regarded as the homologues of the prostatic glands.

The *glands of Cowper* in the male, and of Bartholin in the female, also arise as diverticula from the epithelial lining of the urogenital sinus.

The Urinary Bladder.—The trigone of the bladder is formed from the upper part of the urogenital sinus; the remainder of the viscus is developed from the part of the cloaca which lies above the sinus (Fig. 1187). The bladder is at first tubular in shape, its canal being continuous with that of the allantois, but after the second month its cavity expands to form a sac, from the summit of which the tube of the allantois extends to

FIG. 1188.—Tail end of human embryo, from eight and a half to nine weeks old. (From model by Keibel.)

the umbilicus; this tube undergoes obliteration to form the fibrous cord of the urachus. In some cases the allantoic canal remains patent, and urine may escape by it at the umbilicus. If the urethra be looked upon as the remnant of the cloaca, then the bladder, with the exception of the trigone, must be regarded as being developed by a dilatation of the proximal part of the allantois.

The **external organs of generation** (Fig. 1189), like the internal, pass during development through an indifferent stage in which there is no distinction of sex. It is therefore necessary to describe this stage, and then follow the development of the female and male organs, respectively.

The cloacal membrane, which is composed of ectoderm and entoderm, originally extends from the umbilicus to the tail. The mesoderm around the cloacal chamber gradually extends between the layers of the membrane, stopping short, however, around the margins of the entodermal cloaca, so that the bilaminar cloacal membrane is limited to this part. About the fifth week a prominence, the *genital tubercle*, arises in front of the cloacal membrane, while at the sides the edges of the mesoderm are elevated to form the *labioscrotal* or *outer genital folds*.

Along the under surface of the genital tubercle the ectoderm is thickened, and at the apex of the tubercle projects forward as an epithelial horn. In this ectodermal thickening a longitudinal

¹ The separation of the uterus from the Wolffian duct may be brought about by the absorption of the hinder end of the latter into the genitourinary chamber, and by the growth of the wall of this chamber between the openings. Robinson (Proceedings of the Anatomical Society of Great Britain and Ireland, May, 1903, p. 63) states, regarding an embryo of about seven weeks, that “from the posterior or lower opening of the Wolffian duct a grooved ridge, the *Wolffian ledge*, runs caudally on the wall of the genitourinary chamber and gradually disappears at the junction of the Wolffian angle with the body of the chamber. The lateral margins of the groove are continuous anteriorly with the lateral margins of the Wolffian duct, and apparently fuse together to form the ventral wall of the lower part of the duct. Obviously, if the lateral margins of the groove were to fuse from before backward, the aperture of the Wolffian duct would be carried farther backward in the chamber, and its distance from the opening of the ureter increased.”

groove, the genital groove, appears, and into its lips the mesoderm extends to form the *inner genital folds*. After the rupture of the cloacal membrane this groove becomes continuous with the urogenital sinus. With the formation of these parts the *indifferent stage* of the external genital organs is reached.

In the *female* this stage is largely retained; the lower part of the urogenital sinus persists as the vestibule, the genital tubercle forms the clitoris, the labioscrotal folds the labia majora, and the inner genital folds the labia minora.

FIG. 1189.—Stages in the development of the external sexual organs in the male and female. (Drawn from the Ecker-Ziegler models.)

In the *male* the changes are greater on account of the development of the penile portion of the urethra. The genital tubercle enlarges to form the corpora cavernosa and glans penis. The lips of the inner genital folds meet and fuse from behind forward to form the penile urethra, the bulb, and the corpus spongiosum. The part of the urethral groove on the glans penis is closed independently, and the last part of the urethral tube to be completed is that at the junction of the glans and body of the penis. If the lips of the groove fail to close, the condition known as *hypospadias* results.

The labioscrotal folds meet and unite in the middle line to form the scrotum, their line of union being indicated by the median raphé.

The *prepuce* is formed by the growth of a solid plate of ectoderm into the superficial part of the genital tubercle; on coronal section this plate presents the shape of a horseshoe. By the breaking-down of its more centrally situated cells this plate is split into two lamellæ and a cutaneous fold, the prepuce,¹ is liberated and forms a hood over the glans. "Adherent prepuce is not an adhesion really, but a hindered central desquamation" (Berry Hart, *op. cit.*).

The homologies of the different parts of the sexual organs may be stated in tabular form as follows:

INDIFFERENT STAGE.	MALE.	FEMALE.
Genital Ridge. .	Testis.	Ovary.
Wolffian body. .	Rete testis, vasa efferentia, coni vasculosi, paradidymis.	Epoöphoron or organ of Rosenmüller. Paroöphoron.
Wolffian duct. .	Canal of epididymis, vas deferens, common ejaculatory duct. Seminal vesicle.	Hydatid of Morgagni. (Duct of Gärtner.)
Müllerian ducts. .	Sessile hydatids of epididymis. Uterus masculinus.	Fallopian tubes, uterus, vagina.
Genital tubercle. .	Corpora cavernosa and glans penis.	Clitoris.
Urogenital sinus. .	Prostatic and membranous parts of urethra.	Urethra. Vestibule.
Inner genital folds	Penile urethra, bulb, and corpus spongiosum.	Labia minora.
Labioscrotal folds	Scrotum.	Labia majora.

THE MAMMARY GLAND (MAMMA) (Figs. 1191, 1193).

The **breasts**, **mammary glands** or **mammæ**, secrete the milk, and are accessory glands to the organs of reproduction. They develop fully in the female, but usually remain rudimentary in the male. There are two of these glands, and they are situated in the superficial fascia of the anterior portion of the thorax.

Description of a Well-developed Breast.—Each gland appears as a hemispherical body projecting from the front of the thorax beneath the skin and lying over a portion of the Pectoralis major muscle and a smaller portion of the Serratus magnus muscle. The hemispherical projection extends usually from the margin of the sternum to the axilla and from the level of the second rib to the level of the sixth rib, or from the third rib to the seventh rib, but this does not represent the real size of the gland. The gland is much larger than this, being rendered so by tails or prolongations of breast tissue, which will be described later (p. 1432).

The **nipple** (*papilla mammae*) (Figs. 1190 and 1193) projects from a little below and to the median side of the summit of the hemisphere at or above the level of the fifth rib, and is covered with thin skin. The right nipple may not exactly correspond in situation and direction to the left nipple. The nipple varies considerably in height and shape. In the virgin it is usually cylindrical and is directed forward and slightly upward and outward. The apex of the

¹ Spicer (Journal of Anatomy and Physiology, vol. xliii, 1909) describes the prepuce as arising in the form of an annular hood of mesoblastic tissue which proceeds forward *within the substance of the surrounding epithelium*. "The main portion of this hood springs from mesoblastic tissue considerably posterior to the cervix glandis, is in the form of a crescentic swelling, or collar, and this creeps forward, burrowing always in the epithelial layers, bridging over the groove of the cervix which is filled with epidermal cells, and finally overlaps the body of the glans. This hood is the prepuce."

"The epidermis covering the glans thus becomes divided into two layers—an outer, which forms the superficial covering of the prepuce, and an inner, which remains as a more or less solid layer between the prepuce and the glans until after birth. From it is differentiated a basal layer of cubical or cylindrical epithelium to line the inner aspect of the prepuce, and another to cover the surface of the glans, while central desquamation ensues later and prepares the way for a movable prepuce."

nipple is rendered rough by fissures (Fig. 1190), it exhibits a depression in which are the openings of the milk ducts (Fig. 1192), and its circumference is thrown into concentric ridges (Fig. 1192). The nipple is surrounded by a darker circular wrinkled area, the **areola** (*areola mammae*) (Figs. 1190 and 1191), which contains sweat glands and on which are twelve or fifteen small rounded elevations. These elevations are caused by cutaneous sebaceous glands which in structure represent a transition between sebaceous and mammary glands. They are probably rudimentary portions of the mammary gland and are known as the **glands of Montgomery** (*glandulae areolares*) (Fig. 1192). The color of the nipple and areola varies with the complexion of the individual. In brunettes it is darker than in blondes. The usual color of the nipple in a young woman is rosy-pink, the areola being of a darker shade. During the early months of pregnancy the nipple and areola become dark brown in color, the areola becomes larger in circumference, and the glands of Montgomery increase in size (Fig. 1193). The nipple contains nonstriated muscle, and mechanical irritation or sexual excitement makes it stiff and erect. The skin covering the breast is clear, soft, and delicate, and subcutaneous veins are often visible. The skin of the nipple and areola is particularly delicate.

FIG. 1190.—Dissection of the lower half of the female breast during the period of lactation. (From Luschka.)

Variations in the Mammary.—Before puberty the glands are small, are of the infantile type, grow slowly, and differ but slightly from the male organs. The nipple is small, flat, and pale. At puberty the increase in the size of the breast is rapid and considerable, due to growth of gland tissue and of subcutaneous fat. In the young virgin the breasts are of hemispherical form and of firm consistency. During pregnancy the breasts enlarge greatly and remain very large throughout lactation. This enlargement is due to new gland tissue and increased vascularity. Numerous blue veins are visible in the skin, the areola darkens, and the glands of Montgomery enlarge (Fig. 1193). After the termination of lactation the breasts diminish in size. They do not become as small as the virgin breast, are apt to lose their hemispherical outlines, and become soft and

flabby. They droop as flaccid pendulous masses, the subcutaneous fat is largely gone, and the outlines of the lobular breast tissue can be seen and felt. The nipple is long and hangs down like a teat. At the menopause the breast usually shrinks. In some cases, however, it actually increases in size. In such a case, although the gland atrophies, there is an extensive deposit of fat. In old age the glands undergo atrophy and largely disappear, the skin is flabby and thrown into wrinkles, and the breasts contain very little glandular structure, and are hard from the presence of fibrous tissue. The nipples become pigmented and corrugated. Women vary greatly in the development of the breasts. In some women they are large, firm, and well proportioned; in others they are small, flat, or atrophy occurs in the course of certain bodily diseases, as in phthisis, and in certain mental diseases, as melancholia. If the ovaries are ill-developed the breasts remain flat and small. The outline and direction of the breast and also of the nipple may be altered by corsets. The left mamma is usually somewhat larger than the right.

One gland or both glands may be entirely absent, the nipple being also absent. One or both glands may be absent, one or both nipples being present. When there is only one nipple, it is apt to be the left. The term **polymastia** (*mammæ accessorie muliebri*) means the presence of supernumerary breasts, with or without nipples. **Polythelia** means the presence of supernumerary nipples, the associated glandular structure being rudimentary. There may be one, two, or several supernumerary breasts, and when more than one exists, are usually asymmetrical. If one is functionally active, it enlarges during pregnancy and furnishes milk.

Supernumerary mammæ may secrete milk or may be without function. The most common situation is on the part of the chest below and to the inner side of the normally placed gland. They may also exist in the axilla, the abdomen, the groin, the back and the thigh. Many cases of supposed supernumerary glands have been really instances in which moles, warts, or sebaceous cysts have been mistaken for nipples, but some cases are undoubted.

Prolongations of Mammary Tissue.—As previously stated, the outlines of the breast are not regular, but here and there tails, prolongations, or cusps come off from and are true portions of the gland. Two or even more prolongations pass to the edge of the sternum; others pass toward the axilla, the clavicle, and the origin of the External oblique muscle from the ribs. Underneath the mammary gland prolongations of mammary tissue penetrate the pectoral fascia (Heidenhain). If one of the glandular cusps is of considerable size it is called an **outlying lobule**.

Structure of Mammary Gland and Nipple (Figs. 1190 and 1191).—The glands of the breast (*corpus mammæ*) rest by a smooth posterior surface upon the loose pectoral fascia, which fastens the breast to the muscle beneath, but so loosely that the breast is movable. The mamma consists of gland tissue; of fibrous tissue, connecting its lobes, of fatty tissue in the intervals between the lobes, of retinacula, and of skin. The gland tissue, when freed from fibrous tissue and fat, is of a pale reddish color, firm in texture, generally globular in form, with prolongations here and there, flattened from before backward, thicker in the centre than at the circumference, and presenting several inequalities on its surface, especially in front. On the anterior surface there are many irregular elevated processes with deep spaces between them. From the summits of the elevations connective-tissue strands (*retinacula cutis*) pass to the true skin. The glandular structure consists of numerous glands divided into lobes (*lobi mammæ*), and these are composed of lobules (*lobuli mammæ*), connected by areolar tissue, which contains the bloodvessels and ducts. The smallest lobules consist of a cluster of rounded **alveoli** (Fig. 1190), which open into the smallest branches of the excretory ducts; these ducts, uniting, form larger ducts, which terminate in single canals. Each canal is called a **lactiferous, galactophorous, or mamillary duct** (*ductus lactiferus*) (Fig. 1190). The alveoli are tubular in form and are lined by low columnar epithelial cells which rest upon a basement membrane.¹ Each glandular area possesses one lactiferous duct. This passes to the apex of the lobe and then into the nipple. The lactiferous ducts are white and cord-like, and contrast with the yellowish-red tissue of the gland itself. The number of excretory ducts varies from fifteen to twenty, each representing an individual gland. They converge toward the areola, beneath which each duct possesses a spindle-shaped

¹ According to Laeroix and Benda, there is a thin layer of nonstriated muscle between the basement membrane and the secreting cell.

dilatation, the **ampulla** (*sinus lactiferans*) (Fig. 1190). The ampullæ serve as reservoirs for the milk. At the base of the nipple the ducts become contracted and pursue a straight course to its summit, perforating it by separate orifices considerably narrower than the ducts themselves. Each orifice (*porus lactiferus*) is the orifice of a tube which drains an individual gland. The ducts are composed of areolar tissue, with longitudinal and transverse elastic fibres and some muscle tissue derived from that of the nipple; their mucous lining is continuous, at the point of the nipple, with the integument. The epithelium of the mammary gland differs according to the state of activity of the organ. In the gland of a woman who is not pregnant or nursing the alveoli are very small, few in number, solid, and filled with a mass of granular polyhedral cells. During pregnancy the alveoli increase in number and enlarge and the cells undergo rapid multiplication. At the commencement of lactation the cells in the centre of an alveolus undergo fatty degeneration, and are eliminated in the first milk as **colostrum corpuscles**. The peripheral cells of the alveolus remain, and form a single layer of granular, short columnar cells lining the limiting *membrana propria*. The single nucleus of each cell divides and forms two.

FIG. 1191.—Right breast in sagittal section, inner surface of outer segment. (Testut.)

In the protoplasm, especially in the end of the cells toward the alveolus, drops of fat appear, and the nucleus toward this end of the cell also becomes fatty.

The end of the cell toward the alveolus breaks down, and the liberated material constitutes "the albuminous ingredients of the milk, while the drops of fat become the milk globules. The portion of the cell which remains forms new cytoplasm, and the same process is repeated over and over again. The cells also secrete water and the salts which are found in the milk."

After lactation a number of the alveoli atrophy and disappear, while the remainder become much reduced in size. The gland then consists mainly of adipose and fibrous tissues.

The **fibrous tissue** (Fig. 1191) invests the entire surface of the breast, and sends down septa between its lobes, which serve to hold them together.

The **fatty tissue** (Figs. 1190 and 1191) surrounds the surface of the gland and occupies the intervals between its lobes. It usually exists in considerable abundance, and determines the form and size of the gland. There is no fat immediately beneath the areola and nipple.

Vessels and Nerves.—The arteries supplying the mammary gland are derived from the perforating branches of the internal mammary, the long thoracic branches of the axillary, and branches from the intercostals. The veins describe an anastomotic circle around the base of the nipple, called by Haller the *circulus venosus*. From this large branches transmit the blood to the circumference of the gland and end in the axillary and internal mammary veins. The lymphatics of the mammary gland (Fig. 562) and mammary region have been previously described (pp. 785 and 807). The nerves are derived from the fourth, fifth, and sixth intercostal nerves, and sympathetic filaments from the thoracic cord pass to the breast along the branches of the intercostal nerves.

Applied Anatomy.—Occasionally the mammary gland undergoes enormous *hypertrophy*. This may occur in any age, even in the virgin. The physiological enlargement of puberty may become excessive or the physiological enlargement of pregnancy and lactation may continue and increase after the termination of lactation. The chief elements in the enlargement are fat and connective tissue, and it is doubtful if there is extensive reproduction of glandular tissue.

Abscess of the breast may occur at any age, but is most common by far in nursing women. The portals are opened to infection by a crack in the nipple and bacteria are carried inward by the lymph vessels. In some cases the pus gathers beneath the skin (*supramammary abscess*), in others in the breast tissue (*intramammary abscess*). In rare cases pus gathers beneath the breast (*retromammary abscess*). In intramammary abscess the pus burrows through the fibrous septa or fascia and forms numerous channels, and such a channel is constricted in hour-glass shape at the point where it passes through fascia or a fibrous septum.

FIG. 1192.—Nipple and areola of a virgin. (Testut.)

FIG. 1193.—Nipple and areolæ of a pregnant woman. (Testut.)

In every patient suffering from abscess the nipple should be examined for a sore or crack, and the area when found should be treated antiseptically. A supramammary abscess should be opened by an incision radiating from the nipple.

In intramammary abscess follow the advice of Sheild: Open the abscess by an incision radiating from the nipple, insert the index finger, and when possible pass it to the bottom of the abscess and carry the tip from the depths of the abscess to as near the surface as possible. At this point make a counter opening. The finger breaks down septa which cause constriction and thus converts the tracking sinuses into one large cavity.¹ Drain by tubes.

A retromammary abscess is opened by an incision, following the outline of the breast at the thoracomammary junction, the finger being pushed through the incision and up under the gland.

Tuberculosis of the breast may occur, and if it does, *cold abscess* is apt to form. The best treatment is removal of the gland and the associated lymph nodes.

Chronic mastitis is a condition of mammary fibrosis, most common in neurotic single women, and apt to be associated with ovarian or uterine disease.

Malignant dermatitis or Paget's disease of the nipple is a chronic condition consisting of epithelial proliferation, induration, desquamation, and ulceration, and it is apt to be followed by epithelioma.

Chancre of the nipple is occasionally met with.

Secondary and tertiary syphilitic lesions are seen upon the skin of the breast, the nipple, and the areola.

Cysts and tumors are common in the breast. There may be *cystic degeneration* of the gland in women near the menopause (*involution cysts*); a *lacteal cyst*; a *hydatid cyst*; an *adenoma*

¹ Diseases of the Breast. By A. Marmaduke Sheild.

may become cystic. The nipple may suffer from *epithelioma*, *myoma*, *myxoma*, *angioma*, *papilloma*, or *fibroma*. The innocent tumors of the breast are *fibroadenoma*, *cystic adenoma*, *myxoma*, and *angioma*. The skin of the breast may suffer from any form of growth or cyst which could arise from the skin of another part. Malignant tumors of the glandular structure are ten times as frequent as innocent tumors. *Sarcoma* is rare; *carcinoma* is very common.

Carcinoma of the breast has occupied much of the attention of surgeons during recent years. The old operation was uniformly followed by recurrence. The modern radical operation has been evolved from the studies of Moore, the younger Gross, Heidenhain, Stiles, Banks, Halsted, and others. The modern operation always removes at least the skin and subcutaneous tissue over the hemispherical portion of the breast, the outlying lobules of the breast, the pectoral fascia, and the sternal portion of the great Pectoral muscle, the lymphatic tracts from the breast, the lymphatic nodes and cellular tissue from the axilla, and from beneath the *Latissimus dorsi* muscle. The pectoral fascia and the sternal portion of the great Pectoral muscle must come away in every case, because breast tissue may pass through the fascia. The entire breast must be removed, because even in a recent case the entire breast is regarded as infected. The clavicular portion of the great Pectoral muscle is anatomically distinct from the sternal portion and its removal is not imperative. Some operators remove the lesser Pectoral muscle. To leave it is of no value to the arm, and it frequently causes an annoying rigid band anterior to the axilla. To take it away gives ready access to the axillary vessels at a desirable point above. The sheath of the axillary vein should be removed with the nodes and cellular tissue of the axilla. The nodes receiving lymph from the cancerous area must be removed, of course. In view of the fact that in an undetermined percentage of cases a lymph tract passes direct to the subclavian nodes, it is evident that these nodes may become infected by this route instead of, as is more usual, secondarily to axillary infection; hence it seems wiser in every case to remove the cellular tissue and nodes from the subclavian triangle. All of these structures should be removed as one piece, in order to avoid cutting across lymph tracts and flooding the wound with carcinoma cells which might adhere, grow, and reproduce cancer.

Halsted's operation is the method adopted by most surgeons. The wound cannot be completely closed, and the raw spot is covered at once or later with Thiersch's skin grafts. (For surgical considerations regarding the lymphatics in mammary carcinoma see page 808.)

The **male breast** (*mamma virilis*) is a small, flat structure, consisting chiefly of connective tissue, but containing some branched tubules. Under normal circumstances it remains permanently of the infantile type. It possesses a nipple which is much smaller than that of the female breast, and which usually lies over the fourth intercostal space, but may lie over the fourth or fifth rib. The nipples of the two sides are rarely placed quite symmetrically. Accessory glands and accessory nipples are as common among males as females. The male breast may exhibit some evidence of temporary functional activity at birth and at puberty. Cases have been recorded of actual lactation by the male breast.

Applied Anatomy.—The male breasts may undergo enormous hypertrophy (*gynecomazia*). In these cases the penis is often small and the testicles may be atrophied. The breasts may be absent in the male. Disease of the male breast is not nearly so frequent as disease of the female breast. The organ may be the seat of syphilis, tuberculosis, acute or chronic mastitis, abscess or tumor. A number of cases of cancer of the male breast have been recorded.

THE DUCTLESS GLANDS.

THERE are certain organs, in various situations, which are very similar to secreting glands, but differ from them in one essential feature—viz., they do not possess any ducts by which their secretion is discharged. These organs are known as the **ductless glands**. They are capable of *internal secretion*—that is to say, of forming, from materials brought to them by the blood, substances which have a certain influence upon the nutritive and other changes going on in the body. This secretion is carried into the blood stream, either directly by the veins or indirectly through the medium of the lymphatics.

These glands include the thyroid and the parathyroids, the thymus, the spleen, the suprarenal glands, and the small carotid, coccygeal, and parasympathetic bodies, which will be described in this section. They also include the lymph nodes (or glands) which have already been described on pages 771 to 805; and the epiphysis (pineal gland) and hypophysis (pituitary) described with the brain on pages 907 and 910. Certain isolated cell masses in the pancreas and the testicle, apparently engaged in internal secretion, are described with those organs.

THE THYROID GLAND OR BODY (GLANDULA THYREOIDEA)

(Fig. 1194).

The **thyroid gland** is a highly vascular organ, situated at the front and sides of the neck, and extending upward upon each side of the larynx; it consists of two **lateral lobes** connected across the middle line by a narrow transverse portion, the **isthmus**.

The **weight** of the gland is somewhat variable, but is usually about one ounce. It is somewhat heavier in the female, in whom it becomes enlarged during menstruation and pregnancy.

The **lateral lobes** are conical in shape, the apex of each being directed upward and outward as far as the junction of the middle with the lower third of the thyroid cartilage; the base looks downward, and is on a level with the fifth or sixth tracheal ring. Each lobe is about two inches (5 cm.) in length, its greatest width is about one inch and a quarter (3 cm.), and its thickness about three-quarters (2 cm.) of an inch. The summit of the lateral lobe not unusually is pointed and reaches to the level of the oblique line upon the ala of the thyroid cartilage or even higher. The right lobe is, as a rule, somewhat larger than the left. The lower portion of the gland, when the head is extended, is about one inch above the upper margin of the sternum; when the head is flexed, it is at the level of the upper border of the sternum or even below and behind it.

The **external or superficial surface** is convex, and covered by the skin, the superficial fascia, the deep fascia, the Sternomastoid, the anterior belly of the Omohyoid, the Sternohyoid, and Sternothyroid muscles, and beneath the last-named muscles by the pretracheal layer of the deep fascia, which forms a capsule for the gland (Fig. 299).

The **deep or internal surface** is moulded over the underlying structures—viz., the thyroid and cricoid cartilages, the trachea, the Inferior constrictor and pos-

terior part of the Cricothyroid muscles, the œsophagus (particularly on the left side of the neck), the superior and inferior thyroid arteries, and the recurrent laryngeal nerves.

The deep surface of each lobe is fixed by bands of fibrous tissue passing from the capsule of the isthmus and lateral lobes to the sides of the cricoid cartilage and the posterior fascia of the trachea. These bands are called the **lateral** or

suspensory ligaments. Because of this fixation to the larynx and trachea by the capsule and by the lateral ligaments, the thyroid gland moves with the trachea and ascends during the act of swallowing. The recurrent laryngeal nerve on each side is in contact with the outer and posterior surface of the suspensory ligament.

The **anterior border** is thin, and inclines obliquely from above downward and inward toward the middle line of the neck, while the **posterior border** is thick and overlaps the common carotid artery.

The **isthmus** (*isthmus glandulae thyroidea*) connects the lower two-thirds of the two lateral lobes; it measures about half an inch in breadth and the same in depth, and usually covers the second and third rings of the trachea, but sometimes also the first and fourth rings. Its situation and size present, however, many variations, a point of importance in the operation of tracheotomy. In the middle line of the neck it is covered by the skin and fascia, and close to the middle line, on either side, by the Sternohyoid muscle. Across its upper border run branches of the superior thyroid artery and vein; at its lower border is a branch of the inferior thyroid veins. Sometimes the isthmus is altogether wanting.

The **third, pyramidal or middle lobe** frequently arises from the upper part of the isthmus, or from the adjacent portion of either lobe, but

most commonly from the left lobe, and ascends in front of the thyroid cartilage in the direction of the middle of the hyoid bone. It may reach the bone or may not reach it. If it reaches the bone it is attached to it. If it does not reach the bone, fibrous tissue, which often contains muscle, is prolonged from the tip of the pyramid to the back of the bone or to the thyrohyoid membrane. The pyramid is occasionally quite detached, or divided into two or more parts.

A few muscle bands, derived from the Thyrohyoid muscles, are occasionally found attached, above, to the body of the hyoid bone, and below to the isthmus of the gland or its pyramidal process. These form a muscle, which was named by Soemmerring the *Levator glandulae thyroideae*.

Accessory Thyroids (*glandulae thyroideae accessoriae*).—Frequently small isolated masses of thyroid tissue exist. They are found particularly about the lateral lobes of the thyroid gland in the sides of the neck or just above the hyoid bone, and are called **accessory thyroids**.

Structure of the Thyroid (Fig. 1195).—The thyroid body is invested by a capsule of connective tissue which projects into its substance as a framework and imperfectly divides it into

FIG. 1194.—The thyroid gland. (Spalteholz.)

masses of irregular form and size, known as lobes and lobules. More slender septa separate the secretory alveoli from one another. While the anterior portion of the capsule is thin and easily torn, the posterior portion is thick and dense. When the organ is cut into, it is of a brownish-red color, and is seen to be made up of a number of closed vesicles or alveoli containing a yellow glairy fluid and separated from each other by intermediate connective tissue.

It is a compound tubular gland, each lobule of which consists of a number of short closed tubules or alveoli, which are surrounded by the interstitial reticulum.

According to Baber, who has published some important observations on the minute structure of the thyroid, the vesicles of the thyroid of the adult animal are generally closed cavities; but in some young animals (*e. g.*, young dogs) the vesicles are more or less tubular and branched. This appearance he supposes to be due to the mode of growth of the gland, and merely indicating that an increase in the number of vesicles is taking place. Each vesicle is lined by a single layer of cuboidal epithelial cells which rest upon a delicate basement membrane. Between the tubules exists a delicate reticulum. The vesicles are of various sizes and shapes, and contain as a normal product a viscid, homogeneous, semifluid, slightly yellowish material which frequently contains red corpuscles in various stages of disintegration and decolorization, the yellow tinge being probably due to the hemoglobin, which is thus set free from the colored corpuscles. This normal product is known as **colloid material**, and it is secreted by the epithelium. What part if any the

FIG. 1195.—Minute structure of the thyroid. From a transverse section of the thyroid of a dog. Semi-diagrammatic. (Baber.)

colloid plays in the formation of the internal secretion of the gland is not known. It is quite possible that the colloid corresponds to the external secretion of glands with ducts and that the true internal secretion passes directly into the capillaries which form a network about the alveoli (Szymonowicz), or passes into the lymphatics. In the thyroid gland of the dog, Baber has found large round cells, **parenchymatous cells**, each provided with a single oval-shaped nucleus, which migrate into the interior of the gland vesicles. Between the thyroid vesicles in the human being are collections of **round cells**. They are, in reality, miniature immature vesicles, and are much more numerous in youth than in old age.

The capillary bloodvessels form a dense plexus in the connective tissue around the vesicles, between the epithelium of the vesicles and the endothelium of the lymph spaces, which latter surround a greater or smaller part of the circumference of the vesicles. These lymph spaces empty themselves into lymphatic vessels which run in the interlobular connective tissue, not uncommonly surrounding the arteries which they accompany, and communicate with a network in the capsule of the gland. Small glands may be connected with this network. Baber has found in the lymphatics of the thyroid a viscid material which is morphologically identical with the normal constituent of the vesicle.

Vessels and Nerves.—The **arteries** (Figs. 447 and 499; see also p. 592) supplying the thyroid are the **superior thyroid** from the **external carotid**, and the **inferior thyroid** from the **thyroid axis** of the first part of the subclavian. Sometimes there is an additional vessel, the **thyroidea media** or **ima**, usually arising from the innominate artery, but sometimes from the arch of the aorta or the common carotid. It ascends upon the front of the trachea. The superior thyroid

artery reaches the summit of the upper horn of the gland, and usually at this point gives off a vessel which courses down the posterior surface of the gland. The main trunk passes downward and inward at the junction of the inner and anterior border of the upper horn, giving branches to adjacent structures and sending branches over the anterior surface of the thyroid gland. It reaches the isthmus and crosses the isthmus at its upper border to anastomose with the artery from the other side. The inferior thyroid artery, which is usually larger than the superior, after it has passed posterior to the sheath of the carotid and the sympathetic nerve, reaches the posterior surface of the gland. At this point branches are given off; some pass into the hilum; the others go to the posterior surface of the gland. The relation of the artery to the recurrent laryngeal nerve is very important to the surgeon. "Usually the main trunk of the artery passes behind the nerve; sometimes the artery breaks up before reaching the nerve; in this case one or more of the branches may pass in front of it. Much less commonly the main trunk or all its branches will be found to lie in front of the nerve." If the *thyroidea ima* is present it goes to the lower part of the gland. The larger branches of the thyroid arteries are beneath the capsule and upon the surface of the gland; smaller branches pass to the interior of the gland (Berry). The arteries are remarkable for their large size and frequent anastomoses.

The **thyroid veins** (Figs. 498 and 499; see also p. 718) form a plexus upon the surface of the gland and beneath the capsule. Here and there veins pass through the capsule and go to adjacent venous trunks. Berry, accepting Kocher's description, notes the following veins: The **superior thyroid vein** runs with the superior thyroid artery and passes to the internal jugular vein. A **transverse vein** of the upper border of the isthmus joins the two superior thyroid veins. A single vein, the **middle thyroid**, sometimes emerges from the side of the gland and passes to the internal jugular. Usually, however, instead of this single vein there are two veins, the **superior** and **inferior accessory thyroids**. The **superior accessory thyroid** emerges from the outer side of the upper horn, below the apex, and passes to the internal jugular. The **inferior accessory thyroid** emerges from the posterior and inferior portion of the gland and passes to the internal jugular. The veins from the lower border of the gland vary greatly. A vein passes vertically down on each side in front of the trachea from the isthmus and from the inner side of the inferior horn. It is called by Kocher the **thyroidea ima**. The vein of the left side passes to the left innominate; the vein of the right side passes to the right innominate or left innominate. As Berry points out, the vein of one side may be small or may be absent, or the two veins may unite and form one vein which enters the left innominate. An **inferior thyroid vein** is often present. It is of small size, emerges at the inferior and external part of the gland, and passes to the corresponding innominate vein.¹

The **lymphatics** are numerous and of large size. Collecting trunks arise from a network within the capsule. Some trunks ascend from the upper margin of the isthmus and reach the **node in front of the larynx**; others ascend along the superior thyroid artery and reach the **nodes at the bifurcation of the carotid**. Descending trunks from the lower margin of the isthmus reach the **nodes in front of the trachea**; trunks from the side of the gland descend to the **nodes about the recurrent laryngeal nerve**.²

The **nerves** are derived from the **middle and inferior cervical ganglia of the sympathetic**, and from the **inferior laryngeal nerves**. Probably there is also a branch from each **superior laryngeal nerve**.

Applied Anatomy.—The thyroid gland may be congenitally absent, and when it is the individual suffers from the worst form of *cretinism*. One lobe may be congenitally absent, but this will provoke no trouble unless the other lobe undergoes atrophy.

Complete removal of the thyroid and parathyroids will produce operative *myxedema* (*cachexia strumipriva*), unless accessory thyroids enlarge and perform the functions of the thyroid.

The thyroid gland may be congenitally enlarged. The gland tends to atrophy in old age. It is atrophied in myxedema and cretinism. Some forms of thyroid enlargement are called *goitre*.

When all parts of the gland enlarge the condition is known as *parenchymatous goitre*.

Adenomatous goitre consists of an adenoma or of adenomata. In *cystic goitre* there are one or more cysts due to cystic degeneration of adenomata or to fusion of adjacent tubules.

A *pulsating goitre* is one which receives impulses from the carotid pulsations. In a *fibroid goitre* there is increase of interstitial connective tissue. A goitre which passes back of the sternum is known as *substernal* or *intrathoracic*. A goitre may extend back of the trachea or back of the oesophagus.

Exophthalmic goitre, Graves' disease or Basedow's disease, is a remarkable disease. Its three chief symptoms are enlargement of the thyroid, or *goitre*; prominence of the eyeballs, or *exophthalmos* (see p. 372); and very rapid pulse, or *tachycardia*. Dyspnea, tremor, and various other symptoms are usually found. The thyroid gland may be the seat of a *carcinoma* or *sarcoma* (*malignant goitre*), *syphilitic* or *tuberculous* disease, ordinary *inflammation*, *suppuration*, or

¹ Diseases of the Thyroid Gland. By James Berry.

² Ibid.

³ The Lymphatics. By Poirier, Cunéo, and Delanere. Translated and edited by Cecil H. Leaf.

hydatid disease. For the relief of ordinary goitre various methods have been employed. Tapping, injection of astringents, simple incision, and the seton are obsolete. Ligation of the thyroid arteries is rarely performed as a curative measure. The superior and inferior thyroids of one side have been tied in some cases; all four thyroids in other cases. Jaboulay has performed *exothyropexy*. In this operation the gland is dislocated from its bed, brought out of the wound, and left exposed, in hope that it will atrophy.

Division of the isthmus is occasionally practised to relieve dyspnea. The operation sometimes succeeds, but often fails.

Extirpation of one-half or two-thirds of the gland is a very successful operation. Removal of the entire gland will be followed by operative myxedema. Removal or injury of the parathyroids causes tetany.

In *extirpating* a lobe of the thyroid by the method until recently in vogue, great care must be taken to avoid tearing the capsules, as if this happens the gland tissue bleeds profusely. The thyroid arteries should be ligated on the diseased side before an attempt is made to remove the mass, and in ligating the inferior thyroid the position of the recurrent laryngeal nerve must be borne in mind, so as not to include it in the ligation. In order to preserve the parathyroids from injury, C. H. Mayo recommends that after the vessels entering and leaving the thyroid have been double clamped and divided, the entire lobe should be elevated, the capsule split along the side of the gland and pushed back with gauze, and the gland lifted and removed without disturbing the posterior portion of the capsule. As pointed out before, the posterior portion of the capsule is so thick and strong that it is easier to leave it *in situ* than to bring it out of the wound with the gland.

A cystic or solid tumor of the thyroid may be removed by *intraglandular enucleation*. If operation becomes necessary in exophthalmic goitre, partial extirpation is usually preferred. Bilateral extirpation of the cervical ganglia of the sympathetic (*sympathectomy* or *Jonnesco's operation*) has been practised by some surgeons for exophthalmic goitre. The value of the procedure is uncertain.

THE PARATHYROID GLANDS (Fig. 1196).

The **parathyroid glands** are small, brownish-red bodies, situated near the thyroid gland, but differing from it in structure, being composed of masses of cells arranged in a more or less reticular fashion with numerous intervening bloodvessels. They measure on an average about a quarter of an inch (6 mm.) in length, and from an eighth to a sixth of an inch (3 to 4 mm.) in breadth, and usually present the appearance of flat oval disks. They are classified according to their position into *superior* and *inferior*. The superior, usually two in number, are the more constant in position, and are situated, one on either side, at the level of the lower border of the cricoid cartilage, behind the junction of the pharynx and œsophagus, and in front of the prevertebral fascia. The inferior, also usually two in number, may be applied to the lower edge of the lateral lobe, or may be placed at some little distance below the thyroid body, or may be found in relation with one of the inferior thyroid veins. Although there are usually four parathyroids, there may be but three, or there may be six or even eight. Parathyroid tissue may exist within the thyroid gland even when the superior parathyroids are present. Accessory parathyroids may be found over a wide area. Rogers and Fergusson found one in the middle of the posterior portion of the pharynx. Ogle found a gland in the thorax which was partly parathyroid.

FIG. 1196.—The position of the parathyroid glands. Viewed from behind. (Zuckerkindl.)

Structure.—The structure of the parathyroids is different from that of the thyroid. They are composed of groups of epithelial cells arranged in a chain-like fashion with numerous intervening capillaries. There is a certain type of cell, but the form varies. These variations result from changes due to episodes of rest and activity (Verébely). MacCallum's studies seem to lead to the same conclusion. Thompson¹ states that he finds only one type of cell in the infant gland, and that in the adult there is primarily but one type of cell, the other cells noted being modifications of the principal cell due to degeneration or hyperfunction. There is much lymphoid tissue in the interstitial connective tissue. The capillaries are of the sinusoidal variety. The nerves of the parathyroids are derived from the sympathetic system. Each parathyroid gland is supplied by a parathyroid artery. The inferior parathyroid artery is always a branch of the inferior thyroid artery or of the anastomosing channel between the superior and inferior thyroid arteries of one side (Geist). The superior parathyroid artery may be a branch of the superior thyroid (Poole), but it is usually a branch of the inferior thyroid or of the anastomosing channel. Ginsburg² has shown that each of the glands has an accessory blood supply, by anastomotic channels from the opposite side.

Embryology.—The parathyroids develop chronologically in advance of the thyroid. They are derived from the third and fourth branchial clefts of each side. An independent accessory parathyroid may develop from the fifth cleft (Getzowa, Michand). Some have regarded the parathyroids as embryonic portions of the thyroid, but, as MacCallum says, "there is no histological proof that parathyroid tissue can ever become converted into thyroid tissue." Most observers regard the parathyroids as distinct glands possessed of a special function. Certain it is, as Gley³ and others have shown, removal of the parathyroids from herbivora, leaving the thyroid intact, is followed by spasms, tetany, etc., just as complete thyroidectomy is followed by such symptoms in carnivora.

Applied Anatomy.—Surgeons have become convinced that removal of the parathyroids in man causes tetany, and that damage to them may produce serious symptoms. Because of this danger most surgeons now prefer to remove a goitre from within the capsule of the thyroid gland, after the plan of the Mayos, and thus avoiding the parathyroids.

THE THYMUS GLAND (Fig. 1135).

The **thymus gland** is a temporary organ, attaining its full size at the end of the second year, when it ceases to grow and remains practically stationary until puberty, at which period it rapidly degenerates. It does not entirely disappear,

FIG. 1197.—The thymus gland of a full-time fetus exposed *in situ*.

for the shrunken and degenerated mass, even later in life, maintains a likeness to the original form and retains within its substance small portions of thymus tissue (Waldeyer). If examined when its growth is most active, it will be found to con-

³ Internal Secretions, By William Hanna Thomson, New York Medical Journal, November 19, 1904.

sist of two lateral lobes placed in close contact along the middle line, situated partly in the superior mediastinum, partly in the neck, and extending from the level of the fourth costal cartilage upward as high as the lower border of the thyroid gland. It is covered by the sternum and by the origins of the Sternohyoid and Sternothyroid muscles. Below, it rests upon the pericardium, being separated from the arch of the aorta and great vessels by a layer of fascia. In the neck it lies on the front and sides of the trachea, behind the Sternohyoid and Sternothyroid muscles. The two lobes generally differ in size; they are occasionally united so as to form a single mass, and are sometimes separated by an intermediate lobe. The thymus is of a pinkish-gray color, is soft, and is lobulated on its surfaces. It is about two inches (5 cm.) in length, one and a half inches (3.75 cm.) in breadth below, and about a quarter of an inch (6 mm.) in thickness. At birth it weighs about half an ounce.

FIG. 1198.—A lobule of the thymus of a child, as seen under low power. C, Cortex. c, Concentric corpuscles within medulla. b, Bloodvessels. tr, Trabeculae. (Schäfer.)

FIG. 1199.—Elements of the thymus. $\times 300$. a, Lymph corpuscles. b, Concentric corpuscle. (Schäfer, after Cadiot.)

Structure (Figs. 1198 and 1200).—Each lateral lobe is composed of numerous lobules held together by delicate areolar tissue, the entire gland being enclosed in an investing capsule of a similar but denser structure. The primary lobules vary in size from a pin's head to a small pea, and are made up of a number of small nodules which are irregular in shape and are more or less fused together, especially toward the interior of the gland. Each lobule consists of a cortical and medullary portion, which differ in many essential particulars from each other. The **cortical portion** is mainly composed of **dense lymphoid tissue**, consisting chiefly of lymphocytes and hyaline cells supported by a delicate reticulum. In addition to this reticulum, of which traces only are found in the medullary portion, there is also a network of finely branched cells which is continuous with a similar network in the medullary portion. This network forms an adventitia to the bloodvessels. The **medullary portion** consists of **diffuse lymphoid tissue** (granular cells) and **concentric corpuscles** (corpuscles of Hassal). The granular cells are rounded or flask-shaped masses attached (often by fibrillated extremities) to bloodvessels and to newly formed connective tissue. The concentric corpuscles are composed of a central mass consisting of one or more granular cells, and of a capsule which is formed of concentrically arranged epithelioid cells which seem to be continuous with the branched cells forming the network mentioned above.

Each lobule is surrounded by a capillary plexus from which vessels pass into the interior and radiate from the periphery toward the centre, and form a second zone just within the margin of the medullary portion. In the centre of the medulla there are very few vessels, and they are of minute size.

Watney has made the important observation that hemoglobin is found in the thymus either in cysts or in cells situated near to or forming part of the concentric corpuscles. This hemoglobin varies from granules to masses exactly resembling colored blood corpuscles, oval in the bird, reptile, and fish; circular in all mammals except in the camel. Dr. Watney has also discovered in the lymph issuing from the thymus similar cells to those found in the gland, and, like them, containing hemoglobin either in the form of granules or masses. From these facts

he arrives at the physiological conclusion that the thymus is one source of the colored blood corpuscles.

Vessels and Nerves.—The arteries supplying the thymus are derived from the **internal mammary** and from the **superior and inferior thyroid**. The veins terminate in the two **innominate veins**, and in the **internal mammary** and the **thyroid veins**. The lymphatics are of large size, arise in the substance of the gland, and are said to terminate in the **internal jugular vein**. The nerves are exceedingly minute; they are derived from the **vagus** and **sympathetic**. Branches from the **descendens hypoglossal** and **phrenic** reach the investing capsule, but do not penetrate into the substance of the gland.

FIG. 1200.—Minute structure of the thymus gland. Lobule of injected thymus from a calf, four days old, slightly diagrammatic, magnified about 50 diameters. The large vessels are disposed in two rings, one of which surrounds the lobule, the other lies just within the margin of the medulla. A and B. From thymus of camel, examined without addition of any reagent. Magnified about 400 diameters. A. Large, colorless cells containing small oval masses of hemoglobin. Similar cells are found in the lymph nodes, spleen, and medulla of bone. B. Colored blood corpuscles. (Watney.)

Applied Anatomy.—Sudden death—"thymus death"—with heart failure, and with or without acute respiratory embarrassment, has been recorded in a number of infants and children in whom the thymus was enlarged, and the lymphatic tissues throughout the body showed general hypertrophy, but who showed no other evidence of disease. Such deaths have often occurred during the administration of anesthetics.

Primary tumors of the thymus are rare forms of mediastinal newgrowth, and are usually dermoids or lymphosarcomas.

THE SPLEEN (LIEN) (Figs. 1201, 1202).

The **spleen** is situated principally in the posterior portion of the left hypochondriac region, its upper and inner extremity extending into the epigastric region; it lies between the fundus of the stomach and the Diaphragm. It is obliquely placed, its long axis following the obliquity of the tenth rib. If the abdomen is

opened a spleen of ordinary size is not visible from the front, as it is placed between the left kidney, Diaphragm, and stomach. It moves with the respiratory

FIG. 1201.—The spleen. Internal or visceral surface.

FIG. 1202.—The spleen. Diaphragmatic surface.

movements and with the movements of the stomach. It is the largest of the so-called ductless glands, and varies greatly in size. Usually it measures some five

inches in length. It is of an oblong, flattened, tetrahedral form, soft, of very friable consistence, highly vascular, and of a dark-purplish color.

Relations.—The **external or phrenic surface** (*facies diaphragmatica*) is convex, smooth, and is directed upward, backward, and to the left, except at its upper end, where it is directed slightly inward. It is in relation with the under surface of the Diaphragm, which separates it from the ninth, tenth, and eleventh ribs of the left side, and the intervening lower border of the left lung and pleura.

The **internal surface** is concave, and divided by a ridge into an **anterior or gastric**, and a **posterior or renal portion**.

The **gastric surface** (*facies gastrica*), which is directed forward and inward, is broad and concave, and is in contact with the posterior wall of the fundus of the stomach; and below this with the tail of the pancreas. It presents near its inner border a long fissure, termed the **hilum** (*hilus lievis*), in which are several irregular apertures, for the entrance and exit of vessels and nerves.

The **renal surface** (*facies renalis*) is directed inward and downward. It is somewhat flattened, is considerably narrower than the gastric surface, and is in relation with the upper part of the outer surface of the left kidney and occasionally with the left suprarenal gland.

The **upper end of the spleen** (*extremitas superior*) is directed inward, toward the vertebral column, where it lies on a level with the eleventh thoracic vertebra, within one and one-half to two inches of the midline. The **lower end** (*extremitas inferior*), sometimes termed the **basal surface**, is flat, triangular in shape, and rests upon the splenic flexure of the colon and the phrenocolic ligament, and is generally in contact with the tail of the pancreas. The **anterior border** (*margo anterior*) is free, sharp, and thin, and is often notched, especially below; it separates the phrenic surface from the gastric surface. The **posterior border** (*margo posterior*), more rounded and blunter than the anterior, separates the renal from the phrenic surface; it corresponds to the lower border of the eleventh rib and lies between the Diaphragm and left kidney. The **internal border**, or intermediate margin, is the ridge which separates the renal and gastric portions of the internal surface.

The spleen, with the exception of its hilum, is completely invested with peritoneum, which is firmly adherent to the capsule of the organ. Two folds of peritoneal tissue—the **lienorenal ligament** and the **gastrosplenic omentum**—serve to hold the organ in position. The lienorenal ligament (Figs. 982 and 985) is derived from the layers of the peritoneum forming the greater and lesser sacs where they come into contact between the left kidney and the spleen. Between these two layers the splenic vessels pass. The **gastrosplenic omentum** (*ligamentum gastrosplenicale*) is also formed of two layers, derived from the greater and lesser sacs, respectively, where they meet between the spleen and the fundus of the stomach (Fig. 985). Between these two layers run the vasa brevia and the left gastroepiploic branches of the splenic artery and vein. The spleen is also supported by the **phrenocolic ligament** (see p. 1265).

The size and weight of the spleen are liable to very extreme variations at different periods of life in different individuals, and in the same individual under different conditions. *In the adult*, in whom it attains its greatest size, it is usually about five inches in length, three inches in breadth, and an inch or an inch and a quarter in thickness, and weighs about six and one-half ounces. *At birth*, its weight, in proportion to the entire body, is almost equal to what is observed in the adult, being as 1 to 350; while in the adult it varies from 1 to 320 to 1 to 400. *In old age* the organ not only decreases in weight, but decreases considerably in proportion to the entire body, being as 1 to 700. The size of the spleen is increased during and after digestion, and varies considerably according to the state of nutrition of the body, being large in well-fed, and small in starved animals. In intermittent and other fevers it becomes much enlarged, weighing occasionally from eighteen to twenty pounds.

Frequently in the neighborhood of the spleen, and especially in the gastrosplenic and great omenta, small nodules of splenic tissue may be found, either isolated, or connected to the spleen by thin bands of splenic tissue. Every such nodule is known as a **supernumerary or accessory spleen** (*lien accessorius*). Accessory spleens vary in size from that of a pea to that of a plum.

Support and Mobility of the Spleen.—The spleen is normally movable within certain narrow limits. It moves with respiration and with the stomach movements. It is supported by ligaments (p. 1260). An unduly mobile spleen is called a **movable spleen**. In order that a spleen shall become unduly movable, the ligaments must stretch, and this stretching is often effected when the organ is greatly enlarged, but even an apparently normal spleen may become movable. Movable spleen is usually associated with movable left kidney.

Structure.—The spleen is invested by a **capsule** consisting of an **external serous** and an **internal fibromuscular layer**.

The **external or serous layer** (*tunica serosa*) is derived from the peritoneum; it is thin, smooth, and in the human subject is intimately adherent to the fibromuscular layer. It invests the entire organ, except at the places of its reflection on to the stomach and Diaphragm and at the hilum.

The **fibromuscular layer** (*tunica albuginea*) forms the framework of the spleen. It is composed of white fibrous connective tissue containing smooth muscle cells and elastic fibres, and it invests the organ as a capsule, and at the hilum is reflected inward upon the vessels in the form of sheaths. From these sheaths, as well as from the inner surface of the fibromuscular layer,

FIG. 1203.—Transverse section of the spleen, showing the trabecular tissue and the splenic vein and its tributaries.

numerous small fibrous bands, **trabeculae** (*trabeculae lienis*) (Figs. 1203 and 1204), are given off in all directions; these uniting with the bands from the vessel sheaths constitute the framework of the spleen. This framework resembles a sponge-like material, consisting of a number of small spaces or areolæ. The spaces of the areolæ contain the lymphoid material known as **splenic pulp** (*pulpa lienis*).

FIG. 1204.—Transverse section of the human spleen, showing the distribution of the splenic artery and its branches.

Within the capsule is the **parenchyma**, consisting of the **splenic pulp** and **splenic (Malpighian) corpuscles**. The **splenic pulp** is dark reddish brown in color and consists of a delicate *reticulum*, upon the fibres of which are seen stellate connective-tissue cells. In the meshes of the reticulum are **diffuse lymphoid tissue**, **erythrocytes**, erythroblasts, disintegrating erythrocytes, **pigment granules**, **branched cells**, and certain large polynuclear elements, **splenic cells**. The lymphoid tissue consists of *leukocytes*, mainly lymphocytes, and hyaline cells scattered throughout the

reticulum. The erythrocytes are on their way to or from the blood current; the **erythroblasts** are newly formed red blood cells that have as yet not lost their nuclei. The disintegrating red cells are useless cells that by their disintegration contribute the coloring matters to the bile. The branched cells are large, flattened, stellate elements, the processes of which seem to anastomose to assist in forming the reticular substance, and also seem to connect with the endothelial cells of the capillaries. The **splenic cells** are large polynuclear elements possessing the power of ameboid movements. They often contain pigment granules and red cells in their protoplasm, thus indicating *phagocytosis*. The **trabeculae** are continuations of the capsule, and consist of white fibrous connective tissue and smooth muscle tissue.

The **splenic (Malpighian) corpuscles** are dense, spherical or cylindrical collections of lymphoid tissue (*solitary follicles*) surrounding an arteriole. Each corpuscle shows a lighter **germinal centre** and a darker peripheral zone where the leukocytes are more numerous and more closely packed. Each corpuscle usually exhibits an eccentrically placed arteriole, as the lymphoid tissue is collected in the adventitial sheath of the vessel. These bodies are visible to the naked eye, and appear as whitish dots.

Bloodvessels of the Spleen.¹—The **splenic artery** enters the hilum and divides into branches that follow the trabeculae. Of these, some quickly pass to the pulp, while others follow the trabeculae to their smallest divisions. The spleen is divided into circulatory lobules about 1 mm. in diameter, each of which is divided into histological units, one for each terminal vessel, or *ampulla*. These terminal vessels are large endothelial channels surrounded by a lymphatic sheath, called the *ellipsoidal sheath*. These terminal ampullae are porous and continue as veins, that collect the blood and empty it into the splenic vein at the hilum.

FIG. 1205.—Section of spleen, showing the termination of the small bloodvessels.

The spleen is subject to rhythmical contractions, one per minute; during a contraction the organ is reduced about 18 per cent. in volume. These contractions are produced by the contractions of the smooth muscle tissue in the capsule and trabeculae of the pulp. When the cardiac impulse sends the blood into the arterial channels the blood passes through the porous walls of the ampullae into the pulp. When the rhythmical contractions occur the blood is forced into the veins through the pores of the ampullae, and at the same time the arteries are closed.

The **lymphatics** originate in two ways—*i. e.* from the sheath of the arteries and in the trabeculae. The former trunks are the **deep collecting trunks**, and accompany the bloodvessels; the latter pass to the **superficial lymphatic plexus**, which may be seen on the surface of the organ. Lymphatic channels do not exist in the pulp. The deep trunks at the hilum number from five to ten, and terminate in the **splenic nodes**. The superficial trunks also pass to the hilum and terminate in the splenic nodes.

The **nerves** are derived from the **splenic plexus**, which is a part of or connected with the solar plexus. The nerves enter the spleen with the vessels.

Surface Form.—The spleen is situated under cover of the lower ribs of the left side, being separated from them by the Diaphragm, and above by a small portion of the lower margin of the left lung and pleura. Its position corresponds to the ninth, tenth, and eleventh ribs. It is placed very obliquely. "It is oblique in two directions—*viz.*, from above downward and outward, and also from above downward and forward" (Cunningham). "Its highest and lowest points are on a level respectively with the ninth thoracic and first lumbar spines; its inner end is dis-

¹ F. P. Mall, Amer. Jour. of Anat., 1903, vol. ii, No. 3.

tant about an inch and a half from the median plane of the body, and its outer end about reaches the midaxillary line" (Quain).

Applied Anatomy.—Injury of the spleen is less common than that of the liver, on account of its protected situation and connections. It may be *ruptured* by direct or indirect violence, torn by a broken rib, or injured by a punctured or gunshot wound. When the organ is enlarged the chance of rupture is increased. The great risk is *hemorrhage*, owing to the extreme vascularity of the organ, and the absence of a proper system of capillaries. The injury is not, however, necessarily fatal, and this would appear to be due in a great measure to the contractile power of its capsule, which narrows the wound and thus antagonizes the escape of blood. In cases in which the symptoms suggest such an injury and indicate danger to life, laparotomy must be performed; and if the hemorrhage cannot be arrested by ordinary surgical methods the spleen must be removed. The spleen may become displaced, producing great pain from stretching of the vessels and nerves, and this dislocation may render necessary removal of the organ. The spleen may become enormously *enlarged* in certain diseased conditions, such as ague, leukemia, syphilis, valvular disease of the heart, or without any obtainable history of previous disease. It may also become enlarged in lymphadenoma as a part of a general blood disease. In these cases the mass may fill the abdomen and extend into the pelvis, and may be mistaken for ovarian or uterine disease.

The spleen is sometimes the seat of *cystic tumors*, especially hydatids, and of *abscess*. These cases require treatment by incision and drainage; and in abscess great care must be taken if there are no adhesions between the spleen and abdominal cavity, to prevent the escape of any of the pus into the peritoneal cavity. If possible, the operation should be performed in two stages. *Sarcoma* and *carcinoma* are occasionally found in the spleen, but very rarely as a primary disease. In *movable spleen*, if the organ is normal, follow the advice of Rydygier and loosen the parietal peritoneum to make a pocket, place the spleen in the pocket, and pass sutures through the parietal peritoneum and splenic ligaments. A movable diseased spleen should be removed.

Extirpation of the spleen has been performed for wounds or injuries, floating spleen, simple hypertrophy, and leukemic enlargement; but in the latter case the operation is now regarded as unjustifiable, as it is practically certain to terminate fatally. The incision is best made in the left semilunar line: the spleen is isolated from its surroundings, and the pedicle transfixed and ligated in two portions, before the tumor is turned out of the abdominal cavity, if this is possible, so as to avoid any traction on the pedicle, which may cause tearing of the splenic vein and which inevitably induces grave shock. In applying the ligatures the surgeon must not include the tail of the pancreas, and in lifting out the organ care must be taken to avoid rupturing the capsule.

THE SUPRARENAL GLANDS, OR ADRENAL CAPSULES (GLANDULÆ SUPRARENALIS) (Figs. 1206, 1207).

The **suprarenal glands** are two small flattened bodies, of a yellowish color, situated at the back part of the abdomen, behind the peritoneum, and immediately above and in front of the upper extremity of each kidney; hence their name. The *right* one (Fig. 1206) is somewhat triangular in shape, bearing a resemblance to a cocked hat; the *left* (Fig. 1207) is more semilunar, usually larger and placed at a higher level than the right. They vary in size in different individuals, being sometimes so small as to be scarcely detected; their usual size is from an inch and a quarter to nearly two inches (4 to 5 cm.) in length, rather less in width, and one-quarter of an inch (6 mm.) in thickness. Their average weight is from one to one and one-half drams (6 grams) each.

Relations.—The relations of the suprarenal glands differ on the two sides of the body.

The **right suprarenal** (Fig. 1206) is situated behind the inferior vena cava and the right lobe of the liver, and in front of the Diaphragm and the upper end of the right kidney. It is roughly triangular in shape, and its **base**, directed downward, is in contact with the inner and anterior aspects of the upper end of the right kidney. It presents two surfaces for examination, an anterior and a posterior. The **anterior surface** (*facies anterior*) presents two areas, separated by a furrow, the **hilum** (*hilus glandulae suprarenalis*); one area, occupying about one-third of the

whole surface, is situated above and internally; it is depressed, uncovered by peritoneum, and is in contact in front with the posterior surface of the right lobe of the liver, and along its inner border with the inferior vena cava; the remaining area is elevated, and is divided into a nonperitoneal portion, in contact with the hepatic flexure of the duodenum, and a portion covered by peritoneum forming the hepatorenal fold. The **posterior surface** (*facies posterior*) is divided into an upper and a lower part by a curved ridge; the upper, slightly concave, rests upon the Diaphragm; the lower, or **base** (*basis glandulae suprarenalis*) is concave, and is in contact with the upper end and the adjacent part of the anterior surface of the kidney.

The **left suprarenal** (Fig. 1207), slightly larger than the right, is crescentic in shape, its concavity being adapted to the inner border of the upper extremity of the left kidney. It presents an inner border which is convex, and an outer which is concave; its upper border is narrow, and its lower rounded. Its **anterior**

FIG. 1206.—The right suprarenal gland. (Spalteholz.)

FIG. 1207.—The left suprarenal gland. (Spalteholz.)

surface (*facies anterior*) presents two areas—an upper one, covered by the peritoneum forming the lesser sac, which separates it from the cardiac end of the stomach and to a small extent from the superior extremity of the spleen; and a lower one, which is in contact with the pancreas and splenic artery, and is therefore not covered by the peritoneum. A hilum is present, as in the right suprarenal. Its **posterior surface** (*facies posterior*) presents a vertical ridge, which divides it into two areas. The ridge lies in the sulcus between the kidney and crus of the Diaphragm, while the area on either side of it lies on these parts respectively; the outer area, which is thin, resting on the kidney, and the inner and smaller area resting on the left crus of the Diaphragm.

The surface of the suprarenal gland is surrounded by areolar tissue containing much fat, and closely invested by a thin fibrous coat, which is difficult to remove, on account of numerous fibrous processes and vessels which enter the organ through the furrows on its anterior surface and base.

Accessory suprarenal glands (*glandulae suprarenales accessoriae*) are often to be found in the connective tissue around the suprarenals. The smaller of these, on section, show a uniform surface, but in some of the larger a distinct medulla can be made out.

Structure (Fig. 1208).—On making a perpendicular section, the suprarenal gland is seen to consist of two substances—surrounded by a **capsule**—the **external** or **cortical** and the **internal** or **medullary**. The former, which constitutes the chief part of the organ, is of a deep-

yellow color. The medullary substance is soft, pulpy, and of a dark-brown color. In the centre is often seen a space, not natural, but formed after death by the disintegration of the medullary substance.

The **capsule** consists of white fibrous connective tissue in which some smooth muscle tissue is seen. From the capsule and vessel sheaths the framework of the organ is derived.

The **cortical portion** consists of epithelial cells arranged in three zones. The **zona glomerulosa**—the outermost—consists of oval or round cell groups surrounded by capillary plexuses and reticulum. The cells are polyhedral in shape with clear nuclei; the protoplasm is granular and contains many fat globules. The **zona fasciculata**—or middle zone—consists of columns of epithelial cells (usually two cells wide) supported by reticulum containing bloodvessels and lymphatics. These cells resemble the above, but the nuclei are in the peripheral portion of the cells. The **zona reticularis**, the innermost of the three, consists of anastomosing columns or chains of cells. These cells are smaller than the preceding, are distinct in outline, and possess a granular and pigmented protoplasm.

FIG. 1208.—Section of human suprarenal gland. (Radasch.)

The **medullary portion** (*substantia medullaris*) (Fig. 1208) is usually separated from the cortex by a layer of large smooth cells. Beneath this layer the epithelial cells are arranged in irregular groups and chains, surrounded by reticulum and capillaries. The cells are small and their outlines are indistinct. They color deeply with chromium salts, and are called **chromaffin cells**. Many sympathetic nerve cells are present.

Vessels and Nerves.—The numerous arteries which enter the suprarenal bodies from the sources mentioned below form plexuses in the capsule and penetrate the cortical part of the gland, where they break up into capillaries in the fibrous septa, and these converge to the very numerous thin-walled veins of the medullary portion. These veins usually empty directly into the large central veins. The medullary vessels are derived from the cortical vessels, and pass to the medulla without branching to form plexuses of capillaries around the cells. The veins in this region converge to form from two to four central veins, which unite to become the suprarenal vein, which in turn emerges as a single vessel from the centre of the gland.

The **arteries** supplying the suprarenal glands are three in number and of large size; they are derived from the **aorta**, the **phrenic**, and the **renal**; they subdivide into numerous minute branches previous to entering the substance of the gland.

The **suprarenal vein** returns the blood from the medullary venous plexus, and receives several branches from the cortical substance; it emerges from the hilum and opens on the right side into the inferior vena cava, on the left side into the renal vein.

The **lymphatics** form several collections which are about the beginning of the suprarenal vein. They terminate in the nodes at the corresponding side of the aorta.

The **nerves** are myelinated and amyelinated, are exceedingly numerous, and are derived from the **solar** and **renal plexuses**, and, according to Bergmann, from the **phrenic** and **vagus nerves**. They enter the lower and inner part of the gland. A plexus in the gland sends branches into the cortex, where plexuses are formed around the vessels. Branches are also sent to the medulla, where rich plexuses are formed around the cells and vessels. Many sympathetic ganglia are seen there.

THE CAROTID GLANDS, OR CAROTID BODIES (GLOMUS CAROTICUM).

The **carotid bodies**, two in number, are situated one on either side of the neck, behind the common carotid artery at its point of bifurcation into the internal and external carotid trunks. They are reddish brown in color and oval in shape, the long diameter measuring about one-fifth of an inch (5 mm.) Each is invested by a fibrous capsule and consists of spherical or irregular masses of cells—the masses being more or less isolated from each other by septa which extend inward from the capsule. A network of large capillaries from the carotid artery ramifies among the cell masses, together with numerous sympathetic nerve fibres. The cells are polyhedral in shape, and each contains a large nucleus embedded in finely granular protoplasm which is stained yellow by chromic salts.

Applied Anatomy.—*Tumors* may arise from this structure. Such a tumor is apt to be above the level of the upper margin of the thyroid cartilage, and in most cases it moves with each arterial beat.

THE COCCYGEAL GLAND OR BODY, OR LUSCHKA'S GLAND (GLOMUS COCCYGEUM).

Lying near the tip of the coccyx in a small tendinous interval formed by the union of the Levator ani muscles and just above the coccygeal attachment of the Sphincter ani is a small conglobate body about as large as a millet seed, first described by Luschka, and named by him the **coccygeal gland**. Its most obvious connections are with the middle sacral artery.

Structure.—It consists of a congeries of small arteries with little aneurismal dilatations derived from the middle sacral and freely communicating with each other. The gland is surrounded by a capsule of white fibrous connective tissue which sends in septa to form the framework of the organ and to divide it into spaces which contain groups of polyhedral cells. Each cell contains a large round or oval nucleus, the protoplasm surrounding which is clear and is not stained by chromic salts.¹ Nerves pass into this little body from the sympathetic, but their mode of termination is unknown. Macalister believes the glomerulus of the vessels "consists of the condensed and convoluted metameric dorsal arteries of the caudal segments embedded in tissue which is possibly a small persisting fragment of the neurenteric canal."

THE PARASYMPATHETIC BODIES (ORGANA PARASYMPATHETICA OF ZUCKERKANDL).

The **parasympathetic bodies** were discovered in 1901 by Zuckerkandl. They are from one to four in number, situated retroperitoneally, ventrad of the abdominal aorta at the level of the third and fourth lumbar vertebræ. Each parasympathetic body is from 6 to 10 mm. in length and from 2 to 4 mm. in width, and is surrounded by a capsule of fibrous tissue. In the meshes of the reticulum are found groups of polyhedral or cuboidal epithelial cells, closely packed and of the chromaffin type. These bodies are usually supplied by fine arterial twigs from the aorta. They are best developed in the fetus and in infancy.
